Lateral Dislocation

The most common reason of such dislocation is mandibular fracture. The condylar head can be palpated in temporal space as it migrates laterally away from skull.

Superior Dislocation

It occurs due to direct blow to a half open mouth. It is also known as central dislocation. With such kind of injury, fracture of glenoid fossa can occur with mandibular condyle displacement into middle skull base.

Clinical Presentation

Jaw pain or trismus after extreme mouth opening or direct blow to the jaw are the most common presenting features of jaw dislocation. Immediately after dislocation, a loud crunch noise can be heard against the ear drum. Apart from these, other symptoms are not able to close mouth completely, drooling from mouth, difficulty with speaking, swallowing, and malocclusion. Previous history of similar kind of dislocation or hypermotility syndrome or any injury to TMJ should be elicited. Physical examination is needed to rule out other pathologies apart from jaw dislocation as pain and jaw movement difficulty is present in all patients with mandibular pathologies.

Anterior dislocation will have a palpable and/or visible periauricular depression from displacement of condyle. Deviation of jaw to any one side is evident in unilateral jaw dislocation of the opposite side. In bilateral anterior dislocations, patients generally show an underbite or prognathic with pain over both TMJ. Oral cavity examination is necessary to rule out any laceration that may suggest open injury. Examination of external auditory canal is also necessary to assess any injury. Thorough examination of V and VI cranial nerves are mandatory to rule damage to them while dislocation.

Differential Diagnoses

- Condylar fracture
- Trismus
- Mandible fracture
- Dystonic reaction
- TMJ dysfunction
- Traumatic hemarthrosis

Diagnosis

Before relocation of any joint, a plain X-ray must be done to rule out any fracture. Likewise, X-ray of mandible also must be done to rule out any mandible fracture, especially in traumatic dislocation. Orthopantomogram is the view of choice in case of jaw dislocation. It is a panoramic view that is acquired with camera planning around the patient. CT scan is more sensitive in diagnosing mandibular dislocations and other abnormality hence its use is increasing in traumatic dislocations. It is acceptable now a day to do CT scan as initial imaging modality in traumatic mandibular pathologies. Primarily, MRI is not ordered for acute management. However, it is a useful tool to detect soft tissue injury along with complications of mandibular injuries. It is informative for planning of long-term management in chronic recurrent dislocations. Laboratory tests are not required in healthy patients with isolated jaw injury.

Management

In emergency department, initially assessment of airway, breathing, and circulation (ABC) is to be done primarily. If every sign and investigation is suggestive of isolated acute mandibular dislocation, then it is to be decided whether close reduction in emergency is appropriate or not. Maxillofacial surgeon opinion is required in complicated as well as chronic mandibular dislocations. Close reduction can be done in emergency under proper analgesia and muscle relaxants. Local anesthesia can be five in TMJ as well as masseter and deep temporal nerve block. By reducing spasm and pain, it aids to successful reduction. Systemic benzodiazepine, i.e., IV midazolam also helps in reduction by pain relief and reducing muscle spasms. Various methods are used routinely to reduce anterior jaw dislocation. Eliciting gag reflex may be useful in reducing jaw dislocation according to some case reports.

Classical Technique

This is the most commonly used technique (**Fig. 1**). While doing this maneuver physician stands in front of sitting patient and

FIG. 1: Classic technique.

FIG. 2: Recumbent technique.

FIG. 3: Wrist pivot method.

places gloved thumbs on inferior molars a deep as possible and fingers are curved beneath the body and angle of mandible. Backward and downward pressure is to be given through thumb and fingers with slight mouth opening. This helps to reposition condyles back into fossa by disengaging them from anterior eminences. Sometimes it is difficult as the strength of masseter contractions has to be overcome. A risk of fingers bitten or disease transmission is involved in such procedures.

Recumbent Approach

Standing behind the recumbent patient, physician places both thumb on inferior molars and gives downward and backward pressure until condyles reaches back to normal position (**Fig. 2**).

Wrist Pivot Method

With same position as classical method, cephalad pressure on tip of mentum by thumb and caudal pressure on inferior molars by fingers as shown in **Figure 3** is to be given to reduce displaced mandible.

Postreduction Care

After successful relocation, no specific medicines are required. Sometimes soft collar may be prescribed to support TMJ. Patients must be advised not to open mouth very wide or yawn forcefully. Patients with history of recurrent dislocation or with other complications are requested to follow-up with specialists. Those patients who are suffering from chronic dislocations may get help initially from Barton bandage (elastic fabricated bandage that wraps around the top of the head and mandible). Further surgical management is required for permanent solution of chronic dislocation.

Complications

Complications due to dislocation are as follows:

- Degenerative disease of joint structures
- Injury to facial and external carotid nerve
- Injury to external auditory canal
- Deafness

Complications of reduction are as follows:

- Fracture of mandible
- Physician thumb may get injured

Jaw dislocation is not uncommon to treat for emergency physician. Prompt action and accurate maneuver can relocate mandible without much efforts to its normal location. Patients can be discharged on outpatient (OP) basis with follow-up with specialist, oral analgesics, and safety instructions.

SUMMARY

Facial emergencies are important to address at the right time. Emergency physician should aware of the relevant anatomy of the face-related illness. Facial infection needs immediate attention. As face is the mirror of body, any small or large swelling can be seen very early and hence, the treatment should never be delayed. The facial swelling, etiologically, can be grouped into two types; localized and generalized. Dislocation of TMJ is another condition which needs to be addressed in timely manner in emergency department.

137 CHAPTER

Neck, Throat, Oral, and Dental Emergencies

Aman Sharma, Devendra Richhariya

INTRODUCTION

The oral cavity comprises of many structures with various functions and is also the gateway for the microbes to enter our body that may lead to different pathological conditions. The throat is the continuation of oral cavity anteriorly and comprises of epiglottis, pharynx, and larynx. The neck is among the most complex structures in the body which plays a vital role in head movement and mobility. This chapter will discuss the common emergency conditions associated with these structures. The common presentation of disease related to throat "sore throat" are pharyngitis, epiglottis, and peritonsillar abscess. Emergency physician must evaluate and manage sore throat manifestation and oral lesion carefully as these may be features of serious illness.

PHARYNGITIS

Pharyngitis and tonsillitis are among the most common presenting conditions to the emergency department (ED) worldwide. The affected population may range from infants to elderly with peaked visits during seasonal flu outbreaks. Causative organisms are both bacterial—*group A beta-hemolytic streptococci (GABHS), Fusobacterium necrophorum, Neisseria gonorrhoeae, Mycoplasma pneumonia, and Corynebacterium diphtheriae* and viral origin—*rhinovirus, influenza, parainfluenza, respiratory syncytial virus, and corona virus*. Causative organism invades the mucosa and release multiple toxins and give rise to variety of clinical manifestations (**Flowchart 1**).

Clinical Presentation

Viruses are most common pathogens for the cases of pharyngitis or tonsillitis; however, the clinical symptoms in both viral and bacterial causes may be similar. While the viral pharyngitis is self-limiting and most commonly affecting the adults, bacterial pharyngitis caused due to GABHS can have serious complications in children. Usually the symptoms are of rapid onset in nature with sore throat being the most common presenting complaint. Other symptoms include fever, malaise, body ache, headache, enlarged tonsils, dysphagia, and anorexia. Cough, coryza, and diarrhea are usually associated with viral pharyngitis. Red flags (serious) clinical features are (STD_4) stridor, tachypnea, drooling of saliva, dyspnea, dysphonia, and dehydration.

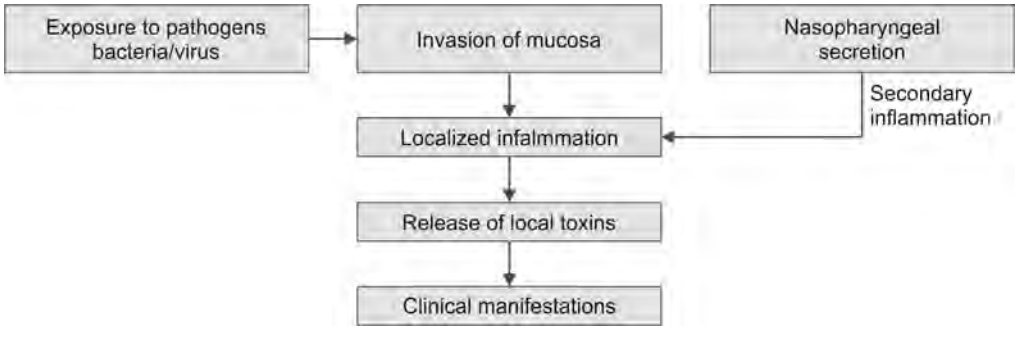
Evaluation

History

Contact with persons having similar clinical features and travel history.

Physical Examination

Bacterial infection—visual examination of oropharynx reveals exudative changes with tonsillar hypertrophy and erythema,



FLOWCHART 1: Pathophysiology of pharyngitis.

diffuse lymphoid hyperplasia of Waldeyer's ring, tender cervical lymph nodes, petechiae at junction of hard and soft palate, and rashes over torso (**Fig. 1**). Viral infection—whitish exudates covering erythematous pharynx and tonsils, cervical lymphadenopathy, and conjunctivitis. Pharyngitis due to GABHS bacteria is most common in children and spikes during seasonal transition from winters to spring.

Investigations

While the viral pharyngitis is self-limiting and does not require any specific investigation, bacterial pharyngitis requires laboratorial evaluation. To identify the likelihood of a bacterial infection in adult the Centor score may be used for patients presenting with sore throat. Throat swab and testing for GABHS pharyngitis by rapid antigen detection test (RADT) should be performed as the clinical features do not differentiate much between the viral and bacterial cause. RADT have a sensitivity and specificity of 95%. Throat cultures should be sent in children and adolescents with negative RADT tests. Antistreptococcal antibody titers are not recommended in the routine evaluation.

Treatment of Pharyngitis

Viral Pharyngitis

Only supportive treatment is recommended. Acetaminophen or a nonsteroidal anti-inflammatory agent (NSAID) may provide relief of sore throat pain. Lozenges, sipping warm beverages, eating soft foods, and warm saline gargles also provide relief from throat pain and soreness.

Group A Beta-hemolytic Streptococci Pharyngitis

Rapid antigen detection test positive and throat culture positive patients require antibiotic therapy for prevention of complications and better recovery. The Infectious Diseases Society of America (IDSA) recommends penicillin or amoxicillin as first-line antibiotics in treatment of GABHS. Single shot of intramuscular 1.2 million units of benzathine penicillin or oral penicillin V 500 mg twice daily for 10 days. For penicillin-allergic patients, the IDSA recommends first-generation cephalosporin, clindamycin or clarithromycin, and azithromycin as alternatives. The routine use of steroids is not recommended, but they may shorten the span of the illness and provide pain relief in adults. Oral prednisolone 40–60 mg per day for 1–5 days or single intramuscular dose of dexamethasone 10 mg may be prescribed. The irrational use of antibiotics worldwide is a growing concern as most of the patients with non-GABHS pharyngitis also receive antibiotics. Only symptomatic supportive treatment should be advised. Summary of treatment for pharyngitis is given in **Flowchart 2**. Since the condition is self-limiting, most of the cases can be treated on outpatient basis. However, the red flags should be always taken into account and in case patient develops any complications they should be advised for an otolaryngologist consultation and hospitalization.

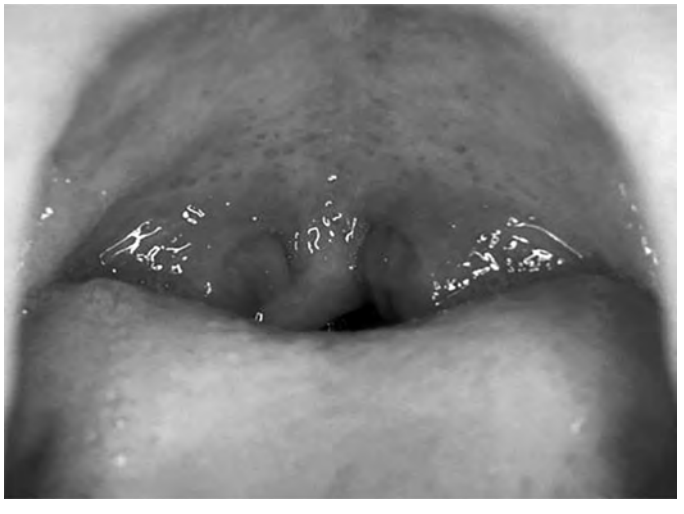


FIG. 1: Redness and edema of the oropharynx and petechiae on the soft palate. ***(For color version, see plate 15)***

EPIGLOTTITIS

It is characterized by inflammation and swelling of epiglottis, and is a potentially life-threatening condition which requires immediate attention. *Causative organism* and *conditions* responsible for epiglottitis are *bacterial—Haemophilus influenzae* type B (Hib), *Streptococcus pneumoniae, Streptococcus pyogenes, Pseudomonas aeruginosa,* and *Candida* in immunocompromised hosts; *burns*—thermal inhalational injury; and *trauma*—upper airway trauma, chemical irritants, and foreign body. Exposure to these pathogens, inhalational injury, and trauma leads to invasion of mucosa of epiglottis and aryepiglottic folds which causes local inflammation with edema and increased secretions. Obstruction of airway during inspiration occurs and leads to serious complications.

Clinical Presentation

Patients usually have symptoms of pharyngitis, i.e., sore throat, fever, and throat pain. The patient also typically has dysphagia and odynophagia along with the above-mentioned symptoms. Dysphonia may also be present; however, hoarseness is not commonly seen. Inspiratory stridor is a characteristic finding of epiglottitis. Emergency physician is expected to identify red flags (serious clinical features), *tripod posture* (**Fig. 2**), *cannot talk, cannot swallow, drooling of saliva, febrile toxic child, altered mental status, hypoxia, and compromised airway*.

Evaluation

History

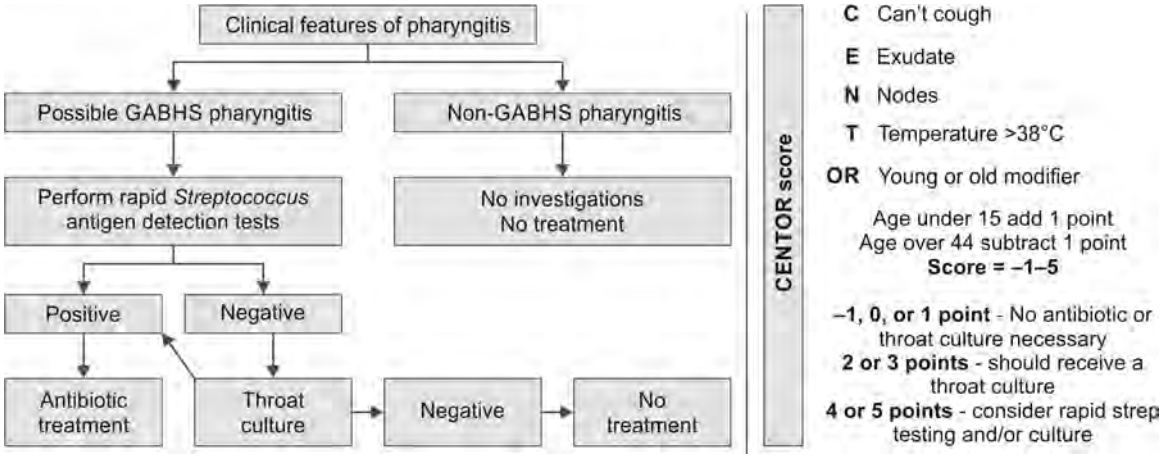
Smokers and persons having frequent upper respiratory infections have more risks for developing this condition.

Physical Examination

Cherry red or pale, swelling, and edema of epiglottis are usually seen (**Fig. 3**); however, routine direct visualization is not advised as it may further cause airway compromise and completely obstruct the airway.

Investigations

Complete blood count should be sent, lateral view X-ray of neck—swelling of the epiglottitis is seen referred to as *"thumb print sign"*. Gold standard is laryngoscopy, flexible laryngoscope should be preferred.



(GABHS: Group A beta-hemolytic streptococci)

FLOWCHART 2: Management steps of pharyngitis.

FIG. 2: Leaning forward on hands, in the "tripod" position; mouth open, tongue out, head forward, and tilted up in a sniffing position in an effort to relieve the acute airway obstruction secondary to swollen epiglottis.

FIG. 3: Redness and edema of epiglottis. ***(For color version, see plate 16)***

Treatment

Airway patency should be addressed at the earliest, if airway is found to be compromised or obstructed patient must be intubated or taken for tracheostomy. Humidified oxygen should be inhaled if oxygen saturation is <94%. Empirical antibiotics should be administered, first-line drugs are cefotaxime and ceftriaxone along with vancomycin, alternatively levofloxacin with clindamycin may be used. Role of steroids is not clear; acetaminophen may be used for pain and fever. In case oral hydration is not maintained, intravenous (IV) hydration should be started. Otolaryngologist consultation should be given at the earliest.

Disposition

Uncomplicated cases with no airway compromise can be treated as outpatient. Hospitalize patients with poor general condition and hydration status, patients with compromised airway may require advanced airway adjuncts thus require critical care.

PERITONSILLAR ABSCESS

Also known as *quincy*, it is the collection of pus in peritonsillar space. It is a complication of tonsillitis which leads to spread of infection to tonsillar crypts further invading peritonsillar tissues causing cellulitis and abscess formation (**Figs. 4** and **5**).

Etiology

It occurs due to complication of tonsillitis. Various bacterial species are responsible for this condition: *Aerobic bacteria—GABHS, Corynebacterium diphtheriae, Staphylococcus aureus,* and *Streptococcus milleri* group and anaerobic bacteria—*Fusobacterium necrophorum, Bacteroides, Peptostreptococcus, and Prevotella.*

Clinical Presentation

Patients usually have prior symptoms of sore throat and fever. The symptoms progress once there is spread of pus through the neck structures. There is worsening of sore throat, dysphagia, odynophagia, otalgia (ipsilateral), high-grade fever, drooling,

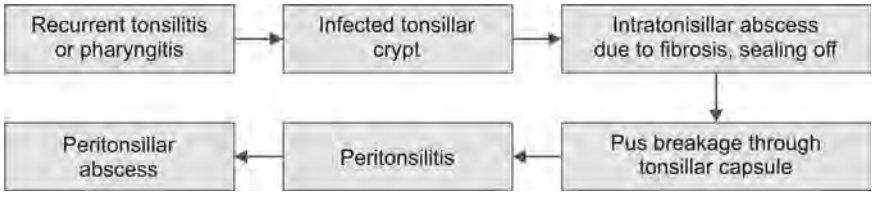


FIG. 4: Pathophysiology of peritonsillar abscess.

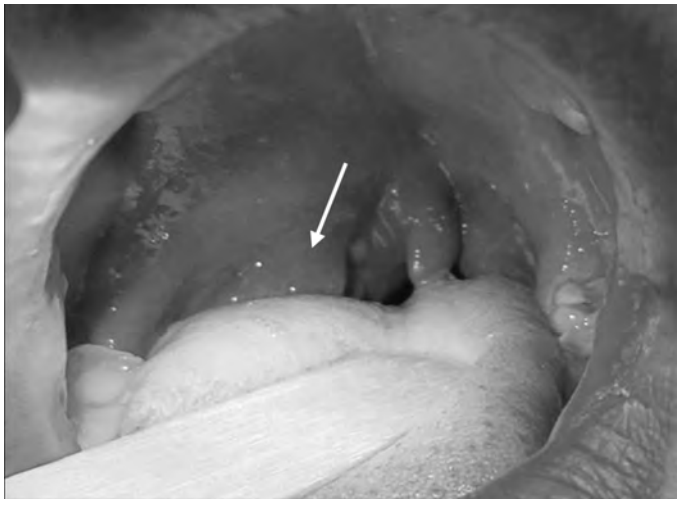

FIG. 5: A right-sided peritonsillar abscess with deviation of uvula to left side. ***(For color version, see plate 16)***

and trismus. Most patients have a characteristic muffled, "hot potato voice" with halitosis. Red flags (serious clinical features) are *toxic general appearance, altered mental status, airway obstruction, poor hydration status, and poor oral acceptance.*

Evaluation

History

Incidence peaks between 20- and 40-year age groups, patients with chronic tonsillitis, and smoking.

Physical Examination

Drooling, restricted jaw opening (trismus), and cervical lymphadenitis are usually seen. Upon direct visualization erythematous swollen soft palate, displacement, and inflammation of tonsillar pillar leading to deviation of uvula to contra lateral side.

Investigations

Aspiration of pus from the affected site establishes the diagnosis of PTA. Complete blood count, renal profile, and electrolytes are important investigations if patient has a toxic look with poor hydration status. Routine radiographs are not recommended if a clinical diagnosis has been established.

Treatment

The main surgical intervention includes needle aspiration, incision and drainage, and tonsillectomy. Needle aspiration of abscess acts a diagnostic aid, is easy to perform, and provides immediate symptom relief. Antibiotic treatment should not be delayed, oral antibiotics may not be suitable due to poor oral compliance thus IV antibiotics are preferred. IV penicillin G along with metronidazole or third-generation cephalosporins with metronidazole are drugs of choice. In case one is allergic to penicillin group IV piperacillin/tazobactam may be used. If the patient is stable with no complications they may be started on oral antibiotics, amoxicillin/clavulanate is the preferred oral drug.

Disposition

Patients with signs of toxemia, poor hydration status, and airway compromise should be hospitalized and surgical intervention should be performed without delay.

LUDWIG'S ANGINA

It is described first in 1836 by a German physician *Wilhelm Frederick von Ludwig*, it is a potentially life-threatening condition with rapid progression within hours, the cellulitis starts from the submandibular space and spreads to the connective tissues of floor of mouth and neck.

Etiology

Odontogenic polymicrobial cellulitis mostly caused by *viridans group streptococci (VGS), staphylococcus aureus,* and anaerobes. *Dental pathologies:* Dental caries, recent dental procedures, and poor oral hygiene. *Trauma*: Mandibular fractures, facial fractures, and piercings of tongue. *Other causes*: Submandibular sialadenitis, oral malignancy, and systemic illness with immunocompromised status [acquired immunodeficiency syndrome (AIDS), diabetes mellitus, and post-transplant patients).

Clinical Presentation

Patients mostly present with neck pain and swelling, along with dysphagia. Other symptoms include dysphonia "hot potato" muffled voice, drooling of saliva, pain over floor of mouth, tongue swelling, restricted neck movement, and fever. Red flags (serious clinical features) are *toxic general appearance, altered mental status, airway obstruction, poor hydration status, and poor oral acceptance*.

Evaluation

History

Dental caries and poor oral hygiene usually precipitates the risks. Any recent dental extraction should raise the suspicion for Ludwig's angina.

Physical Examination

Swelling over submandibular glands (**Fig. 6**), swelling, and protrusion of tongue are most commonly seen. Patients may also have elevation of floor of mouth with displacement of tongue posteriorly. There is marked tenderness of floor of mouth, neck, and surrounding tissue with crepitus on palpation. This tense swelling leads to restricted neck movement often termed as "bull neck".

Investigations

Clinical presentation forms the base of diagnosis, though no specific laboratorial tests are indicated, CT scan of neck with IV contrast enhancement is the study of choice, as it gives a details of airway compromise, soft tissue swelling, and involvement of mediastinum.

Treatment

Comforting the patient's posture, maintaining airway patency, and oxygenation should be the priority. Wide bore IV access should be immediately secured and crystalloid fluid should be administered. Advanced airway should be placed without any delay in case of compromised airway.

Antibiotic Therapy

Broad-spectrum empirical antibiotics should be administered with priority. Both aerobic and anaerobic coverage should be given. Patients with less severe symptoms and patent airway may be treated with oral antibiotics. Oral penicillin VK and amoxicillin are first-line choices while levofloxacin, cefuroxime, and amoxicillin-clavulanate are the second-line choices. Patients with suspicion of deep neck infections should be treated with IV piperacillin/tazobactam, imipenem-cilastatin, and ertapenem. Surgical drainage should be done if CT suggests abscess.

FIG. 6: Swelling of submandibular glands along with swelling of neck and surrounding tissue. ***(For color version, see plate 16)***

RETROPHARYNGEAL ABSCESS

Retropharyngeal abscess (RPA) is a polymicrobial abscess of posterior pharyngeal wall involving the deep tissues of neck mostly seen in children with peak incidence between 3 years and 5 years of age.

Etiopathogenesis

It is a multifactorial (**Fig. 7**) and polymicrobial infection caused by GABHS, *Staphylococcus aureus* [including methicillin-resistant *S. aureus* (MRSA), *H. influenzae, Bacteroides*, *Peptostreptococcus*, and *Fusobacterium* species.

Clinical Presentation

This condition is difficult to diagnose as the symptoms mimic other infective conditions of throat. Fever, neck swelling, throat pain, and dysphagia are most common symptoms. Chest pain is an indication for involvement of mediastinum as well. Increased irritability and poor oral intake in children is a marker of disease progression. Neck stiffness and breathing difficulty can be late presentation and may further lead to airway compromise.

Evaluation

History

It includes poor oral hygiene and lack of regular brushing and cleaning of oral cavity in children. Any penetrating neck injuries in adults along with the above-mentioned complaints should lead to suspicion of RPA.

Physical Examination

Though physical examination alone is not sufficient to make the diagnosis, one should look for cervical lymphadenopathy and restricted neck movement or torticollis. Also look for trismus, stridor, and drooling as these may indicate further worsening of the condition. There may be tenderness on moving larynx and trachea side to side referred to as tracheal "rock" sign. Red

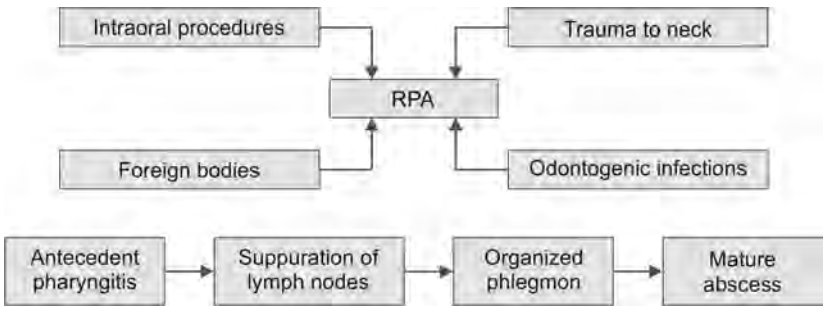

FIG. 7: Multifactorial cause of retropharyngeal abscess (RPA).

flags (serious clinical presentation) are airway compromise, drooling, neck tenderness and rigidity, stridor, respiratory distress, and trismus.

Investigations

There are no specific laboratorial tests for confirmation; however, contrast-enhanced CT scan of neck is the preferred modality of choice for diagnosis of this condition (**Fig. 8**). The abscess appears as a hypodense lesion with peripheral ring enhancement in retropharyngeal space.

Treatment

Assessing and securing the airway, breathing, and circulation is the key to save patients life. Early endotracheal intubation or tracheostomy should be performed on patient with impending obstruction and respiratory distress. Empirical IV antibiotic therapy should be started early; penicillin G with metronidazole or piperacillin/tazobactam is the first-line antibiotics to be given. In case patient does not respond well or there is risk for MRSA, patients should be given vancomycin or linezolid.

Intravenous fluids should be started if patient have dehydration or signs of inadequate perfusion. Supportive care including painkillers should be administered as per symptoms of patients. Urgent otolaryngologic consultation should be taken for any surgical intervention.

Disposition

This is a potentially life-threatening condition. There should not be any delay in hospitalizing these patients. Surgical intervention is required for patients not responding to antibiotics, with impending airway obstruction and if CT scan shows a hypodense lesion >2 cm in size, these cases need to be treated in the critical care units.

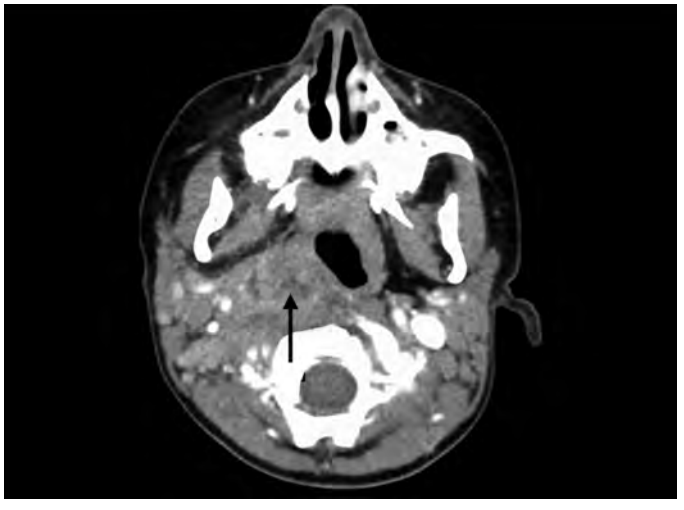

FIG. 8: Large retropharyngeal abscess with surrounding swelling.

INFECTIOUS MONONUCLEOSIS

It is often called as kissing disease or glandular fever that spreads through saliva. Most organisms causing this condition are from *Herpesviridae* family *[Epstein–Barr virus (EBV)]*. Most common causes of infection over 90% of the cases are caused by EBV and their pathogenesis is given in **Figure 9**. *Non-EBV causes* are *Cytomegalovirus* (CMV), adenovirus, hepatitis A, *Toxoplasma gondii*, and GABHS.

Clinical Presentation

The incubation period is between 4 and 6 weeks; the clinical course may vary from person to person. Patient complain that the sore throat is "worst ever" and is often associated with fever, malaise, fatigue, and body ache. Some may complain of breathing difficulty as the enlarged tonsils cause significant narrowing of airway and may cause an impending airway compromise. One should suspect splenic enlargement or splenic rupture if patient present with severe abdomen pain.

Evaluation

History

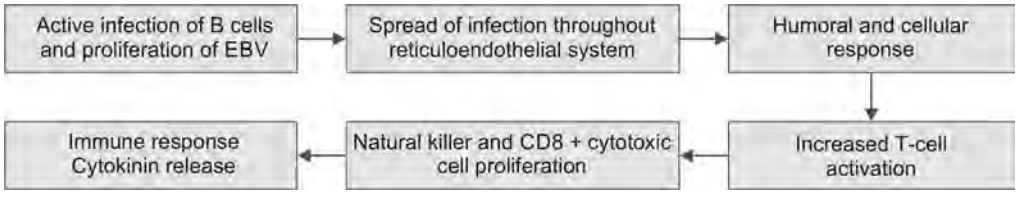
The symptoms usually increase in the initial days followed by a dip in their course often referred to as "waxing and waning". Sore throat along with rashes in young adolescents one should suspect infectious mononucleosis (IM).

Physical Examination

Since it spreads throughout reticuloendothelial system, one should thoroughly examine the lymph nodes. It shows symmetrical lymphadenopathy with tenderness. Exudative pharyngitis may be seen (**Fig. 10**), which may cause airway compromise. Splenomegaly is also common with splenic rupture being a rare but potentially life-threatening complication. Nonspecific rashes or petechiae may also be present. *Red flags* (serious clinical features) are airway compromise—tonsillar enlargement, abdominal tenderness—splenic rupture, anemia and jaundice—hepatic failure, neurological involvement, signs of shock, and secondary bacterial infections—PTA or RPA.

Investigations

Complete blood count is a must; it usually reveals leukocytosis with over 50% lymphocytes. Liver function tests may show elevated transaminases up to three times normal value along



Active infection of B cells and proliferation of EBV
Spread of infection throughout reticuloendothelial system
Humoral and cellular response
Increased T-cell activation
Natural killer and CD8 + cytotoxic cell proliferation
Immune response Cytokinin release

(EBV: Epstein–Barr virus)

FIG. 9: Etiopathogenesis of infectious mononucleosis.

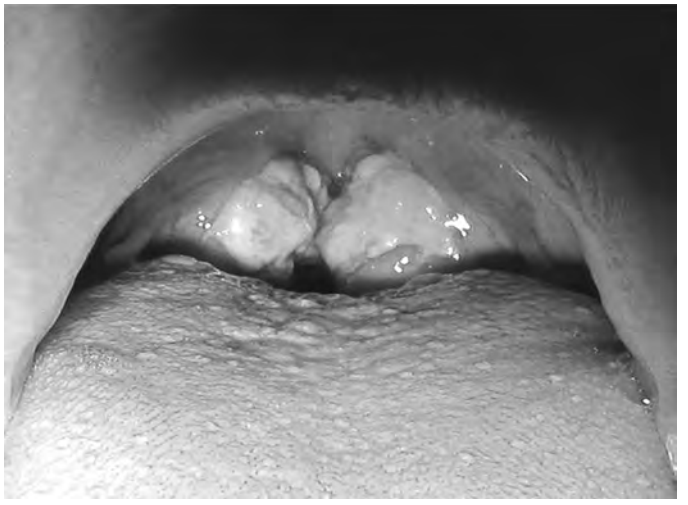


FIG. 10: Exudative pharyngitis in the throat with mononucleosis. ***(For color version, see plate 16)***

with hyperbilirubinemia causing clinical jaundice. Monospot tests detect the presence of heterophile antibodies which has high specificity and sensitivity. Ultrasound of abdomen, if there is splenic enlargement in examination, also helps to differentiate for appendicitis.

Treatment

Always secure airway, breathing, and circulation (ABCs) and access for airway patency. Start patient on crystalloid fluids if dehydration is present, antipyretics and analgesics should be given according to patient's symptoms. Steroids should be given if one has chances for impending airway compromise, methylprednisolone should be administered intravenously for rapid relief. Prednisolone and dexamethasone may also be considered. Patients should be advised to avoid contact sport activities and other strenuous activities. Surgical consultation should be given if one suspects complications including splenic rupture or secondary bacterial infections including PTA or RPA.

Disposition

Patients with significant airway edema causing airway compromise should be hospitalized and treated with utmost swiftness. They may require critical care support as well. Patient may be given symptomatic aid and treated as outpatient. If airway patency is well maintained, other complications are not evident.

ORAL CANDIDIASIS

Candida is among the normal flora present in human body. When there is disturbance of this normal flora it leads to overgrowth leading to candidiasis or thrush. The species most commonly causing infection in humans is *Candida albicans*. Oral thrush in one of the most common fungal infections and can be found in all age groups though mostly found in the early and late stages of life. It is more of a clinical diagnosis; proper history and physical examination are enough to establish a diagnosis but confirmatory laboratory studies must be sent for confirmation. Prophylactic doses should not be given to all affected individuals, but to reduce the severity and incidence for patients falling in high risk groups. The disease has a favorable prognosis in most of the cases. Predisposing conditions leading to infections are mentioned in **Box 1**.

BOX 1: Risk factors for oral candidiasis.

Local factors

- Altered or immature oral flora
- Atrophic oral mucosa
- Dental prosthesis
- Decreased saliva production
- Impaired defense mechanism
- Oral lichen planus
- Poor oral hygiene
- Steroid
- Tobacco

Systemic factors

- Acquired immunodeficiency syndrome
- Broad spectrum antibiotics (long-term use)
- Congenital conditions
- Diabetes mellitus
- Endocrine disorders
- Immunosuppressant medications
- Malignancy
- Malnourishment
- Systemic immune suppression

Etiopathogenesis

These harmless commensals are found in various parts of body as normal flora but opportunistic overgrowth may lead into disease (**Fig. 11**). Other than *Candida albicans* other species of oral *Candida* are: *C. glabrata*, *C. guilliermondii*, *C. krusei*, *C. parapsilosis*, *C. pseudotropicalis*, *C. stellatoidea*, and *C. tropicalis*. Usually it is a self-limiting disease; however, certain local and systemic factors may favor overgrowth and lead to invasive candidiasis. *Candida albicans* is one of the most common inhabitants of oral and gut flora, found in about 50% of individuals.

Clinical Presentation

Oral candidiasis is commonly called as oral thrush. Usually patients do not exhibit any symptoms. Most types of oral candidiasis are painless, but a burning sensation may occur in some cases. It appears as patches of gray or white friable material covering an erythematous base on buccal mucosa, tongue, gingiva, palate, and tonsils. Oral thrush is much more common in infants and usually occurs within the first week of life. *Red flags (severe clinical features)* are lesions >3 weeks, ulcerous/vesicular lesions, fresh lesion over other body area, and inflamed and striated oral patches (**Fig. 12**).

Evaluation

History

Infant—white coating present over tongue and difficulty in lactation. Pediatric—whitish/gray coat over tongue usually asymptomatic. Adults—intake of antibiotics or steroids.

FIG. 11: Etiopathogenesis of oral candidiasis.

FIG. 12: Hyperplastic candidiasis. ***(For color version, see plate 16)***
Courtesy: Devinder Singh, DNB gastroenterology

Physical Examination

Physical examination reveals classical whitish lesions in oral cavity which are usually not easily removable and may cause pain and bleeding, if scraped.

Investigations

Though diagnosing oral thrush is mostly clinical, but samples should be obtained for identification of species causing the disease and its quantification. The following laboratory investigation techniques can be used—whole saliva culture, imprint culture, or swab.

Treatment

The treatment plan consists of conservative measures and pharmacological treatment—topical and systemic. Keeping good oral hygiene, removal of dentures during night hours, and oral rinse with chlorhexidine help in treating the condition. Oral fluconazole and clotrimazole form the first line of treatment. Alternatively, caspofungin or amphotericin B may be used in case patient develops complications or does not respond to the initial pharmacological therapy.

Disposition

The condition usually does not require hospitalization unless one develops any complications or systemic features. Routine follow-up should be advised to elderly and the ones on immunosuppressant medications.

ORAL HERPES SIMPLEX

Oral herpes simplex, commonly known as herpes labialis, is an infection commonly caused by herpes simplex virus (HSV). It is common in the young, very contagious causing blisters over lips, mouth, tongue, or gums.

Etiology

Herpes simplex labialis is most commonly caused by herpes simplex virus type 1 (HSV-1). The infection is typically spread between people by sharing the household objects of infected person, direct nonsexual contact can also leads to spreading of disease, direct exposure of infected fluid from blisters, kissing the infected person, sexual contact, sharing objects of infected person—clothes, linen, and towels, stress, and hormonal imbalances in body.

Pathophysiology

Once a person is infected with HSV, the virus becomes dormant after the primary infection and lays itself in facial nerve cells (trigeminal nerve ganglion). It reinfects when the person is exposed to triggering factors and leads to recurrent infection (**Fig. 13**).

Clinical Presentation

The primary infection may be asymptomatic. One may notice small fluid-filled vesicles/blisters around the lips (**Fig. 14**) or other parts of face within 1–3 weeks of initial contact. The blisters may burst and transform to scab in few cases. During recurrence of infection the severity is usually less than the primary infective state. The common symptoms seen are burning sensation and pain over the affected areas (lips, buccal mucosa, gingival, and other parts of face), itching over the blisters, fever, headache, malaise, and running nose. *Red flags* are central nervous system (CNS) involvement—encephalitis, ocular infections—conjunctivitis, disease in pregnant women and neonates, and bacterial and fungal super infections.

Evaluation

History

Contact with infected person, young individuals, history of cold, cough, or fever. It is usually a self-limiting condition and rarely requires hospitalization. It affects in early stages of life so one must not miss such earlier events during history taking and also the recurrence is associated with any stress.

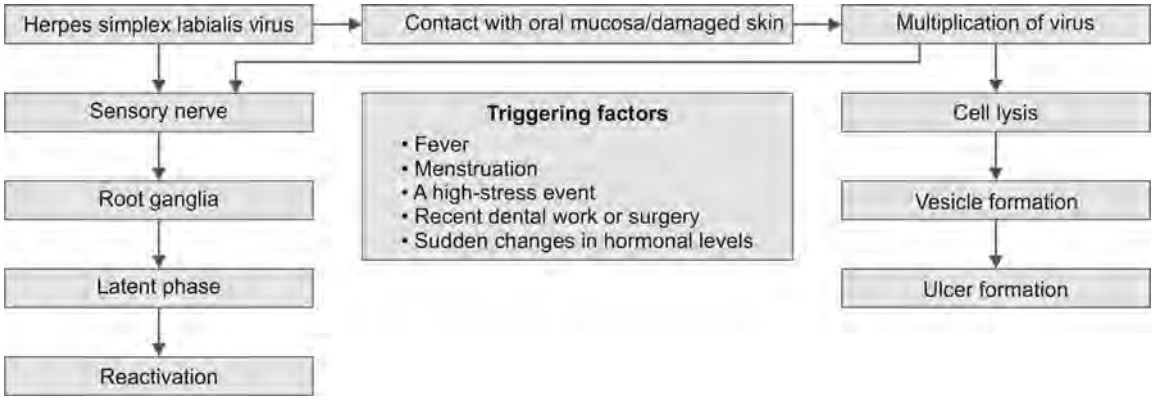

FIG. 13: Pathophysiology of herpes simplex infection.

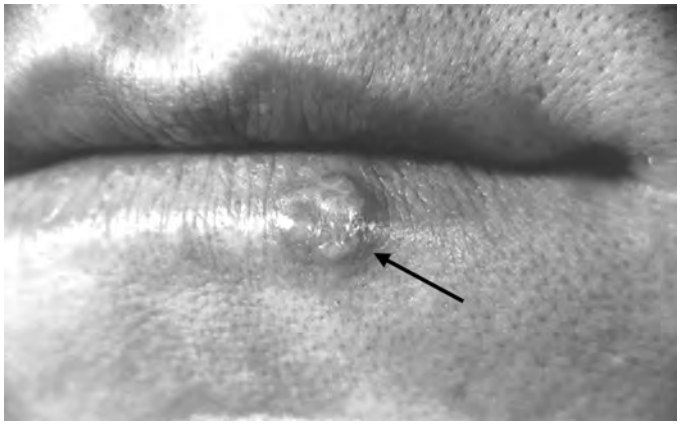

FIG. 14: Vesicles/blisters around the lips. ***(For color version, see plate 16)***

Physical Examination

The physical examination of herpes infection reveals fluid-filled vesicles/blisters.

- *Site*: Lips, oral cavity, tongue, gingival, hard, and soft palate
- *Size*: Small (2–5 mm) usually in groups
- *Shape*: Round/circular

Investigations

Various investigations can be utilized to identify the presence of HSV.

- *Cell culture*: It is the standard test for diagnosis, isolating HSV in the culture is the standard test for confirmation.
- *Polymerase chain reaction (PCR)*: It is more sensitive than cell culture, usually used in CNS involvement and eye infections.
- *Direct fluorescein antibody (DFA) methods*: Differentiates between HSV-1 and HSV-2 infections.
- *Tzanck smear*: Also known as herpes skin test, presence of Tzanck cells confirm infection by HSV.

In case of super infection with bacteria and fungi, punch biopsy may be taken for histological evaluation.

Treatment

It involves preventive measures and pharmacological therapy. Preventive measures—avoid contact with the infected person—touching, kissing, and sexual contact. Do not use linens and clothes of infected person. Pharmacological therapy—topical—*acyclovir*—5% cream, five times a day for 4 days, or *penciclovir*—1% cream, every 2nd hourly (when awake) for 4 days. Oral—*acyclovir:* 400 mg—five times a day for 5 days (adults); 15 mg/kg (maximum of 200 mg per dose) five times a day for 5 days, or *valacyclovir:* 2,000 mg twice daily for two doses, *famciclovir*: 750 mg twice daily for two doses or single dose of 1,500 mg stat.

Disposition

Most of the patients do not require hospitalization and can be treated as outpatient.

DENTAL PAIN

The most common dental problem and symptom is toothache for which a patient can visit an ED. Be it children or adult toothache may occur at any age and due to varying reasons. Most common finding associated with pain is dental caries, leading to inflammation of pulp causing pain. On the basis of its intensity, the time of occurrence and duration of pain, toothache may lead to diagnosis of its origin. It is necessary to know the site of pain and the etiology associated with pain. Pain due to pulpitis and abscess are usually same. Abscess pain is mostly associated with swelling. Teething pain occurs at age of 3–6 months. Pain due to wisdom tooth eruption occurs at 20–30 years age. Pain from teeth are referred to temporal and infraorbital region. Neuralgias are paroxysmal of pain. Here are some most common causes of dental pain for which a patient visits ED—teething pain (**Table 1**), pain due to caries (**Table 2**), pain due to trauma (**Table 3**), pain due to abscess (**Table 4**), pain due to wisdom tooth eruption (**Table 5**), referred pain (**Table 6**), periodontal pain (**Table 7**), pain in temporomandibular joint TMJ (**Table 8**), and neuralgic pain (**Table 9**).

GINGIVITIS

Gum is part of the oral mucosa, partly is fixated in the alveolar bone, cement of the root of the tooth, and partly free. Gingivitis means disease that is manifested in the gum. Gingivitis is a mild form of gum disease, but without proper treatment it can lead to the more serious periodontitis, according people having it to different strengths and due to loss, the teeth. Gingivitis is the first state of gum disorders.

TABLE 1: Teething pain.	
Pathophysiology	As the tooth erupts inflammatory mediators are released at the eruption site, causing pain
Clinical presentation	• There is hyperemia or swelling of the mucosa overlying the erupting teeth • Redness is visible at the mucosa • Increased salivation and drooling
Red flags	• General irritability • Loss of appetite and sleep
History	It is a physiologic phenomenon so teething pain occurs almost in every child. Seen most commonly at the age of 4–6 months
Physical examination	Patches of erythema on the cheeks
Investigations	Radiographic investigations are done
Treatment	• Topical application of lignocaine hydrochloride over the area • Topical application of glycerin • Mild purgatives such as castor oil and milk of magnesia are also used in treating teething

TABLE 2: Dental caries.	
Caries in children as well as in adults leads to pulpitis. According to duration and severity of caries the pulpitis is of two basic types; reversible and irreversible	
Reversible pulpitis	
Pathophysiology	The pain is mainly due to rise in intrapulpal pressure due to exudative force
Clinical presentation	Any external stimuli like temperature change or biting force cause quick sharp pain. The response is hypersensitive or else asymptomatic
Red flags	• There is no spontaneous pain • The pain subsides as the stimuli are removed
History	There is occurrence of prolonged food lodgment because of caries exposing the pulp
Physical examination	• Black lesion over tooth surface • Long-term food lodgment • No pain on percussion
Investigations	Intraoral periapical radiographs are preferred
Treatment	• Treatment of choice is root canal treatment • Nonsteroidal anti-inflammatory drugs (NSAIDs) can be given to relieve pain
Irreversible pulpitis	
Pathophysiology	With pulpal inflammation there is exudates, if the exudates come out of pulpal chamber it relieves pain, but it may cause edema. If exudates remain in pulpal chamber it causes pain
Clinical presentation	It may be of two types: 1. Symptomatic: It is associated with spontaneous pain. Pain occurs even after stimuli are removed 2. Asymptomatic: No pain is felt
Red flags	Prolonged pain to temperature
History	Long-term exposed pulp due to wide caries
Physical examination	• Caries involving very large area of tooth surface • Tenderness on percussion is positive
Investigations	Intraoral periapical radiographs are preferred
Treatment	• Treatment of choice is root canal treatment • NSAIDs can be given to relieve pain

Plaque is the primary cause of gum disease. However, other factors can contribute to periodontal disease. These include hormonal changes, chronic illnesses, medications, smoking, tobacco chewing, poor oral hygiene, and family history of gum disease.

When gingivitis left untreated, it can advance to periodontitis. In a person with periodontitis, the inner layer of the gum pulled away from the teeth and form pocket. These small spaces between teeth and gums collect debris and can become infected. The body's immune system fights the bacteria as the plaque spreads and grows below the gum line.

Toxins produced by the bacteria in plaque as well as the body's "good" enzymes involved in fighting infections—start to break down the bone and connective tissue that hold teeth in the place. As the disease progresses, the pockets deepen and more gum tissue and bone is destroyed. When bacteria build up in the mouth, it forms plaque; a condition characterized by red and inflamed sensitive gums. When this happens, teeth are no longer anchored in place, they become loose, and tooth loss occurs. Gum disease is the leading cause of tooth loss in adults.

Clinical Features Red flags

Bleeding gums (major red flag), canker sours, receding gums, chronic bad breath, and itchy feeling around the gum line. Gingivitis based on the location in the gum are classified with these reaction: exudative, proliferative, and necrobiosis.

Gingivitis Catarrhalis

Gingivitis catarrhalis, also termed as gingivitis superficialis, is inflamed gum with exudative reaction. Gingivitis catarrhalis is a disease that happens often. It is considered that 95% of the population, who has their own teeth, has these diseases. Iatrogenic factors such as dental caries, bad habits, and nutritive factors give rise to this situation. Physiologic state (puberty, menstrual cycle, and pregnanacy) or common disease (diabetes) can also give rise to this condition but only in the presence of local factors. but only in the presents of local factors. Bleeding and being sensitive to food material are the usual symptoms things. Therapeutic measures include removal of dental plaque and dental tartar. To use antiseptic preparation like hydrogen peroxide 3%. Besides that, oral hygiene should be improved.

TABLE 3: Pain due to trauma.

Traumatic injuries to teeth are very common and usually associated with road traffic accidents, contact sports such as boxing, taekwondo, karate, etc., or fights. This is very common with children than adults while playing or falling	
Pathophysiology	Pain due to trauma can be caused by exposure of pulp, avulsion, or luxation
Clinical presentation	Pain is severe like pulpitis but associated with bleeding
Red flags	Fractured crown of tooth
History	It is very important for clinician to know cause of injury, angle of impact, and objet of impact to know the extent of injury
Physical examination	Mobility of tooth is very common, sometimes fracture can occur at the root which is very painful but show no sign clinically. Radiographs are helpful in such cases
Investigations	Radiographs OPG or IOPA are most commonly done
Treatment	• If the fracture is at crown of the tooth exposing the pulp of tooth then root canal treatment is done followed by restoration of the tooth • If there is luxation, splinting is done • In case of avulsion, teeth can be replanted under half an hour of injury • If the tooth is preserved in saliva or milk and periodontal ligament fibers are intact

(IOPA: intraoral periapical radiograph; OPG: orthopantomogram)

TABLE 4: Pain due to abscess.

When a prolonged infection in tooth or in gingival tissue persists for a long time asymptomatically or there is sudden trauma to the tissue there is formation of abscess	
Pathophysiology	Usually of sudden onset on marginal or interdental gingiva. Purulent exudates may be expressed
Clinical presentation	Localized, painful, and rapidly expands
Red flags	Gingiva is fluctuant
History	Long-standing infection of tooth or gingival, forceful embedding of apple core, and tooth brush into gingiva
Physical examination	Purulent exudate in 24–48 h
Investigations	Radiographs OPG or IOPA are most commonly done and FNAC
Treatment	Removal of exudate under LA with an incision or opening the canal

(FNAC: fine needle aspiration cytology; IOPA: intraoral periapical radiograph; LA: local anesthesia; OPG: orthopantomogram)

TABLE 5: Pain due to wisdom tooth eruption.

This pain usually occurs in the early 20s. The pain aggravates and subsides by its own periodically, but sometimes persists for a longer duration	
Pathophysiology	Infection of soft tissue surrounding the crown of partially erupted tooth
Clinical presentation	Spontaneous pain, operculum may get traumatized by opposing teeth
Red flags	Pericoronitis is seen
History	Occurrence at the age of 21 years and onwards, erupting wisdom tooth is visible
Physical examination	It is seen usually around mandibular third molar. Edema in submandibular region and peritonsillar area
Investigations	Circumferential bone resorption around tooth seen in radiograph
Treatment	• Antibiotics—metronidazole 200 mg three times for 7 days • Drainage of abscess • Extraction of concerned tooth • Operculectomy can also be done

TABLE 6: Referred pain.

Pain may be referred to teeth from inflamed nasal mucosa, nonspastic myofascial pain from temporalis and masseter muscle or the pain arriving from the tooth may be referred to temporal and frontal region	
Pathophysiology	Pain occurring in the mandibular posterior tooth is referred to the area where the mandibular nerve arises
Clinical presentation	Pain referred to tooth is intense or sometimes mild. Pain referred from tooth is intense and involves almost half of the face including temporal and frontal bone
Red flags	Referring area is tender to touch
History	Long-term inflammation of the referring area
Physical examination	Trismus and sinusitis
Investigations	OPG
Treatment	Analgesics to relieve pain

(OPG: orthopantomogram)

Hyperplastic Gingivitis

Hyperplastic gingivitis is manifested with exudative inflammation of gingiva. It is a rare disease and appears in children and adolescent. Etiology factors are of the local nature such as dental plaque, poor dental hygiene, and teeth tartar. In this disease medicine has an impact on the epilepsy disease. It is said that the hyperplastic gingivitis is a hereditary disease.

TABLE 7: Periodontal pain.	
Pathophysiology	It may occur due to inflammation of periodontium directly such as trauma, adjacent impacted tooth, or indirectly through pulpal infection
Clinical presentation	Intense pain which can be easily localized, sometimes mobility in teeth
Red flags	Tooth is tender to lateral percussion
History	Inflammation of periodontium occurs due to trauma or long-term caries
Physical examination	Inflammation over periodontium and bleeding on probing from gingiva
Interpretation of findings	Acute or chronic periodontitis
Investigations	OPG or IOPA
Treatment	Complete oral prophylaxis has to be done

(IOPA: intraoral periapical radiograph; OPG: orthopantomogram)

TABLE 8: Pain in TMJ.	
Pain in TMJ occurs due to trauma, infection, dislocation, or disk displacement. The pain is mild or may be sometimes severe	
Pathophysiology	Pain usually emanates from capsular ligament
Clinical presentation	Pain in disk occurs usually during function such as opening, closing, or mastication
Red flags	Pain in response to pressure
History	The pain in TMJ is usually associated with displacement of disk due to trauma, or infection in the TMJ. Patient usually gives history of sudden jerk in the associated area
Physical examination	Pressure bearing surface of the joint are usually painless
Interpretation of findings	The findings are suggestive of TMJ arthralgia
Investigations	OPG, CBCT, or CT scan
Treatment	Occlusal disengagement of TMJ with occlusal splints. Analgesics are prescribed to relieve pain. Injecting local anesthesia into the joint also helps

(CBCT: cone-beam computed tomography; CT: computed tomography; OPG: orthopantomogram; TMJ: temporomandibular joint)

Swelling of gingiva is more common in the upper jaw and in the labial part. Gums are soft and red. There is pain while chewing and bad breath. Removal of local precipitating factors and use of antiseptic preparations are the common modalities of managing this situation.

Fibromatous Gingivitis

Fibromatous gingivitis, also termed as gingivitis neoplastic, is rare gum disease, cause is not known, and these factors have an impact on the formation of connective tissue. It affects mostly kids from 8 to 12 years old. It is believed that this disease is hereditary, but dental plaque does not have an impact in the forming of this gingivitis.

Disease is characterized by hyperplasia of gum, without exudative inflammation, that's why it becomes very hard and pale. Hyperplasia is localized in the region of lateral teeth in the upper jaw; it can cover the teeth entirely. The patient can have problems during chewing and talking. Healing process is mostly done by surgery but recurrence is common.

TABLE 9: Neuralgia.	
These are unilateral or sometimes bilateral paroxysmal pain occurring along the course of the nerve trunk	
Pathophysiology	These pains occur due to neuropathic changes occurring in the sensory fibers of the ganglion and dorsal root sometimes due to unknown causes or due to some conditions such as neoplasm, trauma, and aneurysm
Clinical presentation	Paroxysmal pain lasting for few seconds or minutes but of extreme intensity
Red flags	Usually unilateral pain which is aggravated by triggering factors like touch and movement of face such as yawning, chewing, drinking, and shaving
History	The patient gives history of sharp shooting episodes of pain occurring in response to some triggers and the pain is unresponsive to pain killers
Physical examination	There is no sensory loss along the nerve
Treatment	• Drugs such as phenytoin, carbamazepine, baclofen, and clonazepam can be given • Injection of nerve with anesthetic solution or alcohol • Nerve sectioning or nerve avulsion • Electrocoagulation of ganglion

Ulcerative Gingivitis

It is a gum disease which appears with alterative inflammation type, it appears in form of ulceronecrotic changes in the gum. It is common disease; it affects young people from the ages 20–30 years old, after the age of 45 the disease is rare. The illness has sessional characters; it appears during fall and winter.

Two microorganisms, i.e., *Bacillus fusiformis* and *Borrelia Vincentii* are common infective causative agents of ulcerative gingivitis. Some toxic materials like heavy metals (antimony, mercury, and lead) can toxically damage the parazonium and favor infection. Other precipitating factors are smoking, diabetes, malnutrition, leukemia, agranulocytosis. Gum becomes swollen and red, ulceronecrotic changes are localized in the top of interdental gum, covered with yellow or green membrane. Antiseptics and antibiotics are used for managing this condition. Consequences of the illness are curable with chirurgical intervention, gum massage, and electrophoresis with vasodilatation preparations.

Desquamative Gingivitis

It is a rare disease. Because of the desquamation of gum mucosae, the gum becomes really thin. It appears more on females; it affects at the ages 20–40 years old. It is believed that it is due to imbalance of hormones. Maintaining good oral hygiene, steroid vitamin and hormonal therapy are helpful in managing this situation.

DENTAL ABSCESS

It is a soft fluctuation swelling on tooth and associated tissues which can rapidly expands in facial spaces. Staphylococci-associated infection causes abscess. Incision and drainage is the treatment of choice with antibiotics and analgesics. It can be due to acute as well as chronic reasons.

Etiology/Causes

- Dental infections involving staphylococci are frequently associated with abscess
- Trauma to tooth may lead to abscess formation
- Chemical or mechanical irritation to gingival tissue

Pathophysiology

Staphylococci produce coagulase enzyme which causes fibrin deposition and helps in walling off lesion. Small pockets of necrotic tissues are formed inside cellulitis. Then pockets join together and enlarge to form abscess.

Clinical Presentation

Severe throbbing pain, affected area is sensitive to pressure, and swelling is seen in adjacent tissues. Teeth are nonsensitive to hot, cold, sweet, or sour.

Red Flags

Fluctuant swelling is seen in the associated tissue of teeth. Swelling may extend to facial spaces.

Evaluation

History

A long-standing infection in the periodontium or trauma or wedging of food in gingiva leads to abscess formation.

Physical Examination

Soft and fluctuant swelling in associated tooth. The tissue of swelled surface appears taut and inflamed and becomes distended. Patient may appear irritable, weak from pain, loss of sleep, and may have slight fever.

Interpretation of Findings

Depending upon location of abscess and the duration, it can be classified into acute periapical (PA) abscess, periodontal abscess, acute exacerbation of chronic lesion, and pericoronal abscess.

Investigations

Image quality of intraoral periapical (IOPA) radiograph and orthopantomogram (OPG) are done.

Treatment

Treatment include drainage of the abscess either via root canal or incision.

BLEEDING AFTER DENTAL SURGERY

Bleeding after extractions is not a major complication unless it is associated with any systemic cause or drug side effects. Mild bleeding can be managed by patient. Systemic diseases are associated with severe blood loss. Apply digital pressure over the bleeding area, if it does not work, then control the bleeding by ligating the major vessels.

Etiology/Causes

It includes single/multiple tooth extraction, implant placement, and traumatic injury.

Clinical Presentation

Bleeding after extraction can be of three types; primary—continuously after surgery, reactionary—after few hours of surgery, and secondary—after few days. Bleeding during surgery like implant placement is expected and usually easily controlled. However, if a large vessel is cut, then hemorrhage is uncontrolled, and it requires suturing the vessel.

Pathophysiology

After extraction of tooth, the bleeding usually occurs from small blood vessels which stops by its own by applying pressure for few minutes. However, sometimes if there is any bleeding disorder or if a venous plexus is present at apex of root of tooth the hemorrhage can be difficult to control.

Evaluation

History

If the bleeding is persistent after surgery then past medical history is very important. Systemic bleeding disorders such as hemophilia, thalassemia, or von Willebrand disease are commonly associated with uncontrolled bleeding. Other causes may include drugs like aspirin which usually taken by hypertensive patients.

Physical Examination

Hemophilia

The most common manifestation is hemorrhage in joints, which is spontaneous and associated with warmth and muscle spasm. Superficial trauma causes uncontrolled bleeding. Processes such as tooth eruption and exfoliation cause prolonged and severe bleeding.

Thalassemia

Patient appears pale and weak, with prominent cheek and other bones. Mongoloid appearance—frontal head bossing with overdeveloped malar bone and short nose. Oral mucosa is usually pale due to chronic jaundice.

von Willebrand Disease

It includes excessive bleeding even after minor trauma. Most common intraoral sites of bleeding are gingiva and nose. Menorrhagia is also very common. Bleeding tendencies decrease with age.

Investigations

Investigations for bleeding disorders are done before surgery based on past medical history of the patient. Thalassemia—typical safety pin cells and nucleated RBCs in circulation. Hemophilia—clotting time is prolonged but bleeding time, platelet count, and prothrombin time are all normal. von Willebrand disease—prolonged bleeding time, normal platelet count, decreased factor VIII, or factor IX.

Treatment

Management of Postsurgical Bleeding

As soon as continuous bleeding is detected, apply digital pressure for 2–3 minutes. If bleeding stops, close the wound by sutures to stabilize the clot. If bleeding still persists, it can be due to bony vessels, apply gel foam, fibrin foam, or bone wax over the area and close with suture. If bleeding still persists, then it is very important to identify the bleeding area and cauterize it with diathermy or if there is larger vessel, that can be ligated. The blood sample can be sent for testing for any systemic disorder and appropriate measures should be taken like blood transfusion.

Managing Bleeding after Implants

Bleeding during surgery is expected and usually easily controlled by cauterization or by ligation. Postoperatively patients are given instructions about normal expectation of bleeding and how to prevent and manage it. However, submucosal or subdermal hemorrhage into soft tissue spaces can lead to hematoma formation. Larger hematoma or those occur in systemically compromised individual can cause infections. It is advisable to prescribe antibiotics in such cases.

Bleeding in Systemic Disorder Patients

- *Hemophilia*: Raise factor VIII (in hemophilia A) and factor IX (in hemophilia B) levels. Various replacement therapies are available such as plasma, cryoprecipitate, and factor VIII concentrates.
- *Thalassemia*: Blood transfusion is required in severe blood loss. Folic acid maybe required due to erythropoiesis. Chelating agents like deferoxamine can be given.

DENTAL TRAUMA

Traumatic injuries to teeth are very common and usually associated with any injury occurring in the face. Usually any person having a road traffic accident is prone to dental trauma, also fights and contact sports such as boxing and karate cause trauma over teeth. To know the extent of injury to teeth it is very important to know the object, the angle, and the force of impact on the teeth. If there is only fracture of tooth (without bone) then it is not associated with swelling. Splinting is done in luxated tooth. Avulsed tooth can be replanted.

Types of Dental Traumas

- Fracture of crown of tooth involving only enamel
- Fracture of crown of tooth involving enamel and dentin
- Fracture of crown of tooth involving pulp causing pulpal exposure
- Concussion
- Subluxation and luxation—intrusive, extrusive, and lateral luxation
- Avulsion
- Fracture of alveolar socket wall
- Injuries to gingival and oral mucosa
- Injury to facial bones

Pathophysiology of the Condition

Trauma to tooth, if associated with the alveolar socket wall fracture, causes swelling due to release of mediators of inflammation. These mediators cause swelling and pain in the associated gingival and the face tissues.

Clinical Presentation

Fracture of tooth leading to exposed enamel does not cause any pain unless it is associated with any internal bone fracture. Pain occurs only if pulp is exposed in a fractured crown or if there is concussion or luxation or avulsion of tooth. If the tooth fracture is associated with bone fracture like alveolar bone or maxilla or mandible then it leads to facial edema and mobility in bone fragment.

Red Flags

If traumatized tooth is sore to percussion—concussion. If percussion pain is associated with bleeding—luxation.

Evaluation

History

It is very important to note the: (1) Object of impact, (2) Angle of impact, and (3) Force of impact to decide the amount of harm caused to the orofacial structures. If a soft object hits the face like tennis or rubber ball, then there are less chances of tooth fracture. If a hard object hits and the angle of impact is perpendicular to tooth, then the fracture of tooth can be at the apical, middle, or incisal third, if the impact is from above or the angle is from incisal to root of tooth, then it causes intrusive luxation of tooth, if impact is parallel to long axis of tooth, then there are chances of longitudinal fracture of tooth.

Physical Examination

Pain in percussion—concussion, luxation, and pulp exposed due to fracture. Mobility of segment—fracture of bone.

Investigations

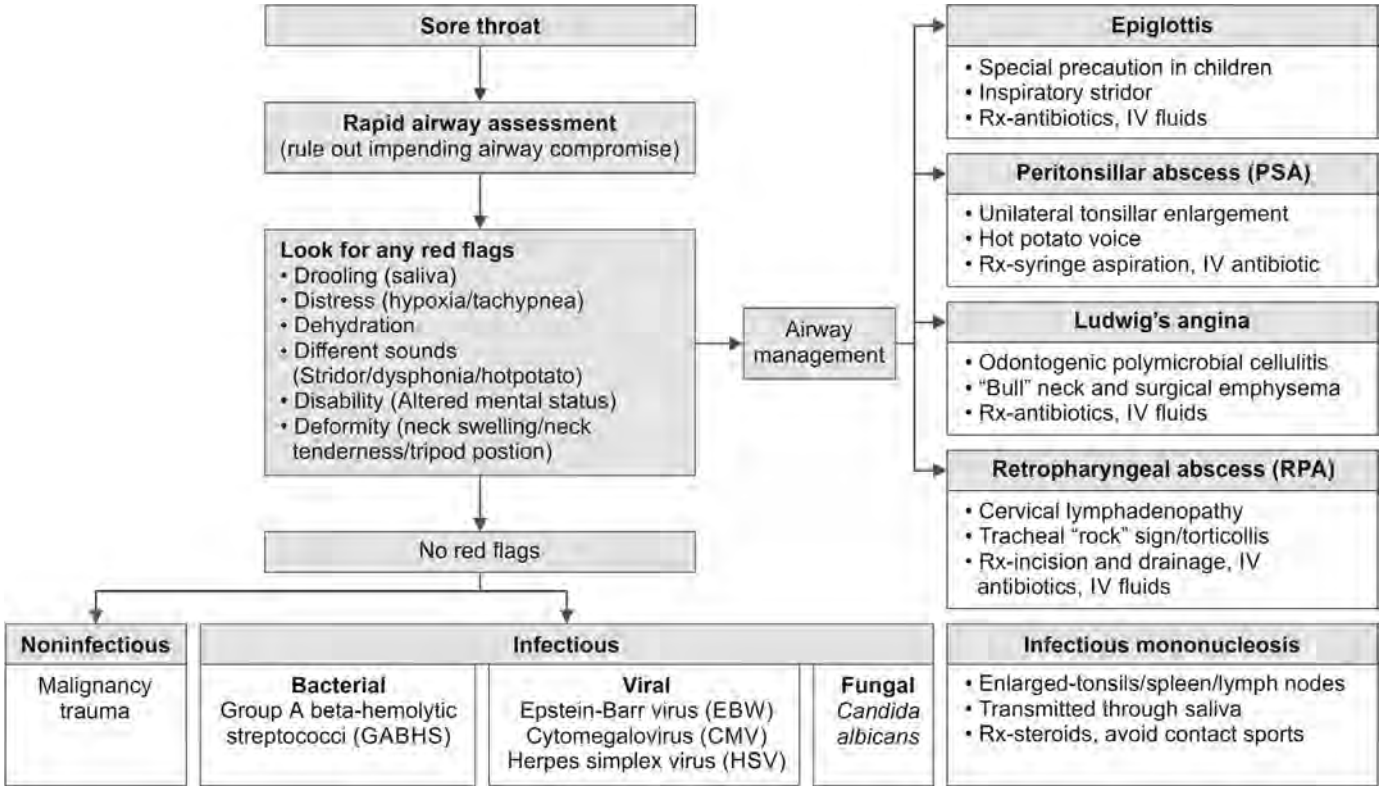
It includes IOPA, OPG, and PA radiographs.

Treatment

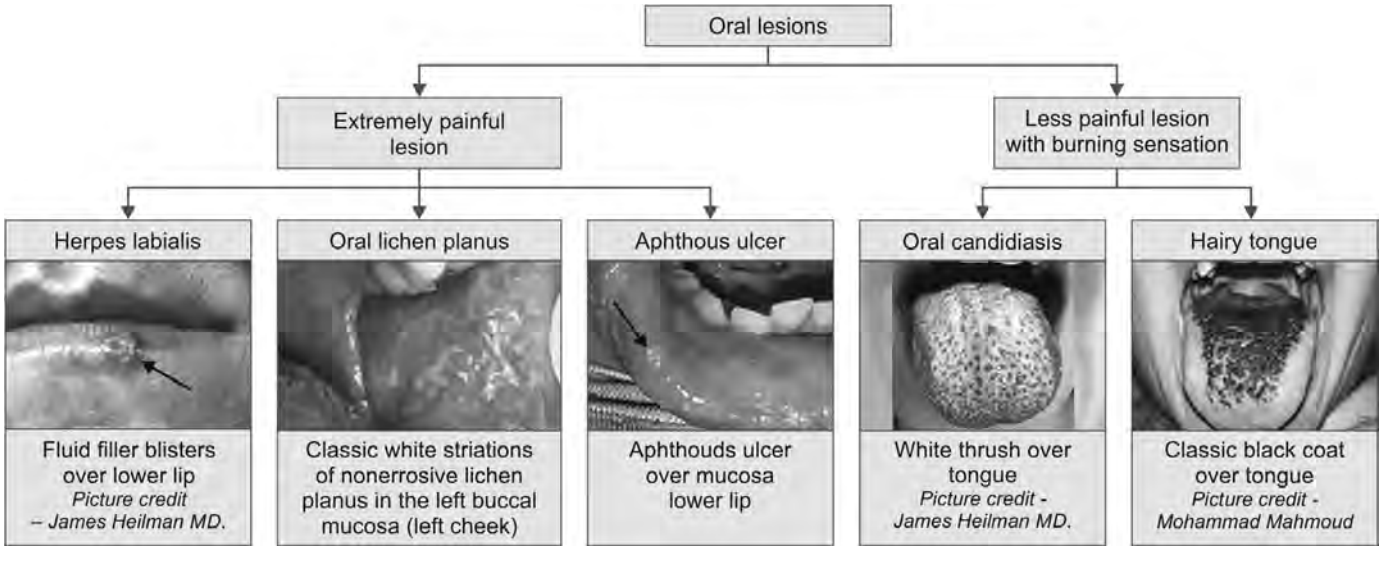
- *Concussion and luxation*: Splinting of the mobile segment is done.
- *Avulsion*: Replantation of teeth, if it is preserved in saliva or cold milk within half an hour of trauma.
- *Bone fracture*: Joining of bony segment with implants or mini plates.

SUMMARY

Oral, neck and throat emergencies are multiple and they may present as various form, most commonly they presents sore throat and oral lesion. Their evaluation is important to figure out life-threatening emergencies. Evaluation of common symptomatology like sore throat is summarized in **Flowchart 3** and oral lesion evaluation is summarized in **Flowchart 4**.



FLOWCHART 3: Evaluation of sore throat.



FLOWCHART 4: Evaluation of oral lesions. ***(For color version, see plate 17)***

138
CHAPTER

Management of Foreign Bodies of Ear, Nose and Throat

Mohammad Anzal Rehman, Neha Hudlikar, El Rasheed Salih

INTRODUCTION

Foreign bodies in the ear, nose, and throat (ENT) are frequently encountered problems in patients presenting to the emergency department (ED), constituting up to 30% of ENT-related emergencies in some centers. The majority of patients are children, with the highest prevalence found in children under the age of 5 years. Although uncommon, adverse events such as tympanic perforation and bronchoaspiration can occur as a consequence of foreign bodies, especially when care is delayed in younger patients, making improved public awareness and access to healthcare vital components in preventing complications.

Most foreign bodies are easily removed within the ED. However, multiple failed attempts can lead to highly preventable complications in patients. Therefore, the ED physician should aim to develop skills and awareness on the various approaches and removal techniques for these cases. Where there is doubt regarding type of foreign body or anticipated difficulty during removal, it is best to either consult ENT specialists or involve them in the removal procedure rather than risk further injury.

HISTORY TAKING AND PRESENTATION

The location of foreign body impaction is variable between different countries and may even differ based on changes in season, cultures, and customs. One study in Japan revealed that foreign bodies in the throat were more commonly encountered during times of the year associated with increased consumption of fish, whereas foreign bodies in the ear and nose were more frequent during rainy days, where children were more likely spend time indoors and insert small objects into the ear and nose. Foreign bodies of the ENT are usually a consequence of explorative curiosity, accidental entry of body or secondary to regular insertion due to irritation or habitual cleaning. Although most commonly seen in children, adults with psychiatric illness may also represent a subset of patients presenting with this complaint, with intentional insertions by nonpsychiatric adults also contributing to the patient population, albeit in smaller frequencies. Most patients are either brought or present themselves to the ED in the first few hours, usually with no obvious symptoms but a history suggestive of witnessed or suspected foreign body insertion into either ear, nose, or throat. Delay in seeking care often leads to a higher chance of symptoms developing, such as pain or discharge from the affected area and even difficulty breathing or swallowing with throat foreign bodies. Often, the risk of complications also goes up with prolonged time before presentation to the ED. Foreign bodies of the ear and nose are more frequently encountered on the right side, likely owing to right hand predominance in the patient population. The foreign substance itself is usually inorganic, such as beads, paper, coins, batteries, toy parts, and rubber. However, organic substances can also be involved and include nuts, seeds, bone, and meat. Animate (living) foreign bodies can also present, usually as insects who become lodged inside the ear canal.

APPROACH AND MANAGEMENT

The primary goals in management of foreign bodies in the ED are centered around removal of the foreign body where possible and feasible. Ideal removal should be immediate, painless, and usually "backtracked" along the same path traversed by the foreign object. Successful removal will invariably depend on several factors, including material composition and dimensions, anatomical location of the impacted foreign body, physician experience, equipment setup, and patient cooperation. As with any patient, it is essential to conduct a primary survey and evaluation of the airway, breathing, and circulation for all patients, with vital signs including blood pressure, temperature, heart rate, respiratory rate, with pulse oximetry to assess for any acute decompensation, and look for and address any other acute pathology that may be present. Once the suspicion of foreign body impaction or insertion is established, the physician should prepare for early removal of the foreign body, except in cases where removal is not appropriate to the patient situation. Specific circumstances and red flags are discussed later in this chapter.

One of the most essential components of successful foreign body removal is good preparation prior to attempting the procedure. Before commencing any maneuver, ensure that all equipment is functional, instruments are available and accessible, the environment is clear of distractions and hazards, and precautions are in place to address any patient destabilization or deterioration during the procedure. The

first attempt is commonly the best opportunity for removal, as subsequent attempts may be significantly hindered by patient apprehension and pain, especially in young children. While adequate instruction may be sufficient to immobilize an adult or older child for foreign body removal, it may be judicious to preemptively stabilize younger children by having a parent or relative hold the child in their lap with limbs wrapped by a sheet or anchored by holding hands and legs in crossed position, leaving the head relatively free. The head can then be held gently by an assistant during the procedure to anticipate any sudden head movements and stabilize accordingly without distraction from limb and body movements. Younger patients can also be offered distractions in the form of colorful objects, music, images, and videos on mobile phones or tablet devices that may reduce the perception of pain and mitigate distress and movement during the procedure.

Use of devices such as the headlamp (**Figs. 1A** and **B**) can enable the physician to free both hands, with one hand used to hold instruments designed to optimize visualization (e.g., speculum, depressor, laryngoscope, and tongue depressor), while the other is used to hold the tool or equipment chosen for removal of foreign body.

FOREIGN BODIES OF THE EAR

While any age group may present with aural (ear) foreign bodies, it is perhaps more prevalent in children younger than 6 years of age, with a higher overall frequency of occurrence in males compared to females. The types of foreign body found in this area range from pieces of cotton, erasers, small stones, popcorn kernels and paper to beans, beads, and even live insects. One US study found that, while the majority of aural foreign bodies were successfully removed by ED physicians, the removal technique depended heavily on the dimensions, consistency, and location of the substance involved in the external auditory canal, where the nonlinear and constrictive pathway lends itself to difficulty during instrumentation.

Anatomy

The ear is divided into three major sections. The inner ear is the most internal portion, existing as a labyrinthine cavity of semicircular canals, the vestibule and cochlea that together function to deliver information on sound to the central nervous system and regulate balance and coordination. The middle ear is primarily involved in bony conduction of sound and consists of the malleus, incus, and stapes between the oval window internally and tympanic membrane externally. The external ear is comprised of the auricle and the external acoustic meatus (external auditory canal). The external auditory canal through the opening at the auricle is understandably where most foreign bodies become lodged. The canal is lined with a thin layer of skin and periosteum and narrows at the bony cartilaginous junction (separating the lateral cartilaginous third of the canal from the bony medial two-thirds), increasing the susceptibility of impaction for inserted objects.

Clinical Features

The majority of patients presenting with foreign bodies in the ear are asymptomatic, with the finding being incidental or guided by a history of witnessed or suspected insertion. However, a number of symptoms may manifest, especially as time progresses since impaction. These include pain in the ear (otalgia), bleeding, otorrhea, hearing loss, and fullness in the ear. Pain with fever and discharge may indicate developed infection, while hearing loss and presence of button batteries are red flags that require judicious evaluation for any secondary insults or disease processes with the aural foreign body. The ED physician should consider differential diagnoses such as otitis media or externa, cerumen impactions, and even tumors.

Evaluation and Management

Attempts to remove the foreign body from the ear are often painful and carry the risk of advancing the object even further down the canal. The first attempt is usually the one with the highest success rate and the least number of complications, which is why care must be taken to adequately prepare both the patient and equipment prior to attempting removal. After counseling the patient or guardian on the need for extraction and obtaining appropriate consent as needed, the physician should ideally assign tasks to any assistants that are available in the room that can facilitate immobilization of the patient as required. This is particularly useful in pediatric and psychiatric patients where compliance cannot be assured during the removal procedure. Identify the affected ear and position the patient to allow for maximal comfort whilst the ear faces

FIGS. 1A AND B: Use of a headlamp can allow for optimized visualization without occupying the hands.

the physician's side, providing them with a clear view of the auricle and external auditory canal. Use of a headlamp can allow for the physician to use both hands during the removal procedure. Some of the techniques that can be used to remove ear foreign bodies are outlined below.

Irrigation

An irrigation syringe or similar syringe filled with saline at body temperature, attached to a plastic cannula can be advanced beyond the foreign object inside the ear and used to instill water at pressure inside the ear canal in an attempt to "flush" the impacted substance outward for removal. This is useful in cases of inorganic objects such as beads or popcorn kernels as well as insects in many cases. It should, however, not be used to remove batteries, organic material such as food, vegetable matter or other substances that may expand with absorption of water (e.g., polystyrene balls and expandable water toys). In addition, irrigation should only be done after ensuring the tympanic membrane is intact.

Grasp and Remove

Various instruments are designed to acquire a direct hold on the foreign object, following which they can be moved toward the exterior of the ear canal and removed. The Hartmann alligator forceps and Bayonet forceps (**Figs. 2** and **3**) are both excellent tools for this purpose and are especially useful when dealing with soft, easily graspable objects or insects within the ear canal. They should be avoided when dealing with spherical objects, as these are inherently difficult to grasp and may even be pushed further into the canal.

Anchor and Drag

The right angle hook (**Fig. 4**) is especially useful for rounded objects. If advanced beyond the midpoint of the object and behind it in the ear canal, the distal end of this instrument anchors the foreign body, allowing it to be dragged outward as the equipment is pulled under direct visualization. The wax loop/curette (**Fig. 5**) uses the same concept with a loop instead of a hook, whereas the Katz extractor (**Figs. 6A** and **B**) uses an inflatable balloon to secure the object as it is pulled out of the ear. All these techniques should avoid being used where proper visualization of the distal ends of foreign bodies is adequately maintained during the procedure (**Figs. 7A** and **B**).

Bonding to Object

Limited evidence exists surrounding use of a bonding agent such as glue (cyanoacrylate) at the end of a cotton-tipped applicator to attach to the foreign body for removal under direct visualization. A similar mechanism is employed when using a magnet to attach to a metallic foreign body within the ear canal. These techniques have been used with variable efficacy and care must be taken not to utilize these methods where the patient is uncooperative or where visualization is suboptimal to avoid complications. Live insects within the ear canal are a cause of significant distress and irritation for patients presenting to the ED. Prior to removal, live insects may be killed by instilling alcohol, mineral oil, or lidocaine (also available as a spray). Removal then proceeds using any of the methods described above. Suction devices have also been successfully used to facilitate extraction.

FIG. 2: Hartmann alligator forceps.

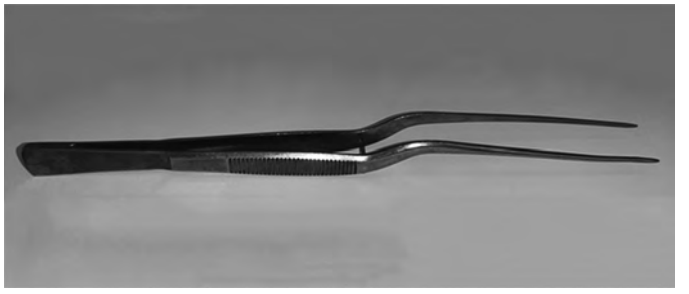

FIG. 3: Bayonet forceps.

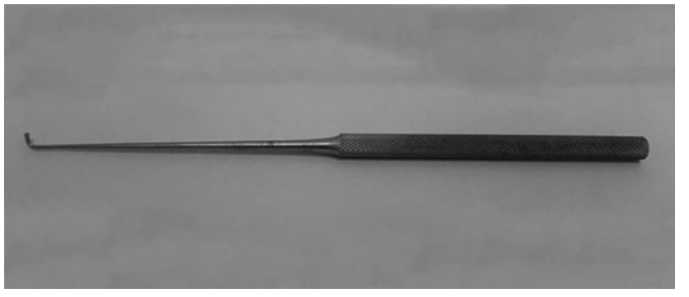

FIG. 4: Right angle hook.

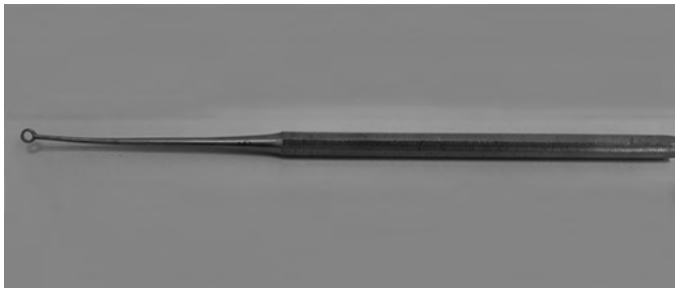

FIG. 5: Wax loop/curette.

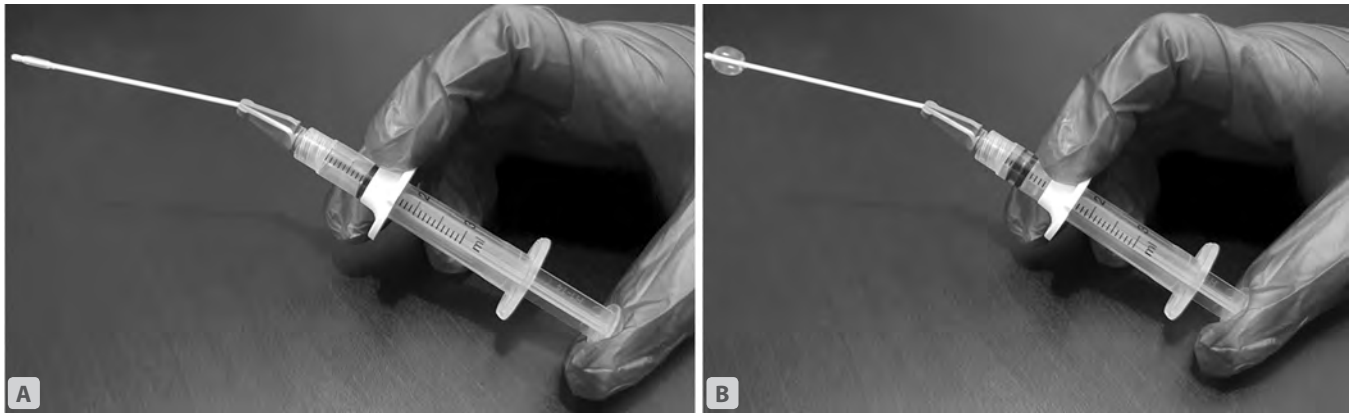
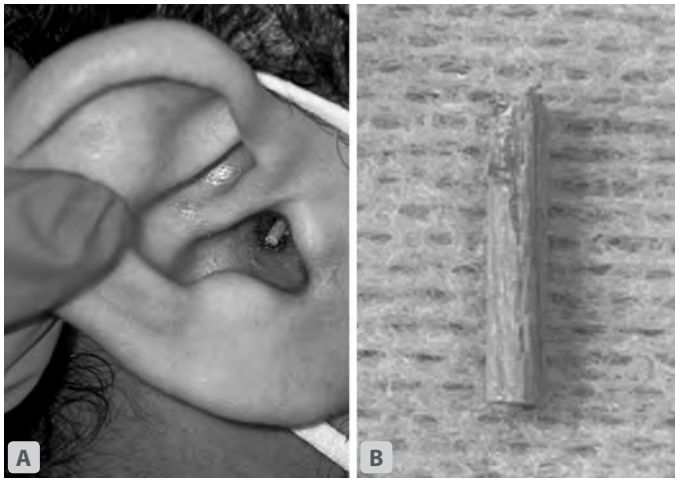
Complications

Repeated attempts at removal of an ear foreign body are associated with an increase in complications, usually encountered with objects that are difficult to grasp, spherical, close to the tympanic membrane, or with prolonged impaction. Button batteries always require urgent removal, as they may corrode into and damage surrounding tissues, especially when left for long periods of time within the ear canal.



FIGS. 6A AND B: Katz extractor.



FIGS. 7A AND B: (A) Foreign body impacted in the external auditory canal, visible on direct visual examination of the ear. (B) Removed foreign body object revealed to be a small piece of wood.

Disposition

The majority of patients with successful foreign body removals, in the absence of significant associated injury, may be safely discharged with no further management needed. Otolaryngologists should be consulted by the ED physician for any foreign body that is considered to be difficult to remove by the responsible physician and where repeated attempts at removal have been unsuccessful. Objects deep within the canal, in contact with or damaging the tympanic membrane and those with significant associated injury, hearing loss, or nerve damage should be managed emergently by or in conjunction with the otolaryngologist.

FOREIGN BODIES OF THE NOSE

Patients presenting with a foreign body in the nose are not an uncommon occurrence in the ED. This population of patients comprises mainly of children <4 years of age, but it may also present in patients with psychiatric disease or intellectual disabilities. Culprit objects found in the nasal cavities are often divided into organic (e.g., seeds, peanuts, insects, and worms) and inorganic (e.g., jewelry, toys, pens/pencils, button batteries, coins, and paper) substances, with inorganic items being more commonly encountered.

Anatomy

The nose can be imagined as an internal cavity that connects the nostrils externally to the nasopharynx internally. Its roof is comprised mainly of the cribriform plate (ethmoid bone) in addition to nasal, frontal, and sphenoid bones. Inferiorly, the floor is formed by the maxilla and palatine bones (hard palate). Medially, the nasal cavity is divided into left and right compartments by the nasal septum (ethmoid bone, the vomer bone, and the septal cartilage). As the cavity extends inward, the lateral walls of the cavity are lined by three (superior, middle, and inferior) bony projections, termed as conchae or turbinates that function to increase mucosal surface area and humidify the air flowing in. The spaces between conchae, called meatuses, function as channels through which various ducts and sinuses communicate with the nasal cavity. Most foreign bodies in the nose are often visible and anterior, found near or below the middle and inferior turbinates.

Clinical Features

Nasal foreign bodies are more likely to be found in the right side of the nose. Children who insert these objects into their nose are often brought by caregivers or parents who witnessed the insertion. Therefore, a significant number of nasal foreign bodies are brought due to an observed or suspected history of insertion, within 24 hours of the incident, and with no clinical symptoms secondary to the foreign body. However, as time passes, patients are more likely to manifest with nasal pain, unilateral nasal discharge, epistaxis, and, less frequently, with features of surrounding cellulitis or even meningitis.

Evaluation and Management

Radiography is seldom useful in the evaluation of nasal foreign bodies since substances such as wood or plastic are unlikely to be easily visualized. While button batteries and magnets can be visualized on plain X-rays, these foreign bodies carry a risk of corrosion and necrosis to the surrounding tissue and, as such, expeditious removal takes priority over pursuing identification through radiography, especially if the object is visible on direct examination. If, however, only suspicion of a nasal foreign body is maintained, a plain radiograph may be useful to rule

out the presence of a foreign body that may otherwise result in significant morbidity if missed.

As with any foreign body removal, the first attempt is most likely to be successful, with subsequent attempts associated with increased complications. Therefore, preparation is key and centers around optimizing visualization and examination of each nostril and nasal cavity, especially when mechanical removal is planned. A head lamp or stand lamp, with or without adjuncts such as nasal speculums (**Fig. 8**) can be used to enhance the visual field. Any object not adequately visualized may lie in the posterior aspects of the nasal cavity and, therefore, may be prone to deeper impaction or risk of aspiration if blind instrumentation is attempted. Therefore, for suspected foreign bodies where visualization is inadequate or perceived to be posterior, it is advisable to involve the otolaryngologist for removal. Since impacted nasal foreign bodies have a tendency to trigger inflammatory reactions in surrounding tissue or mucosa, it is often advisable to apply topical analgesia (e.g., lidocaine nasal drops) or topical decongestant (e.g., phenylephrine or oxymetazoline) prior to initiation of removal techniques. This, in conjunction with adequate restraint or instructions to facilitate patient immobilization, can significantly improve the likelihood of an uncomplicated foreign body extraction.

Techniques for nasal foreign body removal can grossly be divided into two categories.

Positive Pressure Methods

This method generally employs the concept of introduction of positive pressure through an alternate orifice such as the mouth or nostril opposite to the affected side in order to push the foreign body outward from its impacted region. In older children who can follow instructions, you may ask them to blow their nose whilst keeping the unaffected nostril occluded, making sure to have them inhale through the mouth only to decrease risk of aspiration. The "mother's kiss" or "parent's kiss" is another method that originated in the 1960s and requires the parent to form a seal over a child's mouth with their own and, while keeping the unaffected nostril occluded, blow with force into the mouth in an attempt to introduce positive pressure behind the foreign body inside the nostril and push it outward. A systematic review in 2012 discovered this technique to be generally safe with success rates approximating 60%. A bag-valve mask may be incorporated in a similar fashion to form a seal over the patient's mouth and deliver positive pressure.

Mechanical Extraction

Similar to aural foreign bodies, various instruments can be used to grasp or anchor behind the nasal foreign body under direct visualization, including Alligator forceps, Katz extractors, wax curettes, and right angle hooks, with care taken not to push the foreign object further into the nasal cavity during manipulation. Bonding to the object using glue at the end of a cotton tip, similar to the technique described for ear foreign bodies, is also sometimes used. Visualization prior to instrumentation is often augmented with use of a nasal speculum. A nasal washout technique is also found to be effective in many cases, where a bulb syringe with normal saline is advanced into the contralateral nostril until an adequate seal is obtained, following which the syringe is rapidly and forcibly squeezed, causing the saline to push the foreign body outward from the affected nostril. This technique is not recommended for use with button batteries where the saline fluid may exacerbate battery corrosion.

FIG. 8: Nasal speculum.

Complications and Disposition

After a foreign body is successfully removed from the nose, it is important to reexamine both sides of the nasal cavity for retained secondary foreign bodies, injuries from mucosal trauma, persistent epistaxis, or signs of infection within the nasal cavity. Ongoing bleeding should be evaluated and observed and signs of infection or cellulitis may require consideration of antibiotics at discharge. Significant damage to the mucosa or septum warrants urgent ENT consult to aid in repair and prevents further complications, especially in the setting of button batteries and magnets.

FOREIGN BODIES OF THE THROAT

Foreign bodies in the upper aerodigestive tract are a common and important clinical problem seen in the EDs. Other than the pediatric population, those with learning difficulties, psychiatric patients, and prisoners can also present with ingested foreign bodies. Children usually present with foreign bodies such as toy parts and coins while adults commonly present with fish/meat bone, artificial dentures, etc. Foreign bodies in the aerodigestive tract can present with irritation at the back of the throat, drooling, or signs of respiratory distress (such as cough, shortness of breath, and stridor).

Anatomy

The pharynx is a muscular structure comprised of three sections: (1) Nasopharynx, (2) Oropharynx, and (3) Laryngopharynx. It begins at the base of the skull and ends at the inferior border of the cricoid cartilage (C6). The oropharynx is located between the soft palate and the superior border of the epiglottis and is involved in the voluntary and involuntary phases of swallowing. The laryngopharynx is located between the superior border of the epiglottis and the inferior border of the cricoid cartilage (C6) and continues inferiorly with the esophagus. There are two main groups of pharyngeal muscles; circular and longitudinal. The vagus nerve innervates all the muscles of the pharynx except the stylopharyngeus which is innervated by the glossopharyngeal nerve. The pharyngeal plexus provides sensory and motor innervation to the majority of the pharynx. Arterial supply is via the branches of the external carotid artery and venous drainage is by the pharyngeal plexus. The esophagus begins at the inferior border of the cricoid cartilage and has four areas of anatomical narrowing which are the most common sites of foreign body entrapment—

upper esophageal sphincter (UES), aortic arch, left mainstem bronchus, and lower esophageal sphincter (LES) at the diaphragmatic hiatus. The UES or cricopharyngeus muscle is the most common site of impaction.

Clinical Features

Adult patients can often describe the precipitating event and commonly report symptoms such as throat pain, dysphagia, odynophagia, choking, or retrosternal chest pain. Foreign body ingestions in the pediatric population can be challenging, as approximately 40% of the cases are unwitnessed and many children remain asymptomatic. Pediatric patients brought to the ED after witnessed ingestion or lodged foreign body may present with a refusal to eat choking, drooling, new cough, voice change, or stridor. Red flags for ingested foreign bodies include stridor, drooling, dysphonia, surgical emphysema, or signs of esophageal perforation including chest pain or signs of sepsis. The ingestion of a button battery is also considered a red flag as it causes caustic injury.

Differential Diagnosis

In most cases, the history will be enough to confirm the diagnosis. It is important to distinguish the location of the foreign body; airway versus the digestive tract. One of the top differentials to consider is a food bolus. Other differentials based on the symptoms could include ischemic acute coronary syndrome (ACS) for retrosternal chest pain.

Evaluation

The evaluation of ingested foreign bodies begins with looking for airway compromise. Any patient with airway compromise or impending compromise will need emergent management of their airway. A visual inspection of the oropharynx can be done using Lack's tongue depressor and light source. The neck can be palpated for points of tenderness as well as surgical emphysema. Direct visualization with flexible nasal endoscopy can be attempted if the patient is stable.

Investigations

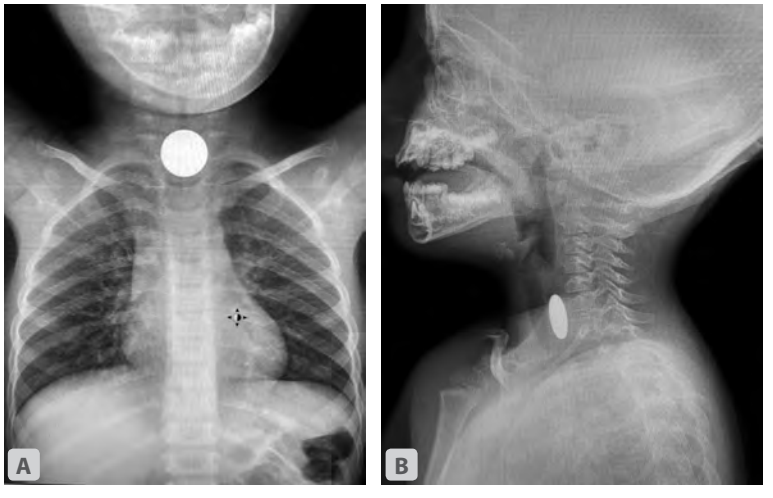
Imaging studies are required in cases where the clinical presentation is unclear or equivocal. Plain radiographs of the neck, chest, and abdomen can be done if a radio-opaque foreign body is suspected (**Fig. 9**). Loss of cervical lordosis or widening of retropharyngeal space in the lateral neck X-ray (>7 mm at C2 and >22 mm at C7 approximately) can be suggestive of an impacted foreign body. Other signs include surgical emphysema and widening of the mediastinum. It is important to note that a negative plain radiograph does not rule out the presence of a foreign body, as false-negative rates can be as high as 47%. Fishbone, which is one of the most common foreign body found in the upper aerodigestive tract is rarely seen in a radiograph. If clinical suspicion remains high, computed tomography (CT) has a sensitivity close to 100% in detecting foreign bodies. Contrast studies (barium or Gastrografin) are not preferred due to the risk of aspiration. Direct visualization by laryngoscopy or endoscopy is other options if clinical suspicion remains high and imaging is equivocal.

Management

Initial management depends on the clinical status of the patient as well as the risk of airway compromise. The other factors include the type of foreign body, location, and time since ingestion of the foreign body. Ingestion of button batteries, coins impacted in the upper esophagus, sharp objects, and objects causing complete obstruction need urgent intervention.

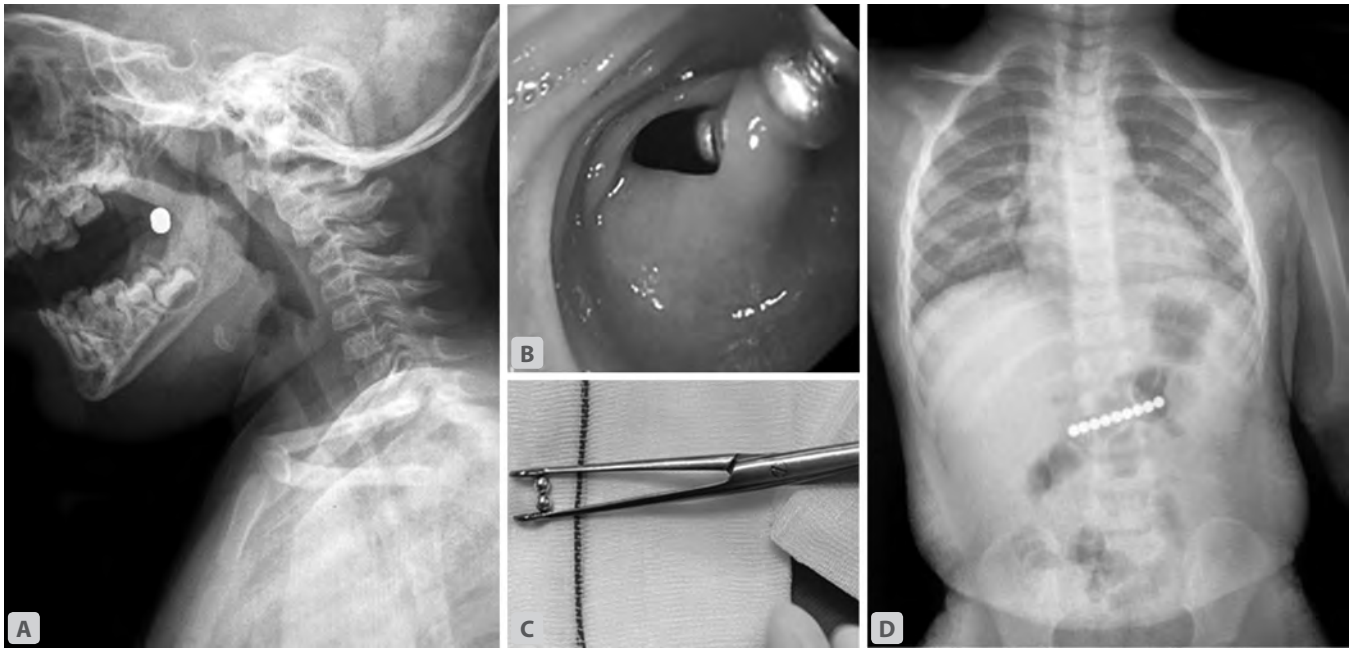
Foreign Body in the Throat

Foreign bodies directly visualized in the oropharynx can be removed using Magill forceps or a Kelly clamp (**Fig. 10**). If removal is not tolerated, one may have to use procedural sedation or attempt removal under general anesthesia (GA) via endoscopy. Blind finger sweeps should never be performed to remove the foreign body.



FIGS. 9A AND B: (A) Anteroposterior (AP) plain X-ray view of a child with coin ingestion, displaying a well circumscribed, radio-opaque density in the upper esophagus. (B) Lateral view revealed coin position to be posterior to the air-filled, radiolucent tracheal pathway, confirming its position in the esophagus.

FIGS. 10A AND B: Adult male who presented to the emergency department with complaints of dysphagia and throat pain after a recent meal. (A) Lateral X-ray of the neck reveals a thin and curved density impacted in the pharynx. (B) Under visualization using a laryngoscope, Magill forceps removed the foreign body, revealed to be a fishbone.



FIGS. 11A TO D: Child who presented after pain and dysarthria after being found playing with magnets. (A) Lateral X-ray revealed two circular and superimposed densities within the oral cavity. (B): Bronchoscopy revealed the patient's uvula to be entrapped between two magnets. (C) Removed spherical magnets. (D) X-ray of the chest and abdomen revealed multiple secondary ingested foreign bodies within the abdomen forming a sequential chain within the intestine. ***(For color version, see plate 17)***

Foreign Body in the Upper Esophagus

A Foley catheter is an inexpensive technique to remove smooth foreign bodies in the upper esophagus. To use this technique, place the patient in a prone position and pass the catheter past the impacted foreign body and inflate the balloon. The catheter is then withdrawn pulling the foreign body with it. This technique is avoided in patients with esophageal perforation/structural abnormalities, sharp objects, and objects that have been impacted for more than a week. Specifically, for impacted coins, an esophageal dilator can be used to advance the coin into the stomach. All button batteries regardless of the location [respiratory or gastrointestinal (GI) tract] are a medical emergency and should be removed endoscopically within 6 hours of ingestion/aspiration to prevent necrosis or perforation (**Fig. 11**).

Food boluses causing incomplete obstruction have traditionally been treated with glucagon [1–2 mg intravenous/intramuscular (IV/IM)], which causes smooth muscle to relax and allows the passage of the food bolus. However, glucagon causes vomiting which increases the risk of aspiration and esophageal perforation. Recent studies concerning its efficacy are mixed and, based on the lack of evidence, glucagon is better avoided in treating impacted food boluses. Other treatments include carbonated drinks and medications such as benzodiazepines, papain, nitroglycerin, and nifedipine. They have been shown to have variable efficacy and are generally

not recommended. While endoscopy is indicated emergently in complete obstruction, it is recommended that food boluses causing incomplete obstruction are removed endoscopically within 24 hours to avoid complications. Gastroenterology consultation for emergent endoscopy is indicated in airway obstruction, complete esophageal obstruction (drooling), button battery in the esophagus, sharp objects (>6 cm long and >2 cm wide), coin at the level of UES, multiple foreign bodies, or if there is any concern for esophageal perforation.

Complications

Complications can range from mild irritation of the pharynx to abscess, esophageal perforation, and mediastinitis. Adverse outcomes of ingested foreign bodies include airway compromise, pneumonia, esophageal stricture/perforation, fistula formation (aortoenteric or tracheoesophageal), and abscess.

Disposition

All patients with red flags or concerns for continued obstruction should have a gastroenterology consult. Patients who undergo endoscopy for removal of the foreign body are typically admitted and observed for a period of time after the procedure. Patients with no red flags and successful removal of the foreign body may be discharged with follow-up. Patients with food bolus impaction will usually require a follow-up endoscopic evaluation for structural abnormalities of the esophagus.

SUMMARY

Foreign bodies in the ENT are frequently encountered problems in patients presenting to the ED, and majority of patients are children, under the age of 5 years. When care is delayed in younger patients, adverse events such as tympanic perforation and bronchoaspiration can occur as a consequence of foreign bodies. Most foreign bodies are easily removed within the ED. However, multiple failed attempts can lead to complications in patients. Therefore, the ED physician should aim to develop skills and awareness on the various approaches and removal techniques for these cases. Where there is doubt, it is best to either consult ENT specialists or involve them in the removal procedure rather than risk further injury.

CHAPTER

Anemia

Akanksha Rastogi, Amit Mittal

INTRODUCTION

Anemia shall be noted as decrease in hemoglobin (Hb), red blood cell (RBC) count, or hematocrit for the patient's age, sex, and altitude of residence. The average Hb values are different in different laboratories. According to the World Health Organization, criteria for anemia are: In men: Hb <14 g/dL and in women: Hb <12 g/dL. This may not apply to certain group of population such as smokers (high Hb level than normal), athletes [low Hb level since dilutional anemia/gastrointestinal (GI) bleed], living at high altitude (high Hb), African-Americans (low Hb), and presence of chronic disease (less Hb). Anemia is one of the most common problems seen in clinical practice, but the cause of anemia can be single to multifactorial. Grossly anemia can be classified as emergent (life-threatening) and nonemergency (no immediate threat to life).

PATHOPHYSIOLOGY

Red blood cells main functions are transport of oxygen from lungs to tissue and carbon dioxide from tissue to lung. This process is affected by hemoglobin level, oxygen affinity of Hb, and blood flow. During severe disease and pathological conditions compensatory mechanism may fail to respond and result in hypoxia and cell death. Anemia stimulates compensatory mechanism of erythropoiesis by erythropoietin hormone (produced in kidney 90% and liver 10%). In bone marrow, RBC production (erythropoiesis) needs following four things:

1. *Stimulus, trophic hormones: Erythropoietin* (secreted from kidney peritubular cells), e.g., reduced in kidney failure, *thyroid hormone,* e.g., reduced in hypothyroidism.
2. *Bone marrow precursor cells* response to that stimulus, e.g., reduced in aplasia and bone marrow infiltration
3. *Nutrients (vitamin B12 and iron),* e.g., less in dietary lack and celiac sprue
4. *RBC life span* (life span ~4 months), e.g., less in hemolytic anemia (<100 days)

In approximately 5 days in circulation (transit time), 1 *proerythroblast* divides to form eight *reticulocyte* (1% of total RBC), which form mature erythrocyte in ~1 day. In *acute anemia*, transit time decrease to 2 days (due to skipped divisions and accumulation of debris), so RBC become macrocytic.

TYPES OF ANEMIA

- *Red cell morphology disorder*:
  - Hypoproliferative anemia (three-fourths cases)
  - Red cell maturation disorder (ineffective erythropoiesis)
  - Hemolysis/blood loss
- *Iron deficiency*:
  - *Increase demand:* Rapid growth and pregnancy
  - *Decreased intake:* Inadequate diet, celiac sprue, and gastrectomy
  - *Increased iron loss:* Menstrual, blood donation, and acute or chronic blood loss
- *Vitamin B12 deficiency*: Vegans, pernicious anemia, gastrectomy, intestinal stricture, tropical sprue, fish tapeworm, and Crohn's disease.

CLASSIFICATIONS

Anemia can be classified by many ways such as (1) *Blood loss*: *Acute blood loss emergent anemia*—(life-threatening)*/ chronic blood loss—nonemergent anemia;* (2) *Morphological classifications,* e.g., microcytic hypochromic, macrocytic hypochromic, normocytic normochromic, and dimorphic anemia; (3) Anemia due to decreased red cell production or due to increased red cell destruction (**Box 1**).

CLINICAL PRESENTATION

Clinical features of anemia depend on how rapidly hematocrit falls and ability to compensate by the patient. Children and young adult tolerate blood loss well without alteration in vital signs. Symptoms are because of:

- *Hypoxia (decreased oxygen delivery to tissues)*: Tiredness, fatigue, breathlessness, palpitations, and confusion.
- *Hypovolemia (acute and marked bleeding)*: Easy fatigability, lassitude, muscle cramps, dizziness, lethargy, syncope, drop in blood pressure (BP). The bleeding can be *obvious, occult, and induced*, i.e., hemodialysis, excess blood donation, or *underappreciated menstrual loss*.
- *Hemolysis*: Dark urine (gold to red to black) and acrocyanosis on exposure to cold

BOX 1: Classification of anemia.

I. **Anemia caused by decreased RBC production/RBC maturation disorder**
   - A. **Nuclear maturation defect** *(macrocytosis—elevated MCV)*
     1. Vitamin B12 or folate deficiency
     2. Drugs: Methotrexate
     3. Alcohol
     4. Myelodysplasia
   - B. **Cytoplasmic maturation defect** *(microcytosis and hypochromia-decreased MCV)*
     1. Iron deficiency
     2. Thalassemia
     3. Sideroblastic anemia
     4. Anemia of chronic disease
   - C. **Hypoproliferative disorder** *(normocytic normochromic-normal MCV)*
     1. *Marrow damage (infiltration/fibrosis and aplastic anemia)*
     2. *Less stimulation (kidney disease, hypothyroidism, and inflammation)*

II. **Anemia caused by increased RBC destruction: Hemolysis/blood loss**
   - A. **Extravascular RBC destruction in liver, spleen, bone marrow, and lymph nodes**
     1. *Intrinsic RBC defects*
        Thalassemia, sickle cell disease, spherocytosis, elliptocytosis, G6PD, or pyruvate kinase deficiency
     2. *Extrinsic RBC defects*
        Hypersplenism, autoimmune hemolytic anemia (AIHA), intravenous immunoglobulin infusion, snake bite, liver disease, dapsone, aniline dyes, and malaria
   - B. **Intravascular RBC destruction**
     1. *Hereditary*
        Hemolytic uremic syndrome (HUS), Wilson's disease, and TTP
     2. *Acquired*
        Mechanical valves, paroxysmal nocturnal hemoglobinuria (PNH), paroxysmal cold hemoglobinuria (PCH), ABO incompatibility, copper poisoning, clostridial sepsis, severe malaria, and TTP

(G6PD: glucose-6-phosphate dehydrogenase; MCV: mean corpuscular volume; RBC: red blood cell; TTP: thrombotic thrombocytopenic purpura)

RED FLAGS

Clinical approach is important. Blood loss can occur in few scenarios which can be missed (repeated blood drawing, surgery, and bleed in upper thigh or retroperitoneal space).

In acute blood loss, Hb and hematocrit values do not tell the volume of blood loss as hypovolemia predominates. Pale skin and mucous membranes indicate Hb <8 g%.

Use two approaches: *Kinetic* (decrease in Hb) and *morphological* [altered mean corpuscular volume (MCV) and reticulocyte count). This can lead to death in few settings such as malignancy, heart failure, and hospitalized elderly.

EVALUATION OF ANEMIA

History

- Onset, duration awareness, severity (more symptomatic in severe anemia), and progression.
- *Past history*: Recurrent blood transfusion, drugs, fever, and surgery (pigment gallstone removal and splenectomy)
- *Personal and family history* (alcohol, smoking, anemia in family members, consanguinity, and low socioeconomic status) *How are the symptoms now?*—progression or improvement

Symptoms

- *Nonspecific:* Weakness, headache, and blurred vision
- *Neurological:* Limb weakness, tingling, numbness, and swaying while walking in dark
- *Cardiovascular:* Chest pain, palpitations, swelling of feet, and breathlessness
- *Gastrointestinal*: Loss of appetite, pica, pain abdomen, altered bowel habits, dysphagia, and jaundice
- *Miscellaneous:* Fever, bony pain, bleeding tendencies, leg ulcers, gallstones, and stunted growth
- *Cause related:* Blood loss (hematemesis, melena, hemoptysis, menstrual blood loss, repeated childbirth, occult peptic ulcer disease, constipation and diarrhea, bleeding spots in skin, mucosa, or joints); nutritional intake (vegetarian, nonvegetarian, and milk ingestion); worm infestation (pain abdomen, worm in stools, and poor hygiene); and malabsorption

Physical Examination

Look for built, nourishment, edema, chipmunk facies, puffiness of face, neck veins, oral cavity, pigmentation over skin, nails, bony tenderness, bleeding spots, retina, leg ulcers, joint status, and systemic examination.

Interpretation of Finding

- *Age and sex*: Vitamin B12 and folate deficiency predominantly noted in elderly population and iron deficiency more in children and pregnant females.
- *Nutrition and socioeconomic status*: Vitamin B12 deficiency in true vegetarian, inadequate intake because of poverty (iron deficiency), poor toilet facility (worm infestation), alcoholics (erosive gastritis, peptic ulcer, and esophageal varices-related bleed), smoker (peptic ulcer, Hb is more normally), consanguinity (hemolytic anemia), and residence in high altitude (high normal Hb)
- *Nonspecific symptoms*: Due to tissue hypoxia
- *Breathlessness*: Exertional (Hb <7 g%) and at rest (Hb <3 g%) indicates cardiac failure
- *Pica, worm, and dysphagia due to postcricoid webs*: Iron deficiency anemia
- *Jaundice*: Hemolytic anemia
- *Pain abdomen*: Peptic ulcer, GI malignancy, and worm
- *Neurological symptoms*: Vitamin B12 deficiency
- *Fever*: Infection, e.g., malaria, lymphoma, leukemia, endocarditis, and collagen vascular disease

- *Bleeding tendencies and bony pain*: Blood cancer, myeloma, and lymphoma
- *Drugs*: Phenytoin, primidone, sulfasalazine (folate deficiency), primaquine, and dapsone [hemolysis in glucose-6-phosphate dehydrogenase (G6PD) deficiency]
- *General physical examination*: Stunted growth (hemolytic anemia), lymphadenopathy [supraclavicular in gastrointestinal tract (GIT) cancer, generalized in lymphoma, and leukemia), edema (cardiac failure, kidney or liver disease, and hypoalbuminemia), chipmunk facies with frontal bossing and protuberant teeth (thalassemia major), bald tongue (iron deficiency), beefy red tongue (niacin deficiency), flat and spoon-shaped nails (iron deficiency), leg ulcers (sickle cell anemia and hereditary spherocytosis), Roth spots in eyes (endocarditis), and venous thromboembolism in autoimmune hemolytic anemia and hereditary spherocytosis
- *Abdominal examination*: Abdominal tenderness (peptic ulcer, stomach cancer, and lymphoma), hepatomegaly (liver cirrhosis and lymphoma), splenomegaly (hemolytic anemia), and ascites (cardiac failure)
- *Hemolysis*: Consider when no bleed, rapid onset of anemia, jaundice, dark urine, recent blood transfusion, new drug, history of hemolytic anemia, unexplained anemia in family, pigmented gallstones, and splenomegaly.

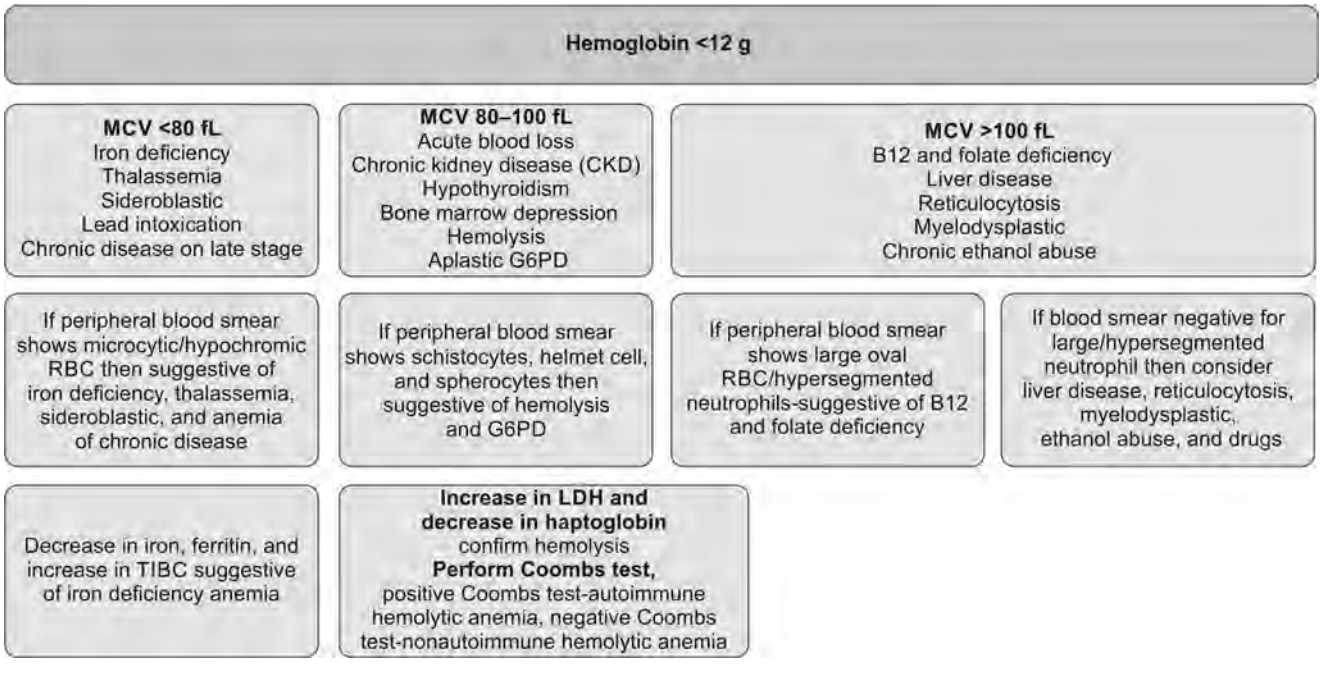
DIFFERENTIAL DIAGNOSIS

Classification of anemia is helpful in differentiating the various types of anemia. Classification which involves decreased RBC production, increased RBC destruction, and blood loss (**Box 1**) with morphological classification (**Fig. 1**) collectively used to narrow down the specific type of anemia.

INVESTIGATIONS

Evaluation of anemia needs series of test as described below while Hb and hematocrit should be measured in emergency department itself. On the basis of this further investigations are planned (**Table 1**).

- *Complete blood count (CBC)*:
  - *Red blood cell count:* (affected by age, sex, pregnancy, smoking, and altitude)
    - Hemoglobin
    - Hematocrit
    - Reticulocyte production index (RPI) (reticulocytes are immature RBC)
      <2 ~inappropriate marrow response: Red cell morphology disorder (i.e., type I and II)
      >2 ~accelerated RBC production: Hemolysis/blood loss (i.e., type III)
      (*Refer **Table 1** as described below*)
  - *Red blood cell indices:*
    - Mean cell volume (MCV in femtoliters, normal ~90) (<80 ~microcytosis and >100 ~macrocytosis)
    - Mean cell hemoglobin (MCH in picograms per cell)
    - Mean cell hemoglobin concentration (MCHC in gram per liter)
      MCH and MCHC denote hypochromia
    - *Red cell distribution width (RDW)*: If RPI <2—*Type I* has normal indices and *Type II* has abnormal indices *(Refer **Table 1** as described above)*
  - *White blood cell count*
- Cell differential
- Nuclear segmentation of neutrophils in vitamin B12 deficiency



Hemoglobin <12 g
MCV <80 fL
Iron deficiency
Thalassemia
Sideroblastic
Lead intoxication
Chronic disease on late stage
MCV 80–100 fL
Acute blood loss
Chronic kidney disease (CKD)
Hypothyroidism
Bone marrow depression
Hemolysis
Aplastic G6PD
MCV >100 fL
B12 and folate deficiency
Liver disease
Reticulocytosis
Myelodysplastic
Chronic ethanol abuse
If peripheral blood smear shows microcytic/hypochromic RBC then suggestive of iron deficiency, thalassemia, sideroblastic, and anemia of chronic disease
If peripheral blood smear shows schistocytes, helmet cell, and spherocytes then suggestive of hemolysis and G6PD
If peripheral blood smear shows large oval RBC/hypersegmented neutrophils-suggestive of B12 and folate deficiency
If blood smear negative for large/hypersegmented neutrophil then consider liver disease, reticulocytosis, myelodysplastic, ethanol abuse, and drugs
Decrease in iron, ferritin, and increase in TIBC suggestive of iron deficiency anemia
Increase in LDH and decrease in haptoglobin
confirm hemolysis
Perform Coombs test,
positive Coombs test-autoimmune hemolytic anemia, negative Coombs test-nonautoimmune hemolytic anemia

(G6PD: glucose-6-phosphate dehydrogenase; LDH: lactate dehydrogenase MCV: mean corpuscular volume; RBC: red blood cell; TIBC: total iron-binding capacity)

FIG. 1: Differentiating various types of anemia.

TABLE 1: Investigations for approach to anemia.

Complete blood count	*Iron and vitamin B12 studies*	*Biochemistry*	*Test for hemolysis*	*Bone marrow studies*	*Others*
Red blood cell (RBC) count: (Affected by age, sex, pregnancy, smoking, and altitude) hemoglobin, hematocrit, and reticulocyte production index (RPI) (reticulocytes are immature RBC) <2—*inappropriate marrow response*: Red cell morphology disorder (i.e., Type I and II] and >2—accelerated RBC production: Hemolysis/blood loss (i.e., Type III) *Red blood cell indices*: Mean cell volume (MCV in femtoliters, normal ~90) (<80—microcytosis, >100—macrocytosis), mean cell hemoglobin (MCH in picograms per cell), mean cell hemoglobin concentration (MCHC in gram per liter). MCH and MCHC denotes hypochromia *Red cell distribution width (RDW)*: If RPI <2—Type I has normal indices and Type II has abnormal indices *White blood cell count*: Cell differential, nuclear segmentation of neutrophils in vitamin B12 deficiency *Platelet count*: Low in hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) *Peripheral blood smear (P/S)/cell morphology*: Abnormal cells, e.g., schistocytes, sickle cells, spherocytes, and burr cells seen in hemolytic anemia *Cell size*: Microcytes in iron deficiency, macrocytes in vitamin B12 and folate deficiency Hemoglobin content Anisocytosis—variation in cell size Poikilocytosis—variation in cell shape Polychromasia—larger greyish blue RBC (in fibrosis and malignancy)	*Serum iron*: <60 µg/dL in iron deficiency anemia *Total iron binding capacity (TIBC)*: >400 µg/dL in iron deficiency anemia *Serum ferritin level*: <10 mg/mL in iron deficiency anemia *Vitamin B12 level*: <200 µg/L suggestive of megaloblastic anemia *Folate level*: <3 µg/L suggestive of megaloblastic anemia	*Blood urea nitrogen (BUN)*: High [in slow gastrointestinal (GI) bleed hemoglobin is being absorbed from gut] *Creatinine*: High (chronic kidney disease) *Bilirubin*: Indirect (raised in hemolytic anemia)	*Haptoglobin*: Low in hemolysis *Lactate dehydrogenase (LDH)*: Raised (intravascular hemolysis) *Coombs test (direct and indirect)*: Positive in autoimmune hemolytic anemia *Urine*: Look for hemoglobinuria and hemosiderin (intravascular hemolysis)	*Bone marrow aspirate to look for*: Myeloid/erythroid ratio Cell morphology Iron stain *Bone marrow biopsy to look for*: Cellularity and morphology	*Ultrasound and CT scan abdomen*: To look for hepatosplenomegaly and ascites *Stool test*: Positive occult blood indicates loss of blood, routine microscopy to look for worm infestation GI endoscopies to look for bleed

    - *Platelet count*: Low in hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP)
    - *Peripheral blood smear (P/S)/cell morphology* (Abnormal cells, e.g., schistocytes, sickle cells, spherocytes, and burr cells seen in hemolytic anemia)
        - Cell size (microcytes in iron deficiency and macrocytes in vitamin B12 and folate deficiency)
        - Hemoglobin content
        - Anisocytosis—variation in cell size
        - Poikilocytosis—variation in cell shape
        - Polychromasia—larger greyish blue RBC (in fibrosis and malignancy)
- *Iron and vitamin B12 deficiency studies*:
    - Serum iron
    - Total iron binding capacity (TIBC)
    - Serum ferritin
    - Vitamin B12
    - Folate
- *Bone marrow studies*:
    - *Aspirate to look for*
        - Myeloid/erythroid ratio
        - Cell morphology
        - Iron stain
    - *Biopsy to look for*
        - Cellularity
        - Morphology
- *Biochemical tests*:
    - *Blood urea nitrogen (BUN):* High (in slow GI bleed Hb is being absorbed from gut)

- *Creatinine:* High (chronic kidney disease)
- *Bilirubin:* Indirect raised in hemolytic anemia

- Test that depicts hemolysis:
  - *Haptoglobin:* Low in hemolysis
  - *Lactate dehydrogenase (LDH):* Raised (intravascular hemolysis)
  - *Coombs test (direct and indirect):* Positive in autoimmune hemolytic anemia
  - *Urine*: Look for hemoglobinuria and hemosiderin (intravascular hemolysis)
- *Others*:
  - *Ultrasound and CT scan abdomen:* To look for hepatosplenomegaly and ascites
  - *Stool test*: Positive occult blood indicates loss of blood and routine microscopy to look for worm infestation
  - *GI endoscopies to look for bleed*

HEMOLYTIC ANEMIA

Whenever suspicion of hemolytic anemia: Low Hb (with no another obvious cause) and high reticulocyte count (with no recent bleed, no repletion of iron, vitamin B12, folate, or erythropoietin) (**Table 2**)

Features of *RBC destruction*: High LDH and indirect bilirubin, low haptoglobin, and it is important to localize site of hemolysis, It tells the:

- By-products of hemolysis will route through reticuloendothelial system (RES) *(extravascular)* or directly into blood circulation *(intravascular)*
- Cause
- Need for more aggressive treatment

TREATMENT

Treatment depends on individual clinical status. Emergent anemia due to acute blood loss due to trauma should be stabilized in emergency department. Nonemergent anemia needs admission if they develop chest pain, breathlessness, or unexplained drop in Hb or hematocrit. Nutritional improvement is important aspect of management.

Blood transfusion (uncrossmatched blood only if life-threatening condition), if acute blood loss results in severe hypovolemia, autoimmune hemolytic anemia (AIHA), ongoing hemorrhage, tissue hypoxemia, or cardiovascular instability.

Iron Deficiency Anemia

- *Oral iron* (elemental ~200 mg/day, in empty stomach) (ferrous sulfate, gluconate, and fumarate) in individual with iron deficiency without any symptom
  Side effect: Nausea, vomiting, and constipation
  Target: Till 6–12 months after normalization of Hb
- *Intravenous iron (*ferric carboxymaltose, sodium ferric gluconate, and sucrose dextran) if oral iron is not tolerated, requirement of iron on ongoing basis
  Dose calculated by *2.3 × body weight (kg) × (15 – Hb of patient) and add 500/1,000 mg for stores*

Side effect: Anaphylaxis more with dextran

TABLE 2: Suspicion of hemolytic anemia and indicators for hemolysis.

Subtle indicators of extravascular hemolysis	*Subtle indicators of intravascular hemolysis*
• History of jaundice • P/S: Spherocytes and sickle cells • High indirect bilirubin	• History of pink (oxyhemoglobin) or brown (methemoglobin) serum • Dark urine • Free serum hemoglobin (it binds to haptoglobin and this complex is removed by liver) • Reduced haptoglobin • High LDH • Urine hemoglobin/heme • Urine hemosiderin (after few days as kidney degrades heme to hemosiderin) • Kidney damage, thrombosis, and disseminated intravascular coagulation

(LDH: lactate dehydrogenase; P/S: peripheral blood smear)

Vitamin B12 Deficiency

- Six 1,000 µg intramuscular injections (hydroxocobalamin) after every 3–7 days, then once in 3 months
- Sublingual or oral treatment if bleeding tendencies (intramuscular not allowed)

Folate Deficiency

About 5–15 mg oral folic acid daily for minimum 4 months.

Hemolytic Anemia

- Treat the cause.
- AIHA is a medical emergency. Consider blood transfusion only if life-threatening, otherwise immediately start prednisolone 1 mg/kg/day and consider rituximab (second-line treatment). If relapse occurs, plan splenectomy. Hematopoietic stem cell transplantation in refractory in very severe cases.
- *Paroxysmal nocturnal hemoglobinuria (PNH)*: Supportive and blood transfusion
- *Cold agglutinin disease*: Avoid cold exposure (mild case) and azathioprine (severe case)

SUMMARY

- Is there any history of bleeding?
- Young age and slower development of anemia are better tolerated.
- Iron deficiency can be detected several weeks after bleeding.
- Always order for CBC, reticulocyte count, and peripheral blood smear tests before hematinics or blood transfusion.
- Low serum ferritin confirms iron deficiency anemia.

- If bone marrow does not respond appropriately to anemia (e.g., iron/vitamin B12/folate/copper deficiency, chronic inflammation, alcohol, and transient RBC aplasia); hemolytic anemia can be seen without reticulocytosis.
- If bone marrow has sufficient capacity to overcome the anemia caused by hemolysis, hemolysis can be seen without anemia.
- Prognosis depends on underlying cause.
- Mortality is low in hemolytic anemia, though risk is more in elderly and cardiac patients.
- In elderly people, anemia is linked with prolonged hospitalization
- Do follow-up of patient at regular interval.

140 CHAPTER

Approach to Pancytopenia

Benita Florence, Dodiy Herman

INTRODUCTION

Pancytopenia is not an illness or disease in itself; it is the laboratory manifestation of underlying bone marrow dysfunction or failure in the production or reduction in the levels of all the three types of blood cells—erythrocytes, leukocytes, and platelets, manifested with symptoms resulting from anemia, leukopenia, or thrombocytopenia.

Emergency physicians are expected to acquire a high index of suspicion to the subtle signs and symptoms of pancytopenia, which may present as a benign or some of which are life-threatening condition. In most cases of pancytopenia, management of these patients will require multidisciplinary approach and timely referral to a hematologist.

DEFINITION

The presence of anemia with a hemoglobin (Hb) < 13.5 g/dL in males or 11.5 g/dL in females, leukopenia where leukocyte count < 4×10^3/L and thrombocytopenia with platelet count < 150×10^3/L is termed as pancytopenia.

Neutropenia is defined as mild (1,000–1,500/mm^3), moderate (500–1,000/mm^3), and severe (<500/mm^3) based on the absolute neutrophil count (ANC). This number is directly proportional to the prognosis of the patient. Agranulocytosis describes a virtual absence of neutrophils in peripheral blood which the ANC is <100/mm^3.

Thrombocytopenia is classified as platelet count of mild (100,000–150,000/mm^3) moderate (50,000–100,000/mm^3), and severe (<50.000/mm^3). Risk of bleeding increases significantly with platelet count < 20,000/mm.[3]

More often, diagnostic confirmation of pancytopenia is an incidental laboratory report. However, thorough history taking and clinical examination will aid with the diagnosis and the subsequent management of these patients. Further probing into the etiology leads to a range—transient suppression or dysfunction of the bone marrow due to infections, nutritional deficiencies, and may extend to malignancy.

ETIOLOGY

Major causes of pancytopenia are geographically and socioculturally determined, as hematological malignancies are more common in industrialized and developed nations, whereas vitamin deficiencies, hypersplenism, and infections are seen in developing countries.

Causes of Pancytopenia

- Idiopathic
- Bone marrow failure:
  - Aplastic anemia
  - Acute leukemia
  - Bone marrow fibrosis
  - Myelodysplastic syndrome and infiltrative diseases
- Hypersplenic state
- Autoimmune disorders—systemic lupus erythematosus (SLE)
- Infections [tuberculosis, human immunodeficiency virus (HIV), leishmaniasis, and brucellosis]
- Iatrogenic/drug-induced, e.g., drugs used in the treatment of rheumatoid arthritis
- Chronic liver disease
- Nutritional deficiencies (folate and B12)
- Macrophage activation syndrome (MAS) or hemophagocytic syndrome (rare)
- Paroxysmal nocturnal hemoglobinuria
- Miscellaneous

Eating disorders (anorexia nervosa), bariatric surgery, malabsorption syndromes, inadequate consumption of food, and alcoholism also lead to nutritional deficiencies. Inadequate dietary intake and alcoholism lead to folate deficiency, however, vitamin B12 deficiency occurs due to ineffective absorption. Megaloblastic anemia is commonly caused by folate and B12 deficiency and these usually present with anemia and thrombocytopenia; however, may present solely as thrombocytopenia. Pancytopenia may also be noted in pregnancy. Patients on long-term total parenteral nutrition, gastrointestinal surgery, weight reduction surgery, excessive zinc intake, and renal failure may develop pancytopenia due to copper deficiency.

Infections are known to lead to bone marrow failure. These are mostly reversible causes. Hence patients who are unwell with indwelling catheters, these should be considered as a primary source of infection and treated accordingly with a background picture of sepsis.

Infections can also cause acquired hemophagocytic lymphohistiocytosis (HLH). The clinical diagnosis of this syndrome requires the presence of five or more of the following:

- Fever
- Splenomegaly
- Cytopenia involving two or more cell lines
- Hypertriglyceridemia or hypofibrinogenemia
- Hepatitis
- Low or absent natural killer cell activity
- Serum ferritin level > 500 mg/L
- Soluble CD25 > 2,400 U/mL
- Hemophagocytosis as demonstrated in bone marrow, spleen, or lymph node

CLINICAL FEATURES

Patients may present to the emergency department (ED) acutely unwell as in fulminant sepsis, disseminated intravascular coagulation or rapid hemolysis or with chronic manifestations progressing over weeks or months. There are no specific signs and symptoms directly correlating to the presentation of the disease condition. Mild pancytopenia may be asymptomatic and may be an incidental finding. Presentation may be as follows:

- Nonspecific fever, fatigue, dizziness, weight loss, anorexia, and night sweats
- Anemia causing pallor, shortness of breath, and pedal edema
- Neutropenia causing features of sepsis, skin lesions, and oral ulceration
- Thrombocytopenia causing prolonged bleeding, easy bruising, petechial rashes, menorrhagia, epistaxis, and melena may be seen

Hepatomegaly, splenomegaly, and lymphadenopathy may be seen on clinical examination.

History of splenectomy, any other conditions treated, medications prescribed, nonprescribed, recreational drugs, smoking and alcohol, occupation, hobbies, etc., should be noted along with travel history, family history, any previous history of blood transfusion, or if the patient has been a donor also should be recorded.

DIAGNOSTIC WORKUP

Pancytopenia patients pose a diagnostic challenge, due to variable etiology which may be influenced by demography—country and other living conditions. It is essential to reach a definitive diagnosis as treatment and disease progression depend on the etiology of the pancytopenia. Therefore, clinical evaluation should include:

- Medication history
- Family history
- Recreational drug history
- Environmental exposure history
- Comorbid illnesses

Initial laboratory workup includes full blood count with peripheral smear, erythrocyte sedimentation rate, C-reactive protein, renal and liver function tests, lactate dehydrogenase levels, iron studies, clotting studies, reticulocyte count, and blood type and screen. A chest X-ray at presentation will help to exclude infection and as a comparison for subsequent films.

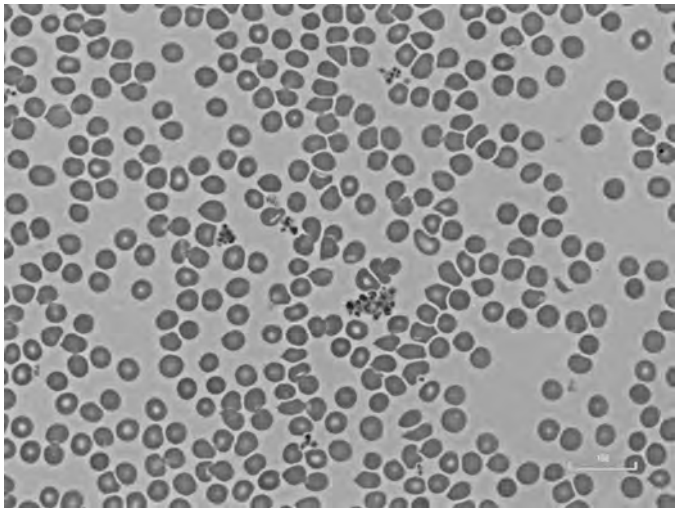

FIG. 1: Platelet clumping. Not an emergency but can give an erroneously low platelet count. ***(For color version, see plate 18)***

Bone marrow examination may reveal the underlying condition causing pancytopenia, but is not always conclusive. Hypoplastic bone marrow, megaloblastic anemia, and hematological malignancies, i.e., acute myeloid leukemia and erythroid hyperplasia are the common causes of pancytopenia seen on bone marrow examination. Unexplained pancytopenia, macrocytosis, hypersegmented neutrophils, and unexplained neurological signs and symptoms can be caused by folate and vitamin B12 deficiencies.

A caveat to remember that rarely, pseudothrombocytopenia may be a laboratory finding discovered incidentally, in an asymptomatic individual. Additionally, patient should be tested for copper, zinc, Coombs test, vitamin B12, folate level, HIV, hepatitis, and ultrasound of abdomen to look for hepatosplenomegaly. Ultrasonography with abnormal or anatomically displaced kidneys is a feature of Fanconi anemia.

Platelet clumping may be due to the calcium chelator in the ethylenediaminetetraacetic anticoagulant contained in the sample collection tube (**Fig. 1**). A repeat sample for confirmation should be sent in a citrated or heparinized tube.

APLASTIC ANEMIA

Aplastic anemia is a rare disorder which, if untreated, is associated with very high mortality. The incidence of aplastic anemia is approximately two to three per million per year in Western countries with the incidence is estimated to be two- to three-fold higher in East Asia. There is a biphasic distribution with peaks at 10–25 years and >60 years and a sex ratio of 1:1. The exact mechanism by which aplastic anemia occurs is still unknown in most of the cases. Important causes of aplastic anemia are shown in **Table 1**. It is defined as pancytopenia (reduction in the number of red cells, neutrophils, and platelets in the peripheral blood) with hypocellular marrow in absence of abnormal infiltrate or increased fibrosis. In order to diagnose aplastic anemia, there must be at least two of the following criteria:

- Hemoglobin concentration < 100 g/L
- Platelet count < 50×10^9/L
- Neutrophil count < 1.5×10^9/L

TABLE 1: Causes of aplastic anemia.

Drugs, radiation, and toxins	• Cytotoxic chemotherapy • Azathioprine • Gold • Chloramphenicol • Sulphonamides • Nifedipine • Carbamazepine • Valproic acid • Phenytoin • Ionizing radiation • Industrial chemicals • Insecticides • Benzene
Viral infection	• Hepatitis virus • Human immunodeficiency virus
Miscellaneous	• Systemic lupus erythematosus • Graft-versus-host disease • Paroxysmal nocturnal hemoglobinuria • Pregnancy • Anorexia nervosa

For purposes of risk stratification and severity, aplastic anemia further classified according to the following criteria:

- *Nonsevere aplastic anemia*:
  - Hypocellular bone marrow as per severe aplastic anemia
  - Peripheral blood cytopenia not fulfilling the criteria for severe aplastic anemia or very severe aplastic anemia
- *Severe aplastic anemia*:
  - Bone marrow cellularity <25% (or 25–50% with <30% of residual cells are hematopoietic)
  - At least two of the following:
    - Neutrophils $<0.5 \times 10^9$/L
    - Platelets $<20 \times 10^9$/L
    - Reticulocyte count $<20 \times 10^9$/L
- *Very severe aplastic anemia*: As for severe aplastic anemia but neutrophils $<0.2 \times 10^9$/L

INHERITED APLASTIC ANEMIA

Fanconi Anemia

Fanconi anemia is the most common form of inherited aplastic anemia, characterized by pancytopenia, predisposition to malignancy, and any of the physical abnormalities such as short stature, limb abnormalities, café-au-lait lesions on the skin, microcephaly, vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, structural malformations of the urogenital tract, or developmental delay. Though diagnosis is made in children there may be late presentation in adulthood. Fanconi anemia was first described in 1927 by a Swiss pediatrician Guido Fanconi. It is a rare, genetic heterogeneous multisystem disease transmitted as autosomal recessive with the exception of *FANCB*, which is X-linked transmitted.

Shwachman–Diamond Syndrome

Shwachman–Diamond syndrome also known as Shwachman–Bodian–Diamond syndrome, Shwachman–Diamond–Oski syndrome, or Shwachman syndrome is a rare inherited autosomal recessive disorder characterized by hematological abnormalities with pancytopenia, aplastic anemia, vulnerability to acquire myelodysplastic syndrome, and/or acute myeloid leukemia; exocrine pancreatic dysfunction with malabsorption, malnutrition, short stature, skeletal anomalies, cardiac defects, ear malformations/hearing loss, or skin rashes.

Approach to Clinical Treatment for Aplastic Anemia

- Eliminate exposure to causative agents
- Supportive therapy
- Immunosuppressive treatment, e.g., antithymocyte globulin
- Hemopoietic stem cell transplantation
- Screening for paroxysmal nocturnal hemoglobinuria

In the ED, supportive therapy and symptomatic care play a major role (**Flowchart 1**). In patients with aplastic anemia who have severe anemia/thrombocytopenia requiring transfusion; it is advisable that the red blood cell (RBC) units given are leukoreduced to minimize the risk of febrile nonhemolytic transfusion reactions and reduce transmission of cytomegalovirus (CMV) to CMV-negative patients. This is also important for those patients who may undergo allogeneic hematopoietic cell transplantation (HCT) in the future. Irradiation depletes lymphocytes and reduces the risk of transfusion-associated graft-versus-host-disease (ta-GVHD), during the initial phase of intensive immunosuppressive therapy (IST). Irradiation may not be required for all patients with supportive care as those who are not severely T cell immunodeficient are unlikely to develop ta-GVHD.

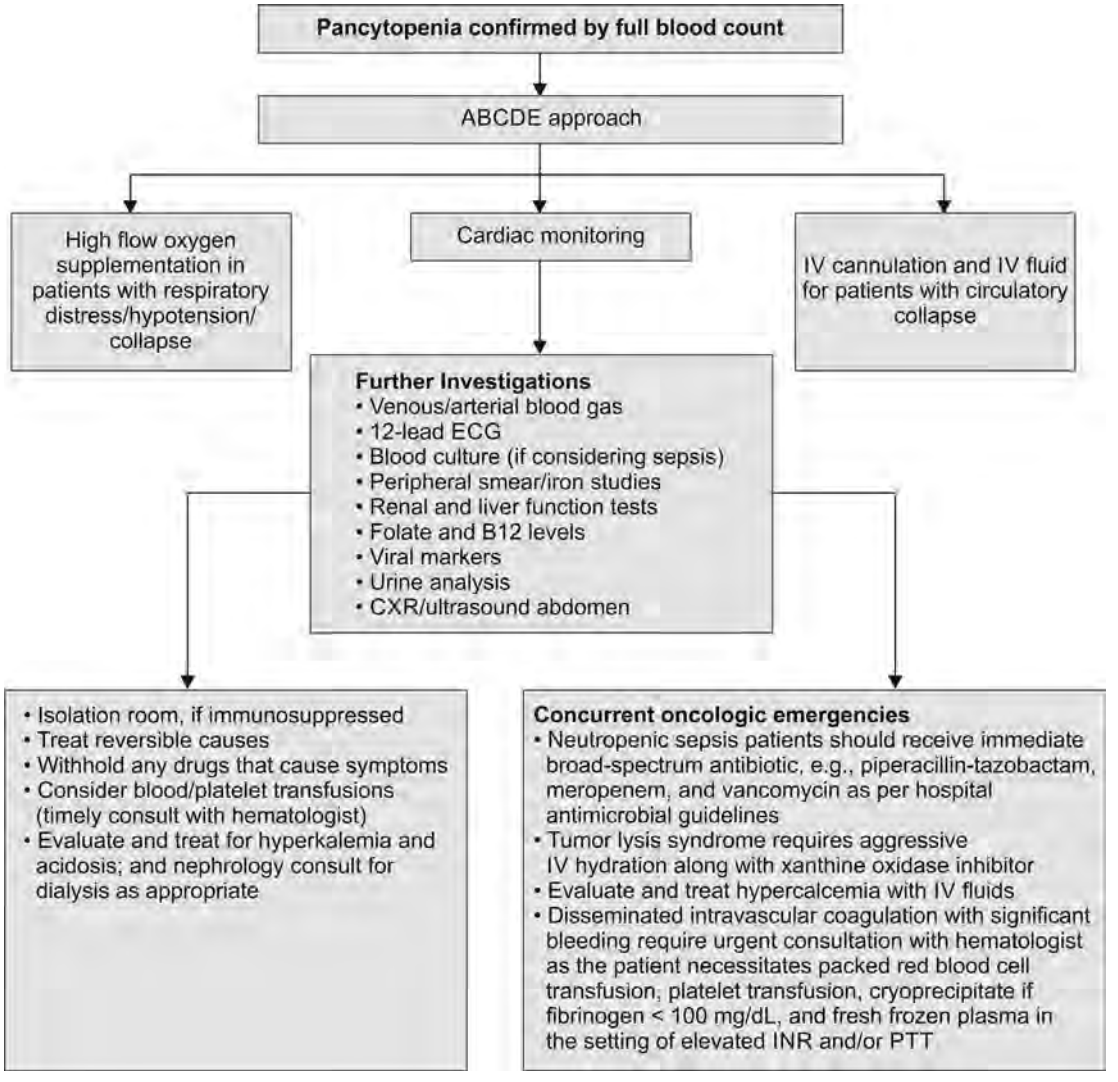
SUMMARY

Identification of potential causes of pancytopenia present a diagnostic challenge for emergency physicians. It is important to identify the etiology of the pancytopenia rather than the primary disease itself. Furthermore, multitude of diseases presenting with pancytopenia are potentially life-threatening if not treated with caution. Detailed history taking, systematic examination in conjunction with initial screening and laboratory evaluation, an early consultation with multidisciplinary team, and hematologist will assist emergency physicians to optimize clinical treatment and guiding further workup.

- Aplastic anemia is the most common cause of pancytopenia worldwide.
- Review various etiological factors that lead to pancytopenia.
- Vitamin B12 deficiency should be considered as the cause for pancytopenia in low-income countries.
- Pseudothrombocytopenia may be a laboratory finding discovered incidentally, in an asymptomatic individual.

ACKNOWLEDGMENT

We are grateful for the help of Dr Dewi Eden, Consultant Hematologist, Shrewsbury and Telford Hospital, who was instrumental in providing us with the histopathological images.



Pancytopenia confirmed by full blood count
ABCDE approach
High flow oxygen supplementation in patients with respiratory distress/hypotension/ collapse
Cardiac monitoring
IV cannulation and IV fluid for patients with circulatory collapse
Further Investigations
• Venous/arterial blood gas
• 12-lead ECG
• Blood culture (if considering sepsis)
• Peripheral smear/iron studies
• Renal and liver function tests
• Folate and B12 levels
• Viral markers
• Urine analysis
• CXR/ultrasound abdomen
• Isolation room, if immunosuppressed
• Treat reversible causes
• Withhold any drugs that cause symptoms
• Consider blood/platelet transfusions (timely consult with hematologist)
• Evaluate and treat for hyperkalemia and acidosis; and nephrology consult for dialysis as appropriate
Concurrent oncologic emergencies
• Neutropenic sepsis patients should receive immediate broad-spectrum antibiotic, e.g., piperacillin-tazobactam, meropenem, and vancomycin as per hospital antimicrobial guidelines
• Tumor lysis syndrome requires aggressive IV hydration along with xanthine oxidase inhibitor
• Evaluate and treat hypercalcemia with IV fluids
• Disseminated intravascular coagulation with significant bleeding require urgent consultation with hematologist as the patient necessitates packed red blood cell transfusion, platelet transfusion, cryoprecipitate if fibrinogen < 100 mg/dL, and fresh frozen plasma in the setting of elevated INR and/or PTT

(ABCDE: airway, breathing, circulation, disability, and exposure; CXR: chest X-ray; ECG: electrocardiogram; INR: International Normalized Ratio; IV: intravenous; PTT: partial thromboplastin time)

FLOWCHART 1: Approach to clinical management of patient with pancytopenia.

141
CHAPTER

Approach to Leukemia

Dodiy Herman, Benita Florence

INTRODUCTION

Leukemia in the emergency department (ED) often presents as persistence of vague symptoms. However, the role of the emergency physician (EP) is to ensure early recognition of life-threatening complications, management of reversible causes, and initial therapeutic stabilization of this patient. Delay in prompt management increases the risk of morbidity and mortality.

Acute leukemia is characterized by rapid proliferation of abnormal white cells, due to bone marrow dysfunction. Transformation occurs due to abnormal proliferation, clonal expansion, aberrant differentiation, and diminished apoptosis leading to replacement of normal blood elements with malignant cells. It also suppresses production of normal blood cells and suppression of the immune system. Any organ system may become affected, although lymph nodes, liver, spleen, central nervous system (CNS), and skin are the most common sites for clinical detection.

EPIDEMIOLOGY

Globally around 300,000 new cases of leukemia (2.8% of all new cancer cases) are diagnosed annually. Chronic lymphocytic leukemia (CLL) constitutes the most frequent type of leukemia with 25% of cases, chronic myeloid leukemia (CML) represents 20% of cases, and acute myeloid leukemia (AML) represents 20% of cases in the Western countries. About 30% of the patients presenting with CML may be asymptomatic and may present as an incidental finding on complete blood count (CBC).

The global 5-year survival is 20% with all leukemias put together. In developing countries, 15% survive for 5 or more years compared to developed countries which is 30%.

RISK FACTORS

- Genetic predisposition—Down's syndrome and neurofibromatosis
- Exposure to radiation—atomic bomb survivors, radiographers before 1950, patients with cancer receiving cancer therapy, exposed to multiple computed tomography scans
- Exposure to benzene
- Exposure to household pesticide
- Obesity
- History of hematological malignancy
- Familial
- Smoking

CLINICAL PRESENTATION

Undiagnosed cases may present to the ED with a broad spectrum of nonspecific signs and symptoms:

- Fatigue
- Anemia
- Loss of appetite
- Weight loss
- Easy bruising and bleeding
- Persistent fever/recurrent infections
- Generally feeling unwell
- Night sweats
- Poorly healing skin wounds
- Sepsis

In the extremes of age groups, difficulty or refusing to walk should raise a suspicion, although bone and joint pain are less common presenting symptoms of leukemia. Hypoxia, retinal hemorrhage, altered sensorium, and diffuse pulmonary shadowing are all features of leukostasis. Splenomegaly causes satiety, left hypochondriac pain, and sensation of fullness. Patients diagnosed with leukemia and those on treatment may present to the ED with:

- *Fever/neutropenia*: In patients undergoing chemotherapy, severe underlying infection may present as a single fever spike as other inflammatory response of the body system is weakened. A single documented temperature of >38.3°C (101°F) or a sustained temperature >38°C (100.4°F) for >1 hour is significant. Absolute neutrophil count (ANC) of 500 cells/mm^3 or that which decreases to <500 cells/mm^3 during the next 48 hours is defined as neutropenia.
- Bleeding due to thrombocytopenia
- Bleeding may be the presentation to ED in 60% of patients with leukemias
- Thrombosis
- Gastrointestinal symptoms—nausea/vomiting/diarrhea causing dehydration

CLASSIFICATION

Classification of leukemia is derived from two main systems.

1. The French–American–British (FAB) classification
2. The World Health Organization (WHO) classification

The FAB classification is based on the morphology of the abnormal leukocytes, providing a diagnostic type and does not provide any prognostic value. The WHO classification is a combination of clinical, morphologic, immunophenotypic, and genetic features. They are broadly classified as acute or chronic, based on the number of blasts in the bone marrow or blood and as myeloid or lymphoid which is determined by the lineage of the malignant cells.

The American Cancer Society, in 2020, estimated the distribution of new US cases of leukemia as:

- Acute myeloid leukemia: 33%
- Acute lymphoblastic leukemia: 10%
- Chronic myeloid leukemia: 14%
- Chronic lymphocytic leukemia: 35%
- Other leukemias: 8%

CLINICAL MANIFESTATION AND ASSESSMENT

The initial presentation to the ED may be with vague symptomatology and repeated hospital visits. Patient may be febrile with tachycardia, hypotension, and tachypnea or in respiratory distress. Anemia may cause shortness of breath and heart failure. Ecchymosis and excessive bleeding from intravenous sites may be seen.

Examination may also reveal splenomegaly, hepatomegaly, or lymphadenopathy. Further clinical assessment includes dentition which shows dental abscesses and/or gum hypertrophy.

Fundoscopy

Eyes and the CNS are the common sites where vascular obstruction secondary to leukostasis and thrombosis is noted.

In the early 1,800 patients with splenomegaly and abnormal blood viscosity were found to have more number of white blood cells (WBCs) on blood smear. However, leukocytosis is present in only about one-third of patients with leukemia.

INVESTIGATIONS

In the acute emergency setting, a CBC and peripheral smear will aid as screening tools in diagnosing leukemia. Bone marrow aspirate and biopsy is essential for definitive diagnosis (**Fig. 1**). Hyperleukocytosis (white cell count >100 × 10^9/L) (**Figs. 2A** and **B**) should be considered in newly diagnosed AML patients with either dyspnea or altered mental status. These manifestations are due to by impairment of microvascular perfusion.

Clotting studies, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) form part of the routine investigations. Venous blood gas analysis facilitates identification of patients presenting with life-threatening emergencies. Serum electrolytes, renal function tests, liver function tests, lactate dehydrogenase, calcium, phosphate, and random blood sugar are necessary to risk stratify the disease and treat reversible causes. Potassium may be falsely elevated due to release of intracellular cations from blasts in sample collection tube, hence to correlate with echocardiogram (ECG) and clinical

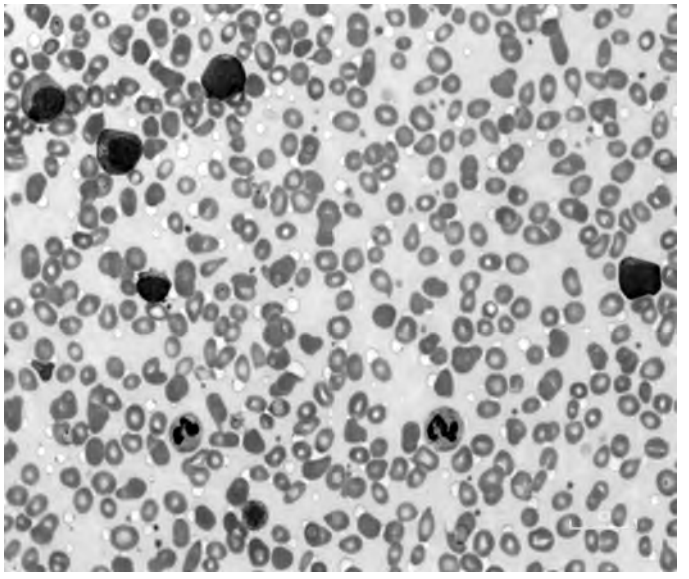

FIG. 1: Slide of acute myeloid leukemia, myelocytes, myeloid blast, dysplastic giant platelets, and polychromasia. ***(For color version, see plate 18)***

presentation. Procalcitonin levels have shown good specificity and sensitivity in helping differentiate bacterial infections from tumor fevers in febrile neutropenic patients.

Viral serology, Epstein–Barr virus, and cytomegalovirus are to be included in patients who are newly diagnosed or in those with no clear etiology of infection. Blood grouping and screening may be requiring for transfusion of blood and blood products.

Blood Cultures

If a central venous catheter is present, a set from each lumen is to be collected from a peripheral vein site. In the absence of a central venous catheter, two blood culture sets from separate venipuncture sites should be collected and sent for analysis.

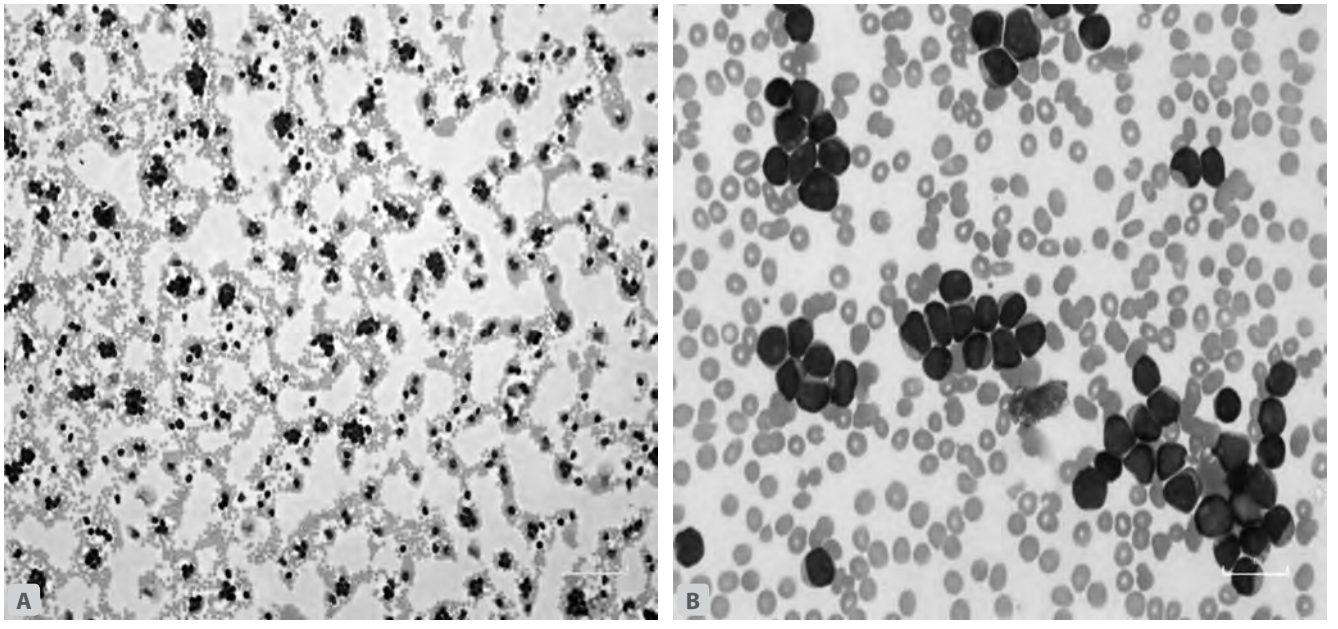
Culture of certain other sites should be done guided by clinical signs and symptoms and not be performed routinely.

- *Stool*: In a patient with diarrhea for *Clostridium difficile* toxin assay and if there is any history of recent travel to or residence in areas of endemicity.
- *Urine*: If signs or symptoms of urinary tract infection exist, a urinary catheter is in place, or urine microscopy is abnormal.
- *Cerebrospinal fluid*: If meningitis is suspected. Platelet transfusion should be given prior to lumbar puncture in patients whom thrombocytopenia is a concern.
- *Skin*: Cytological testing, Gram staining, and culture should be done if skin lesions are suspected of being infected.
- *Respiratory specimens*: In patients with a productive cough sputum samples should be sent for bacterial culture.

The majority of patients who develop fever with neutropenia have no clear identifiable site of infection and negative culture results. However, every patient with fever and neutropenia should receive empirical antibiotic therapy urgently, because of rapid progression of infection.

Chest X-ray

A chest radiograph is indicated for patients with respiratory signs or symptoms. ECG, if cardiac dysfunction is noted.



FIGS. 2A AND B: (A) Slide shows hyperleukocytosis in a patient with acute myeloid leukemia (AML). (B) Slide shows myeloid blasts seen in the AML with hyperleukocytosis. Myeloid blasts contain granules, best seen in the highlighted cells. ***(For color version, see plate 18)***

TREATMENT IN THE EMERGENCY DEPARTMENT

Management primarily starts with an ABC approach of airway, breathing, and circulation. Intravenous access and hydration where appropriate and should be established. These patients may also present with bone pain, neuropathic pain, or other discomfort. Analgesics need to be prescribed according to the WHO pain ladder scale consisting of opioids, nonopioids, and adjuvant therapy. Ibuprofen is not recommended in children as it may affect platelet function. Antipyretics, if patient has fever and also to prevent hypothermia. Antiemetic may be added based on the clinical presentation.

Risk stratification helps in determining the route of empirical antibiotic therapy, inpatient or outpatient care, and the duration of antibiotic therapy. This helps to avoid unnecessary hospital admissions as this group of patients are more prone to iatrogenic infections. **Table 1** shows risk stratification of patients.

Apart from bloodstream infection, other sites are the respiratory tract (pneumonia and sinusitis), skin and soft tissue infection (mucositis and cellulitis), gastrointestinal (diarrhea, typhlitis, perirectal abscess, and enterocolitis) with the oral cavity causing polymicrobial bloodstream infection and the genitourinary tract (urinary tract infection). Neutropenic enterocolitis has high morbidity and mortality rate.

Monotherapy is started with an antipseudomonal β-lactam agent, such as cefepime, a carbapenem (meropenem or imipenem-cilastatin), or piperacillin-tazobactam. Other antimicrobials (aminoglycosides, fluoroquinolones, and/or vancomycin) may be added for the management of associated systemic illness (e.g., hypotension and pneumonia) or if antimicrobial resistance is suspected or proven. Vancomycin is not routinely used in the empiric treatment of neutropenic fever. As the emergence of resistance has increased, vancomycin is started if the patient meets any of the following criteria: positive blood cultures with smears showing gram-positive cocci, in critically ill patients, with the presence of skin or soft tissue infection, suspicion of catheter-related infection, or prior infection with methicillin-resistant *Staphylococcus aureus* (MRSA).

Afebrile neutropenic patients who have signs or symptoms suggestive of new infection should be evaluated and treated as high-risk patients. In low-risk patients, ciprofloxacin plus amoxicillin-clavulanate in combination is recommended for oral empirical treatment. Other treatment regimens with levofloxacin or ciprofloxacin monotherapy or ciprofloxacin plus clindamycin can be used. In patients with persistent or recurrent fever after 4–7 days of antibiotics empirical antifungal therapy and investigation for invasive fungal infections should be considered. This is for the treatment of any “occult" fungal infection presenting as persistent neutropenic fever despite empirical antibiotic therapy. In systemically unwell patients and in those patients with uncertainty of diagnosis, consider high-dose steroid, hydroxyurea, broad-spectrum antibiotics, and hydration with approach from an expert multidisciplinary team.

OTHER EMERGENCIES

Apart from febrile neutropenia, sepsis, and septic shock the other conditions that need to be dealt with immediately are hypercalcemia, acute transfusion reactions, hyperviscosity syndrome, disseminated intravascular coagulation, tumor lysis syndrome, hyperleukostasis, and paraparesis/spinal collapse.

Hyperleukocytosis

Total leukemia blood cell count > 50 × 10/L (50,000/μL) or 100 × 10/L (100,000/μL) is referred to as hyperleukocytosis (**Figs. 2A and B**). The diagnosis of hyperleukocytosis and leukostasis (also called symptomatic hyperleukocytosis) in patients with leukemia (common in those with AML or CML) is an oncological emergency. The presence of elevated blast cell count and symptoms of decreased tissue perfusion leads to high mortality rates.

TABLE 1: Risk stratification—leukemia.

	High risk	*Low risk*
Duration of symptoms	>7 days	<7 days
Absolute neutrophil count (ANC)	Profound neutropenia (ANC) ≤100 cells/mm^3	
Renal function	Creatinine clearance <30 mL/min	Normal renal function
Liver function	Aminotransferase levels more than five times normal value	Normal liver function
Associated symptoms: • Clinically unstable • Gastrointestinal symptoms • Not tolerating orally • Altered mental status intravascular catheter infection • Respiratory: New oxygen requirement, lung infiltrates on chest X-ray (CXR)	Many	None/few
Underlying comorbid conditions	Diabetes Chronic obstructive lung disease Recent surgical procedures	None
Multinational Association for Supportive Care in Cancer (MASCC) scoring system	Score of <21	Score ≥21
Disposition	Inhospital admission for antibiotics and further management	Consider oral empirical antibiotic therapy

Prophylaxis for tumor lysis syndrome should be started immediately to prevent its exacerbation. Hematology or expert advice should be obtained as early as possible.

- Administer oxygen
- Intravenous fluid hydration should be started promptly (with input/output charting). This helps in enhancing renal blood flow and promotes urinary excretion.
- Unless transfusion of packed red blood cell (PRBCs) is required as a life-threatening emergency, leukocyte reduction needs to be achieved as blood products (especially PRBCs) may increase serum viscosity exacerbate leukostasis.
- Consider allopurinol and/or rasburicase. This reduces the risk of uric acid crystallization in the kidneys.
- Monitor for disseminated intravascular coagulation.
- Keep platelet count above 20×10^9 per liter to minimize bleeding risk.

PRECAUTIONS

Hand hygiene and standard barrier precautions should be followed for all patients, and infection-specific isolation should be used. Patients with hematopoietic stem cell transplantation (HSCT) require strict isolation. Menstruating immunocompromised patients should not use tampons, which can cause abrasions leading to infection. In patients with neutropenia rectal thermometers, enemas, suppositories, and rectal examinations are contraindicated. For patients with mucositis, oral rinses four to six times/day with sterile water, normal saline, or sodium bicarbonate solutions are recommended.

SUMMARY

The ED should have treatment guidelines keeping the following factors in mind:

- The disease characteristics and patient's condition
- The type and stage of leukemia
- The clinical presentation and reason for admission
- Prognosis of the disease, if applicable
- Escalation of care when required

Multidisciplinary care involving the physicians, hematologists, and intensivists should be obtained whenever appropriate. Age, ethnicity, and presence of neutropenia should not influence the EP in making a decision on the prognosis of the disease. Population-based registries are required due to variations in genomics based on race and ethnicity.

In this era of rapid advances in diagnostic techniques and development of newer chemotherapeutic and antibiotic medications in the fight against leukemia, the spectrum of infections continues to change yet a patient-oriented approach to achieve the best outcome should be given priority.

ACKNOWLEDGMENT

We acknowledge the help of Dr Dewi Eden, Consultant Hematologist, Shrewsbury and Telford Hospital, who was instrumental in providing us with the histopathological images.

142 CHAPTER

Oncological Emergencies

Amit K Jain

INTRODUCTION

An oncologic emergency is any acute, potentially morbid, or life-threatening event, related directly or indirectly to a patient's tumor or its treatment. It needs to be managed urgently and appropriately to avoid its devastating consequences such as permanent damage and death. It is broadly classified into four types as given in **Table 1**.

ONCOLOGICAL EMERGENCIES RELATED TO LOCAL TUMOR EFFECTS

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is the clinical manifestation resulting from obstruction of blood flow to the right atrium due to compression, invasion, thrombosis, or fibrosis of the SVC. Important causes of SVC are malignant (60–85%): Lung cancer, lymphomas, and other malignancies (primary and metastatic) and benign (15–40%): Thrombosis due to central vein catheters and other causes.

TABLE 1: Classification of oncological emergencies.

Types	*Oncological emergencies*
Related to local tumor effects	• Superior vena cava syndrome • Increased intracranial pressure • Malignant spinal cord compression • Malignant pericardial effusion • Malignant central airway obstruction • Bone metastasis
Related to biochemical derangements	• Tumor lysis syndrome • Hyponatremia • Hypercalcemia • Lactic acidosis
Related to hematological derangements	• Febrile neutropenia • Hyperviscosity syndrome • Thromboembolic disease
Related to therapy	• Chemotherapy-induced nausea and vomiting • Chemotherapy-induced diarrhea • Extravasation of chemotherapy • Cytokine release syndrome

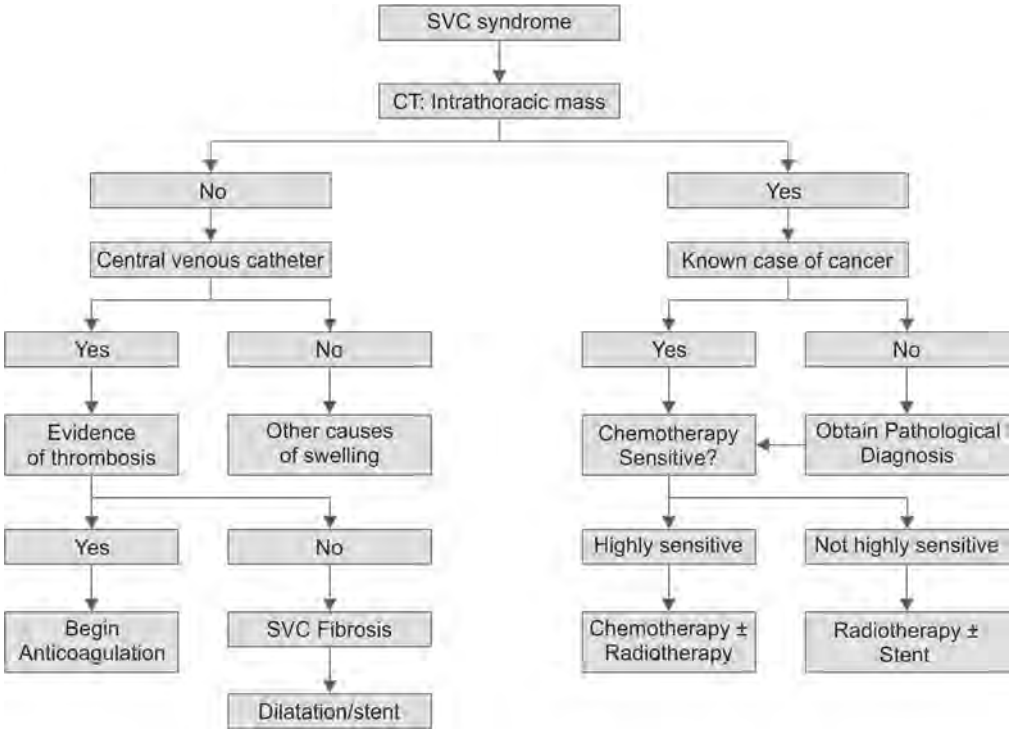
Superior vena cava syndrome develops when the flow of blood in SVC is obstructed; venous collaterals develop if it gradually develops allowing time for the collateral veins to form. Collateral pathway arises from the azygos (most important), internal mammary, lateral thoracic, paraspinal, and esophageal venous systems. Despite well-developed collateral pathway, the venous pressure of the upper compartment is elevated in SVC syndrome. *Common symptoms of SVC syndrome are*: Dyspnea, facial swelling and head fullness, cough, arm swelling, etc., which aggravates on lying down or bending. Common physical findings: Distention of neck and chest wall veins, plethora of face, facial edema, cyanosis, etc.

Diagnostic workup of SVC syndrome includes chest X-ray: Superior mediastinal widening and pleural effusion. Contrast-enhanced computed tomography (CECT) chest (magnetic resonance venography if iodinated contrast is contraindicated): Cause of obstruction, level and extent of blockage, and evaluation of collaterals. In a patient with suspicion of malignant etiology, if feasible pathological diagnosis should always be established prior to initiation of therapy via endobronchial fine-needle aspiration cytology (FNAC), mediastinoscopy, CT-guided biopsy, thoracentesis, supraclavicular lymph node biopsy, thoracoscopic biopsy or thoracotomy, and also staging workup, thus guiding into the intent of treatment.

Treatment of the SVC syndrome depends on cause and extent of the disease (**Flowchart 1**).

Supportive measures: Bed rest, oxygen, head end elevation (decrease the hydrostatic pressure), steroids (relieve inflammation and edema; avoid before pathological diagnosis), loop diuretics, and avoid placement of cannula in the arms.
Definitive therapy includes:

- Radiation treatment
- *Chemotherapy*: In chemosensitive tumor such as lymphoma, germ cell tumors, or small cell lung cancer
- *Endovascular therapy, i.e., thrombolysis, stenting, and angioplasty*: In patients with thrombosis and patients not responding to cancer treatment



FLOWCHART 1: Management of superior vena cava (SVC) syndrome.

- *Surgery*: Failure of radiotherapy, chemotherapy, and endovascular therapy, like in cases of retrosternal goiter and aortic aneurysm

Increased Intracranial Pressure

Increased intracranial pressure (ICP) refers to increase in ICP ≥ 20 mm Hg. Etiolgy of the raised ICP includes *increase in cerebral parenchymal pressure, e.g.,* brain tumor (primary or metastatic), intracranial hemorrhage, edema, and infection. *Disorders affecting cerebrospinal fluid (CSF) flow, production, and/or reabsorption*: Carcinomatosis, meningitis, subependymal, or intraventricular tumors. *Venous flow obstruction*: Cerebral venous thrombosis, dural sinus stenosis or occlusion by mass lesion, obstruction/compression of internal jugular vein or SVC by mass lesion. *Pathophysiological process for raised ICP*: Intracranial volume is fixed and increase in volume of one component occurs at the expense of the others. Increase in ICP leads to decrease in cerebral perfusion pressure which can lead to ischemia. Raised ICP can also lead to shift of brain structures, hydrocephalus, and brain herniation.

Clinical presentation of raised ICP includes headache (severe, maximum intensity in morning on awakening, resistant to common analgesics, and relieved by vomiting), nausea, vomiting, somnolence, and ultimately coma. Seizures and paresis/plegia may also occur. Chronic increased ICP: Sphincter incontinence. Increased ICP in infants: Increased head circumference. In patients with meningitis: Kernig's sign and Brudzinski's sign. Cushing reflex is present with raising ICP and may indicate impending herniation. It consists of systolic hypertension, bradycardia, and irregular and decreased respiration. Focal neurological deficits may be present and may help localize mass. Example: Tectal mass—upward gaze paresis. *Diagnostic workup for raised ICP includes*:

- *Fundus*: Absence of venous pulsations, papilledema, small hemorrhages, and optic nerve atrophy may be seen
- *CT brain*: Presence of mass lesion and CSF obstruction
- *Contrast-enhanced magnetic resonance imaging (CEMRI) brain*: More comprehensive neuroanatomic imaging distinguishing neoplastic, infectious, inflammatory, or ischemic process
- *Cine MRI scan*: CSF flow studies
- *MRI spine*: Unexplained cases of communicating hydrocephalus
- *MRI or CT venography*: Dural venous sinus obstruction or infiltration
- CSF pressure measurement by lumbar puncture in lateral decubitus position. It should not be done in cases with CSF obstruction resulting in compartmentalization.

Treatment

- Head end of bed to be elevated at approximately 30°.
- Avoid body temperature >100.5°F by use of antipyretics, if needed.
- Maintain serum osmolality towards upper limit of normal.
- Maintain blood pressure avoiding mean arterial pressure peaks.
- *Steroids*: Dexamethasone in moderate to high doses to reduce vasogenic edema. In cases of suspected lymphoma, before pathological diagnosis is established use of steroids should be avoided.
- Hyperosmolar agents like mannitol or glycerol to induce osmotic diuresis. Mannitol first dose of 0.75–1 g/kg, followed by 0.25–0.5 g/kg every 4–6 hours with serum osmolality monitoring to avoid hyper osmolality.
- *Intubation and mechanical ventilation*: Decreasing and maintaining partial pressure of carbon dioxide between 25 and 30 mm Hg (most rapid method, but the effect is only transient).
- In obstructive hydrocephalus with clinical features of cerebral herniation—urgent external ventriculostomy.

When CSF obstruction cannot be definitively cannot be treated ventriculoperitoneal (VP) shunt or endoscopic third ventriculostomy. VP shunt may be avoided in patients with leptomeningeal disease to prevent peritoneal seeding.

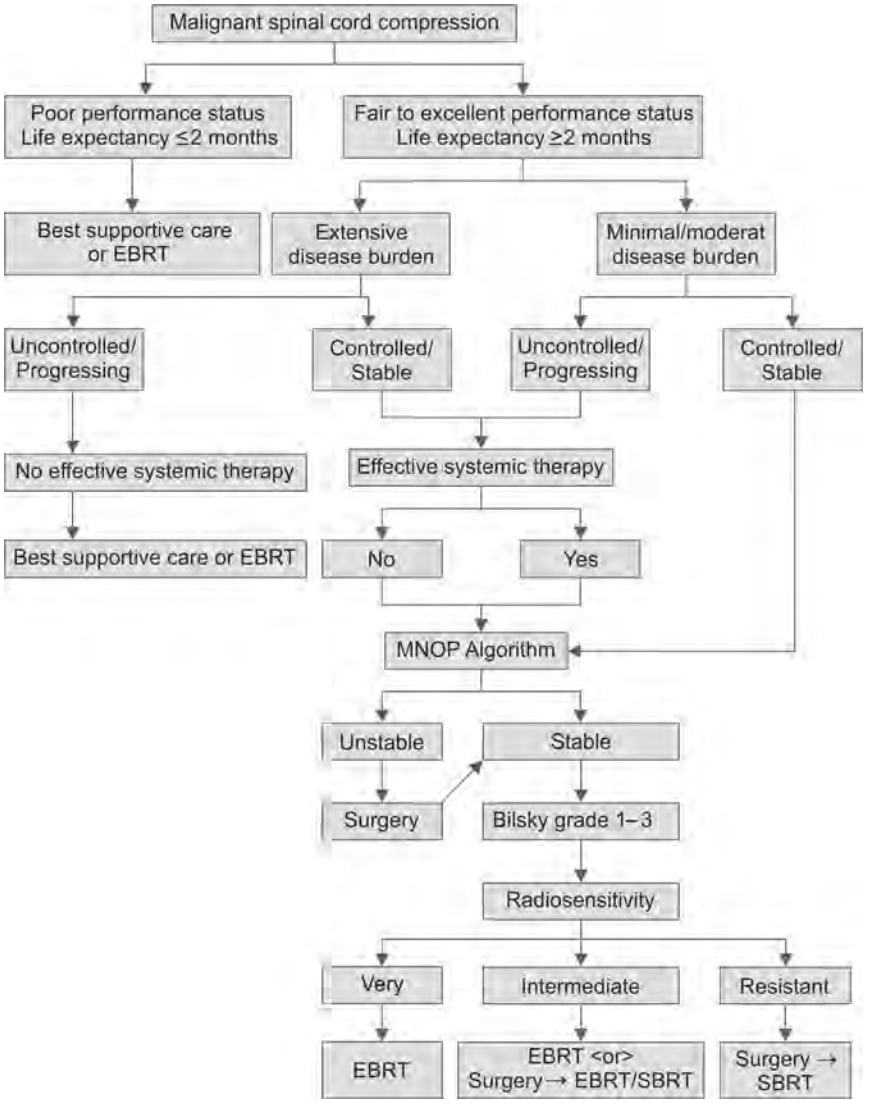
Malignant Spinal Cord Compression

Malignant spinal cord compression (MSCC) refers to compressive indentation, displacement, or encasement of the dural sac that surrounds the spinal cord and/or cauda equina by tumor, spinal fracture, or other conditions related to tumor. Spine is the most common (60%) site of bone metastases and among them ~10% of the cases develop MSCC. Thoracic spine (~60%) is the most common location. The most common cancers associated with MSCC in adults are lung, prostate, multiple myeloma, and breast. In children Ewing's sarcoma, primary vertebral osteosarcoma, neuroblastoma, germ cell tumors, and lymphomas are common cause of MSCC. Direct extension of tumor from osseous vertebral column (usually from hematogenous spread) is the most common mechanism and pathological fracture is the second most common method. Compression leads to obstruction of the epidural venous plexuses, thus development of vasogenic edema. If untreated, can lead to spinal cord infarction and permanent damage. In *MSCC,* pain, sensory deficit, weakness, and autonomic dysfunction are the most common clinical presentation. *Diagnostic workup includes* MRI (if MRI not possible then CT myelogram).

Histological diagnosis, i.e., biopsy (excision or CT-guided) in patient with no history of any malignancy (~20%) or history of very early stage tumor should be done on urgent basis as pathology would guide appropriate management of the tumor including use of steroids for therapy. (Bilsky grading system based on MRI: Grade 0—bone only disease. Grade 1—epidural extension and impingement of on the thecal sac without spinal cord compression. Grade 2—epidural extension without spinal cord compression or obliteration of CSF space. Grade 3—spinal cord compression, deformation of spinal cord, and obliteration of CSF space.)

Treatment options includes (**Flowchart 2**):

- *Steroid*: High dose, reduces cord edema
- Further treatment is guided by patient's life expectancy, performance status, disease burden, and systemic therapy



(EBRT: external beam radiation therapy; MNOP: mechanical, neurologic, oncologic, and preferred treatment; SBRT: stereotactic body radiation therapy)

FLOWCHART 2: Management of malignant spinal cord compression.

options available (patients with life expectancy >2 months, good performance status, minimal/moderate disease burden, and/or effective systemic therapy available will probably benefit from neurosurgery and/or radiation).
- International spine oncology consortium has developed mechanical, neurologic, oncologic, and preferred treatment (MNOP) algorithm for management of MSCC.
  - *Mechanical*: Neurosurgical intervention is required in an unstable spine.
  - *Neurologic*: MSCC with Bilsky grade 1–3 and neurological deficits of <72 hours may benefit from neurosurgical decompression based on tumor pathology and radiosensitivity.
  - *Oncologic*: Radiosensitivity of various tumor pathology is different with some (example lymphoma) being highly sensitive.
  - *Preferred treatment*: Final decision usually is based on multidisciplinary decision after discussion between doctors with patient.
- *Surgery*: Decompress spine, stabilize an unstable spine, establish pathological diagnosis, remove epidural tumor to allow delivery of stereotactic body radiation therapy (SBRT) in a radioresistant histology, and local disease control when radiation cannot be delivered safely.
- *External beam radiation therapy (EBRT)*: Lymphomas, multiple myeloma, and germ cell tumors are highly radiosensitive whereas melanoma, sarcoma, and renal cell carcinoma are radioresistant.
- *SBRT*: Solid tumor spinal metastasis.

Malignant Pericardial Effusion

Malignant pericardial effusion (MPCE) refers to accumulation of extra fluid in the pericardial space. Various etiological factors includes: Tumor: Primary (mesothelioma, lymphangioma, and others), metastasis to pericardium (lung cancer, breast cancer, leukemia, and others), and other causes: Treatment-related complication and others. MPCE is a condition in which extra fluid accumulates due to excess secretion or/and obstruction of lymphatic drainage. It leads to compression of the ventricle and collapse of the right atrium, thus reducing cardiac output and increasing the venous back pressure. Clinical features depend on the rate and amount of fluid accumulated. Dyspnea, chest discomfort, and fatigue are the most common symptoms. The classical presentation (Beck's triad) of hypotension, tachycardia, and muffled heart sounds may be present in cardiac tamponade. *Diagnostic workup should include*—CXR: Water bottle pericardial silhouette. Electrocardiogram (ECG): Low voltage, sinus tachycardia is the most common feature seen. Electrical alternans and atrial fibrillation may also be present. Echocardiography: Fluid and its distribution, tumor location and size, and hemodynamic consequences of MPCE. Pericardial fluid cytology and/or pericardial biopsies as effusion can also be secondary to other causes like treatment-related complications. Treatment option includes for MPCE are:
- The goals of treatment are relief of symptoms with minimum morbidity and prevent recurrence.
- Further treatment is guided by patient's life expectancy, performance status, and systemic therapy options available.
- Pericardiocentesis with or without percutaneous tube pericardiostomy
- Sclerotherapy
- Subxiphoid pericardiostomy
- Transthoracic partial pericardiectomy or pericardial window

Malignant Central Airway Obstruction

Central airway obstruction (CAO) refers to the obstruction of the airflow in the trachea and mainstem bronchi. Important causes are:
- *Malignant*: Primary endoluminal tumors—bronchogenic carcinoma, carcinoid tumor, etc. Metastatic—renal cell carcinoma, carcinoma breast, thyroid cancer, colon cancer, sarcoma, melanoma, etc. Others—laryngeal carcinoma, nasopharyngeal carcinoma, esophageal carcinoma, mediastinal tumors (thymic carcinoma and germ cell tumor), and lymphadenopathy (lymphoma)
- *Nonmalignant*: Benign tumors—squamous cell papilloma and hamartoma. Others—lymphadenopathy (sarcoidosis, tuberculosis), vascular (aneurysm, ring), granulation tissue (tracheal tubes, airway stents, and foreign bodies), tracheomalacia, bronchomalacia, goiter, mucus plug, etc.

Airway obstruction may be mechanical, dynamic, or combined. Clinically present as dyspnea, cough, hemoptysis, wheeze, and stridor. *Diagnostic workup should include* bronchoscopy ± endobronchial ultrasound ± bronchial wash ± biopsy (after airway stabilization), chest radiography, CT chest, and pulmonary function tests (in patients with subacute symptoms).

Treatment modalities include:
- *Airway management*: Securing airway is pivotal. In case of severe CAO (life-threatening) bag valve mask ventilation followed by endotracheal intubation. If intubation is not feasible or unsuccessful, options include an emergency cricothyrotomy or tracheostomy, or rigid bronchoscopic intubation.
- *Bronchoscopy*: Diagnostic and in some cases, it is both diagnostic and therapeutic.
- *Management of cause*: Etiology-specific intervention, which may include debulking, removal, and/or by stenting which is usually done via bronchoscopic intervention but occasionally surgery or external beam radiation is needed.
- Various bronchoscopy interventions used single or in combination are laser, electrocautery, cryotherapy, brachytherapy, argon plasma coagulator, photodynamic therapy, debridement, dilatation, and stent.

Bone Metastasis

Bone is third most common site of tumor metastasis. The most common causes of bone metastasis are breast cancer, prostate cancer, lung cancer, thyroid cancer, and renal cancer. *Pathophysiologic process involved is* tumor cell disengagement, invasion into vascular and/or lymphatic system, arrest in sinusoids of bone marrow, migrate to bone marrow stroma, response to microenvironment, tumor cell proliferation, and bone metastasis. Based on metastatic bone interference with bone remodeling it is classified in three types, namely: osteolytic, osteoblastic, and mixed. *Clinical presentation* includes pain, hypercalcemia, pathological fracture, and MSCC. Morbidity associated with bone metastasis is known as skeletal-related events (SRE). *Diagnostic workup* includes X-rays, bone scans, CT (size of osseous lesion with its cortical

involvement extent), MRI (epidural and marrow disease), and positron-emission tomography (PET). Treatment options are:

- Analgesics and systemic therapy against malignancy
- *Bone-specific agents*: Bisphosphonates and denosumab—decreases risk of SRE
- *Radiotherapy*: Relieves bone pain, prevents impending fractures, and promotes healing of pathological fractures
- *Systemic radionucleotides*: Strontium 89 and samarium 153
- *Pathological fracture*: Surgery (pain relief, stabilization, and restore function) ± radiotherapy (pain relief and tumor control)
- *Impending fracture*: Surgery (fixation) ± radiotherapy (pain relief and tumor control). In highly vascular bone metastasis example: renal cell carcinoma, pre- or perioperative embolization may be done to reduce intraoperative blood loss.

ONCOLOGICAL EMERGENCIES RELATED TO BIOCHEMICAL DERANGEMENTS

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) refers to metabolic consequences resulting from sudden release of intracellular metabolites, nucleic acids, and proteins from tumor cells undergoing death spontaneously or post-treatment. It is divided into two groups, i.e., laboratory and clinical based on Cairo-Bishop definitions.

Laboratory TLS is defined as presence of ≥2 of following laboratory abnormalities, i.e., uric acid ≥8 mg/dL, potassium ≥6 mEq/L, phosphorus >4.5 mg/dL in adults (≥6.5 mg/dL in children), and calcium ≤7 mg/dL or 25% change in these laboratory values from baseline, present within 3 days before or 7 days after initiation of therapy. Clinical TLS is defined as laboratory TLS accompanied with ≥1 of the following: Serum creatinine ≥1.5 times the upper limit of normal, seizure, cardiac dysrhythmia, or death.

Risk of TLS depends on tumor-related factors such as high proliferation rate, high chemosensitivity, and large tumor burden and clinical features such as pretreatment hyperuricemia, impaired renal functions, and inadequate hydration. It is most frequently associated with acute leukemias and high-grade non-Hodgkin's lymphomas.

Tumor lysis syndrome occurs when the changes in electrolytes resulting from lysis of tumor cell exceeds body's ability to regulate them. When the compensatory mechanism of hyperphosphatemia is saturated, phosphate binds with calcium and precipitates in tissues and kidney (renal failure) resulting in hypocalcemia. Hyperuricemia which results due to excess of purine metabolism can also contribute to renal failure due to intraluminal tubular obstruction by urate crystals. Symptoms are largely due to the associated metabolic derangement and may include anorexia, lethargy, nausea, vomiting, diarrhea, muscle cramps, tetany, syncope, hematuria, heart failure, cardiac arrhythmias, seizures, and sudden death.

Risk stratification—Cairo et al., in 2010, classified risk of various tumor types in three risk groups (**Box 1**).

BOX 1: Risk stratification of tumor, Cairo et al., 2010.

High risk:

- Acute lymphoblastic leukemia (ALL) with leukocytes count >100,000/μL or lactate dehydrogenase (LDH) >2 times the upper limit of normal (ULN)
- Acute myeloid leukemia (AML) with leukocytes count >100,000/μL
- Burkitt leukemia
- Burkitt lymphoma with LDH >2 times the ULN or stage III/IV
- Other high-grade lymphomas (diffuse large B-cell lymphoma, blastoid variant mantle cell lymphoma, adult T-cell lymphoma, peripheral T-cell lymphoma, and transformed lymphoma) with LDH > ULN and bulky disease (>10 cm)
- Any tumor of the intermediate risk group and baseline renal dysfunction, uric acid, phosphate or potassium > ULN, renal involvement, or contraindication to allopurinol

Intermediate risk:

- AML with leukocyte count 25,000–100,000/μL or LDH >2 times the ULN
- ALL with leukocytes count <100,000/μL and LDH <2 times the ULN
- Chronic myelomonocytic leukemia and plasma cell leukemia
- Chronic lymphocytic leukemia (CLL) on targeted and/or biological therapies or white blood cell (WBC) count >50,000/μL
- Burkitt lymphoma with LDH <2 times the ULN and stage I–II
- Other high-grade lymphomas with LDH > ULN and nonbulky disease
- Any leukemia or lymphoma with renal dysfunction or renal involvement
- Bulky solid tumor and sensitive to chemotherapy such as germ cell tumors, small cell lung cancers, etc.

Low risk:

- AML with leukocyte count <25,000/μL and LDH <2 times the ULN
- Chronic myeloid leukemia
- CLL on alkylating agents
- Hodgkin's lymphoma
- Indolent non-Hodgkin's lymphoma
- Anaplastic large cell lymphoma
- Other high-grade lymphomas without LDH elevation
- Multiple myeloma
- Other solid tumors (even in preexisting renal dysfunction or renal involvement)

Diagnostic Workup

Complete blood count (CBC), electrolytes, urea, creatinine, uric acid (sample must be sent on ice, if post rasburicase), phosphorus, calcium, albumin, and ECG.

Uric acid, potassium, phosphorus, and creatinine should be monitored at least twice daily until risk of TLS with monitoring of weight, blood pressure, and urine output.

Prevention

- *Low risk*: Adequate hydration
- *Intermediate risk*: Aggressive hydration and allopurinol prophylaxis up to 7 days
- *High risk*: Aggressive hydration and rasburicase prophylaxis
- Aggressive hydration (3,000 mL/m^2/day) with urine output ≥100 mL/m^2/h (may require diuretics to maintain urine output and prevent fluid overload). Urine alkalinization is not recommended as it increases the risk of calcium phosphate precipitation.
- Allopurinol—300 mg/m^2/day or 10 mg/kg/day (max: 800 mg/day) in three divided doses begin 1–2 days before therapy and continue up to 3–7 days after therapy.
- Rasburicase—0.05–0.2 mg/kg/day for 1–7 days.

Treatment

- Aggressive intravenous (IV) hydration
- Correction of electrolyte disturbances. Hypocalcemia to be treated only if symptomatic.
- *Hemodialysis*: If there is persistent hyperkalemia, intractable hyperphosphatemia and hypocalcemia (calcium phosphate product ≥70 mg^2/dL^2), intractable fluid overload and oliguria or anuria (in absence of hypovolemia).
- *Rasburicase*: 0.2 mg/kg/day. Allopurinol to be used only in case of rasburicase hypersensitivity or glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Hyponatremia

Hyponatremia refers to serum sodium <135 mEq. Important causes are summarized in **Table 2**.

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is the most common cause of hyponatremia in malignancy and is due to increased production of arginine vasopressin (AVP) (mainly ectopic, by the tumor cells). In SIADH, increased levels of AVP result in water resorption/retention and sodium loss. Clinical features depends on rate of development of hyponatremia, instead of actual sodium levels (unless severely low). It ranges from being completely asymptomatic to coma. It consists of nausea, vomiting, dysgeusia, headache, memory loss, confusion, lethargy, fatigue, loss of appetite, irritability, muscle weakness, spasms or cramps, seizures, and decreased consciousness. *Diagnostic workup includes* serum electrolytes, serum osmolality, urine sodium, and urine osmolality. Treatment is guided by serum sodium levels, symptomatic or asymptomatic, duration of hyponatremia, and volume status of the patient (**Flowchart 3**). *Rate of Correction* up to 8 mEq/L/day whereas only 4–6 mEq/L/day in patients with high risk for osmotic demyelination syndrome (ODS). High-risk patients for ODS are one who has one or more of the following: serum sodium <105 mEq/L, associated hypokalemia, history of heavy alcohol intake, advanced liver disease, and malnutrition. Various therapeutic options for hyponatremia are isotonic fluids (hypovolemic hyponatremia), fluid restriction, 3% hypertonic saline, loop diuretics, sodium supplementation, urea, demeclocycline, and vaptans.

TABLE 2: Causes of hyponatremia.

Euvolemic	SIADH • Cancer: Lung cancer and head and neck cancer • Drugs: Cyclophosphamide and vincristine • Infections: Central nervous system, pulmonary • Hypothyroidism • Head and Neck cancers (paraneoplastic)
Hypovolemic	• Gastrointestinal losses: Chemotherapy-induced nausea and vomiting and chemotherapy-induced diarrhea • Cerebral salt wasting: Intracranial tumor
Hypervolemic	• Heart failure: Drug-induced (anthracyclines) • Liver failure: Drug-induced (methotrexate) and metastatic liver disease • Kidney failure: Drug-induced (cisplatin) and malignancy-associated nephrotic syndrome

(SIADH: syndrome of inappropriate antidiuretic hormone secretion)

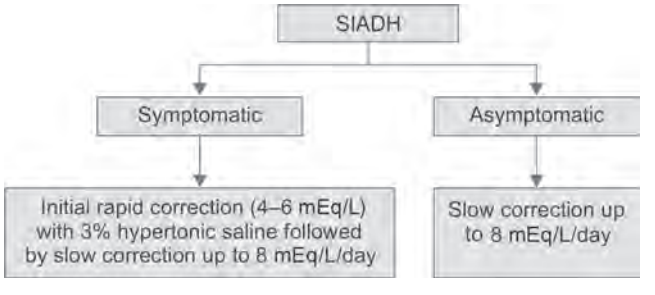
Hypercalcemia

Hypercalcemia of malignancy is rise in serum calcium levels above the upper limit of the normal laboratory reference range, related directly or indirectly to tumor. Causes are: Secretion of parathyroid hormone (PTH)-related peptide—any squamous cell carcinoma; osteolytic metastases—lung cancer, breast cancer, and prostate cancer; production of vitamin D analogs—lymphomas; and ectopic hyperparathyroidism.

Clinical symptoms depend on rate of development of hypercalcemia, instead of actual calcium levels (unless very high levels). A well-known mnemonic describes it: Stones (kidney/biliary), bones (bone pain), groans (abdominal discomfort), moans (nonspecific symptoms), thrones (constipation and urinary frequency), muscle tone (muscle weakness and decreased reflexes), and psychiatric overtones (depression, anxiety, and cognitive dysfunction). Hypercalcemic crisis can also present with life-threatening complications such as acute pancreatitis, renal failure, and coma.

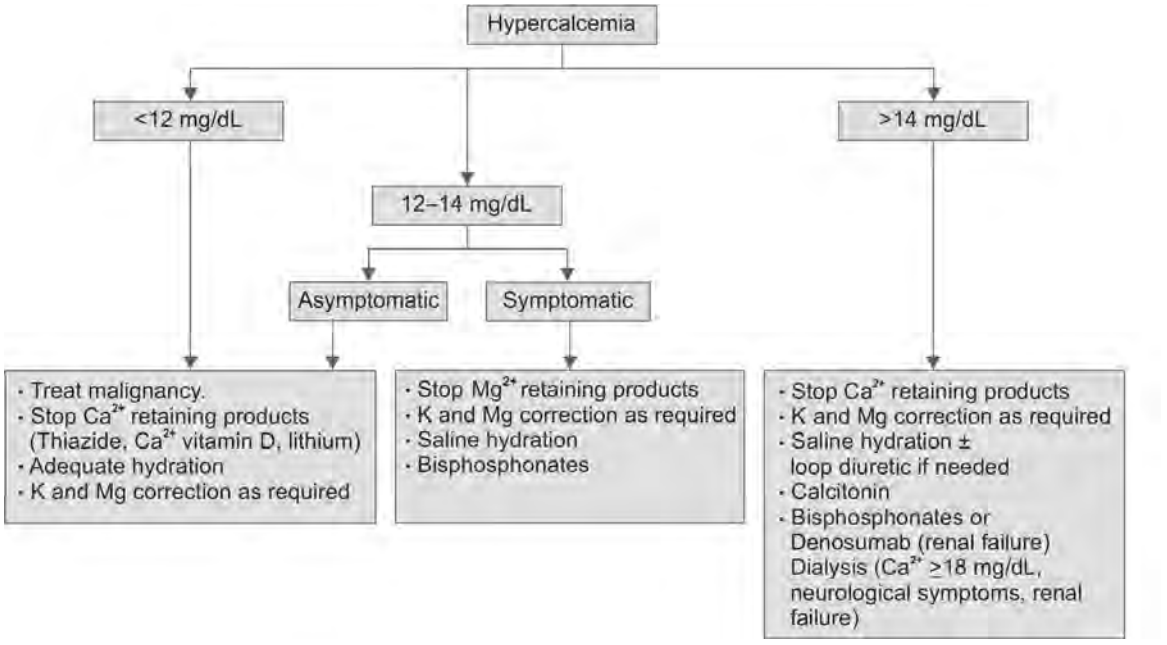
Diagnostic workup includes serum total and ionized calcium, serum albumin, PTH levels, urinary calcium, vitamin D levels, serum protein electrophoresis, and serum-free light chain assay. Treatment of hypercalcemia associate to malignancy includes the following and summarized in **Flowchart 4:**

- Treatment of underlying malignancy
- Stop any calcium retaining products (thiazides, calcium, vitamin D, and lithium)
- Correction of hydration (normal saline)
- Potassium and magnesium to be corrected as required. Hypophosphatemia should not be corrected unless



SIADH
Symptomatic
Asymptomatic
Initial rapid correction (4–6 mEq/L) with 3% hypertonic saline followed by slow correction up to 8 mEq/L/day
Slow correction up to 8 mEq/L/day

FLOWCHART 3: Management of syndrome of inappropriate antidiuretic hormone secretion (SIADH).



Hypercalcemia
<12 mg/dL
12–14 mg/dL
>14 mg/dL
Asymptomatic
Symptomatic
· Treat malignancy.
· Stop Ca2+ retaining products (Thiazide, Ca2+ vitamin D, lithium)
· Adequate hydration
· K and Mg correction as required
· Stop Mg2+ retaining products
· K and Mg correction as required
· Saline hydration
· Bisphosphonates
· Stop Ca2+ retaining products
· K and Mg correction as required
· Saline hydration ± loop diuretic if needed
· Calcitonin
· Bisphosphonates or Denosumab (renal failure)
Dialysis (Ca2+ ≥18 mg/dL, neurological symptoms, renal failure)

FLOWCHART 4: Management of hypercalcemia.

symptomatic, as it can lead to precipitation of salts of calcium.

- *Loop diuretics*: Enhance urinary excretion
- *Calcitonin [6–8 U/kg; subcutaneous (SC) or intramuscular (IM)]*: Rapidly acting (6–24 h)
- *Bisphosphonates-zoledronic acid (preferred):* Onset of action ~48 hours, nadir calcium levels in 5–7 days, duration of response ~32 days, and can be repeated weekly in persistent hypercalcemia
- *Rank ligand inhibitors (denosumab)*: Refractory to bisphosphonate and renal failure
- *Steroid*: In steroid-sensitive malignancy
- *Hemodialysis*: Renal failure, unable to tolerate the fluid load, and profound changes in mental status.

Lactic Acidosis

Lactic acidosis is defined as serum pH ≤7.35 and plasma lactate of ≥5 mEq/L. Causes includes hematological malignancies, solid tumors with liver metastasis, shock, heart failure, sepsis, hypoxia, hepatic insufficiency, and drugs (metformin and propofol). Pathophysiologic process includes—lactate is mainly metabolized in the liver. Unlike normal cells, tumor cell relies on anaerobic glycolysis disproportionately, even in presence of oxygen (Warburg effect). This leads to production of large quantities of lactate exceeding its ability to be metabolized leading to imbalance. It can lead to cardiac arrhythmias and hypotension with potential for cardiovascular collapse. *Diagnostic workup* includes lactate levels, arterial blood gas analysis, serum electrolytes, and serum albumin. Management strategy includes treatment of the underlying malignancy and other causes, if present, aggressive hemodynamic support (fluids and vasopressors), hemodialysis, and hemofiltration.

ONCOLOGICAL EMERGENCIES RELATED TO HEMATOLOGICAL DERANGEMENTS

Febrile Neutropenia

Febrile neutropenia (FN) is defined as "single oral temperature of >38.3°C (>101°F) or a temperature of >38.0°C (>100.4°F) sustained for >1 hour and an absolute neutrophil count (ANC) of <500 cells/mm^3 or expected to fall to <500 cells/mm^3 in next 48 hours". In FN, cultures are usually positive only in about 20% of the patients. Bacterial pathogens particularly gram-negative organisms are the most common followed by gram-positive organisms. Anaerobic organisms, polymicrobial infections, and fungal and viral organisms also occur, but are not so common. Neutropenia along with qualitative defects in neutrophil function, disruption of mucociliary barriers, invasive devices, and shifts in normal microbial flora predispose patients to infection. Risk assessment of FN patient can be done by Multinational Association for Supportive Care in Cancer (MASCC) risk index (**Table 3**).

It is critical to recognize FN early and initiate therapy promptly to avoid progression to sepsis.

Initial assessment includes targeted history, physical examination with emphasis on hydration, oral cavity, oropharynx, skin including any indwelling catheter, lungs, abdomen, perianal area, and mental status. CBC, creatinine, electrolytes, liver function test, blood culture (two sets), culture and stain samples from suspected site of infection, and imaging studies, if any site suspected.

Outpatient management may be considered in low-risk patient who resides close to the hospital, can come for frequent clinic visits and has a 24 hours care giver. Patient is advised to visit if any symptoms or signs of hemodynamic instability, persistent neutropenic fever, new symptoms or signs, oral

TABLE 3: Risk assessment of febrile neutropenia patient: MASCC risk Index.

Characteristics	*Weight*
Burden of FN with no or mild symptoms	5
No hypotension (systolic BP >90 mm Hg)	5
No chronic obstructive pulmonary disease	4
Solid tumor or hematological malignancy with no previous fungal infection	4
No dehydration requiring parenteral fluids	3
Burden of FN with moderate symptoms	3
Outpatient status	3
Age <60 years	2

***High-risk patient*:** Patient with any one of the following criteria, i.e., Multinational Association for Supportive Care in Cancer (MASCC) score <21

- Neutropenia anticipated to be >7 days
- Hemodynamic instability
- Mucositis
- Abnormal mental status
- New pulmonary infiltrate or hypoxemia or underlying chronic lung disease
- Hepatic insufficiency and/or renal insufficiency

***Low-risk patient*:** Patient with all of the following criteria, i.e., MASCC score ≥21

- Neutropenia expected to resolve within 7 days
- No active medical comorbidity

(BP: blood pressure; FN: febrile neutropenia)

medication no longer possible or intolerable, and microbiologic tests identify species not susceptible to oral regimen.

Antibiotic: Fluroquinolone + amoxicillin-clavulanate (or clindamycin, if allergic to penicillin).

Inpatient management includes broad-spectrum antibiotics guided by patient's history and examination, allergies, and culture data of the institution should be started within 60 minutes of presentation.

Infectious Diseases Society of America (IDSA) recommends: Cefepime 2 g/8 hourly, ceftazidime 2 g/8 hourly, piperacillin tazobactam 4.5 g/6 hourly, meropenem 1 g/8 hourly, and imipenem cilastatin 500 mg/6 hourly. Aminoglycoside and fluoroquinolones may be added in patients with complicated presentation (example, hypotension and/or mental status changes) and focal findings (e.g., pneumonia and cellulitis). Anaerobic coverage should be included if there is evidence of necrotizing mucositis, sinusitis, periodontal cellulitis, perirectal cellulitis, intra-abdominal, or pelvic infection. Gram positive coverage should be included if patient has any of the following: hemodynamically instability or other evidence of severe sepsis, pneumonia, catheter-related infection, skin or soft tissue infection, severe mucositis, or positive culture for gram-positive organism awaiting susceptibility results. Empiric antifungal coverage should be considered in patients who have persistent fever even after 4–7 days of antibiotics or suspected to have fungal infection. In patients with diarrhea with abdominal signs, empiric *Clostridium difficile* therapy may be instituted. In case of catheter-related infection removal of catheter is recommended. IDSA does not recommend routine use of colony-stimulating factor in FN. American Society of Clinical Oncology state that colony-stimulating factor use can be considered in high-risk patients or who have prognostic factors that are predictive of poor outcome.

Hyperviscosity Syndrome

Hyperviscosity syndrome (HVS) refers to the clinically manifestation resulting due to increase in the viscosity of blood. *Causes include:* Increase in acellular component—Waldenström macroglobulinemia, multiple myeloma, systemic lupus erythematosus, etc. and increase in cellular component—leukemia, polycythemia, and myeloproliferative disorder. Disorders cause increase in blood viscosity, sluggish blood flow, relative decreased microvascular circulation, and hypoperfusion of tissues. Classical triad of HVS consists of mucosal bleeding (gum bleed, epistaxis, gastrointestinal (GI) bleed, menorrhagia, and prolonged bleeding after a procedure), visual changes (blurring of vision and loss of vision), and neurological symptoms (headache, giddiness, hearing defects, paresthesia, ataxia, seizures, stroke, stupor, and coma). Other feature may include chest pain, shortness of breath, heart failure, and myocardial infarction. *Diagnostic workup includes* serum viscosity, CBC with peripheral blood smear, total protein and albumin, and serum electrolytes. Other test: Coagulation profile, serum electrophoresis, urine routine, and bone marrow examination. Imaging: CT head (neurological symptoms) and chest radiograph (chest symptoms). Fundus: Retinal vein dilation or engorgement (sausage link or boxcar appearance), papilledema, and retinal hemorrhage. *Management strategy includes* IV fluids (hydration), plasmapheresis (increase in plasma component), or cytapheresis (increase in cellular component), when it is not immediately available phlebotomy may be done. Definitive therapy: Avoid blood transfusion unless emergency until plasmapheresis or cytapheresis as it can further increase the viscosity of blood.

Thromboembolic Disease

Cancer-associated thrombosis is a common complication of malignancy with venous thromboembolism (VTE) being the most common. VTE is one of the frequent causes of death in cancer patients and incudes deep vein thrombosis (DVT), pulmonary embolism (PE), superficial vein thrombosis, and thrombosis of other veins. Various risk factors predispose a patient to develop thrombosis such as patient related (advanced age, obesity, etc.), treatment related (surgical interventions, etc.), and cancer related (advanced metastatic cancer, etc.).

Exact pathophysiology of cancer-associated thrombosis is not understood and mostly is due to multiple factors by various mechanisms such as production of procoagulants by the tumor cells (like tissue factor), suppression of fibrinolytic activity (like by plasminogen activator inhibitor-1), and platelet activation.

Clinical presentation includes DVT—pain, swelling, tenderness, discoloration/redness, and venous distension and PE—dyspnea, chest pain, cough, tachypnea, tachycardia, fever, crackles, and features of DVT. *Diagnostic workup includes* DVT—Doppler ultrasound and CT/MRI venography and PE—D-dimer, proBNP, troponin, CT pulmonary angiography, ventilation/perfusion scan, echocardiography in massive/submassive PE, right ventricular dysfunction, and ECG—sinus tachycardia and S1Q3T3.

Prophylaxis for VTE in cancer patients: Hospitalized patient, surgical patient with any of the high-risk feature like abdominal or pelvic surgery, history of VTE, anesthesia >2 hours, advanced cancer, perioperative bed rest of ≥4 days and age ≥60 years for up to 4 weeks postoperative, multiple myeloma patient receiving immunomodulator drugs with IMPEDE VTE score ≥3 (or SAVED score ≥2) and other cancer patients with Khorana score ≥2. Contraindication to anticoagulation prophylaxis: Active bleeding, platelet count <30,000–50,000/cu mm, hemorrhagic coagulopathy or bleeding disorder, and indwelling neuraxial catheter.

Contraindication to mechanical prophylaxis: Acute DVT and severe arterial insufficiency.

Agents: Low molecular weight heparin, apixaban, and rivaroxaban.

Treatment of DVT: DVT of femoral vein, popliteal vein, pelvic vein, iliac vein, and inferior vena cava (IVC): Anticoagulation, consider catheter-directed thrombolysis. If anticoagulation is contraindicated IVC filter.

Calf veins, peroneal veins, anterior and posterior tibial veins, soleal veins, and gastrocnemius vein: Anticoagulation. If anticoagulation is contraindicated IVC filter. *DVT of* upper limb veins, brachiocephalic vein, subclavian vein, axillary vein, internal jugular vein, brachial veins, and SVC: Anticoagulation, consider catheter-directed thrombolysis. *DVT of* catheter-related DVT: Anticoagulation for at least 3 months or as long as central venous catheter in place. Consider catheter removal if symptom persists, infected, dysfunctional, or no longer needed. Consider catheter-directed thrombolysis. If anticoagulation is contraindicated remove catheter.

Treatment of PE includes anticoagulation. Consider systemic or catheter-directed thrombolysis or embolectomy in hemodynamically unstable patients. Consider rescue thrombolysis or thrombectomy in hemodynamically stable patients who deteriorate on anticoagulation. If anticoagulation is contraindicated consider IVC filter ± embolectomy. Contraindication to anticoagulation: Active major bleeding and indwelling neuraxial catheter. Contraindication for thrombolysis: History of hemorrhagic stroke, history of ischemic stroke in last 3 months, brain tumor, history of major trauma, surgery or head injury in last 3 weeks, active bleeding, and bleeding diathesis. Agents: Unfractionated heparin, low molecular weight heparin, fondaparinux, warfarin, apixaban, rivaroxaban, dabigatran, and edoxaban.

ONCOLOGICAL EMERGENCIES RELATED TO THERAPY

Chemotherapy-induced Nausea and Vomiting

Chemotherapy-induced nausea and vomiting (CINV) includes acute, delayed, and anticipatory nausea and vomiting. Acute CINV is nausea and vomiting which occurs within 24 hours of chemotherapy. Delayed CINV is nausea and vomiting which occurs after 24 hours of chemotherapy. Anticipatory nausea and vomiting is nausea and vomiting which occurs due to conditioned response, prior to chemotherapy.

Intravenous antineoplastic agents are divided based on percent risk of emesis into high emetogenic agents: >90%; moderate emetogenic agents: 30–90%; low emetogenic agents: 10–30%; and minimal emetogenic agents: <10%. Common agents in these groups are given in **Table 4**. Oral antineoplastic agents are also divided based on percent risk of emesis into moderate or high emetogenicity >30% and minimal or low emetogenicity <30%.

TABLE 4: Classification of chemotherapeutic agents based on percent risk of emesis.

	Intravenous antineoplastic agents	***Oral antineoplastic agents***
Highly/emetogenic agents	Anthracycline + cyclophosphamide, cisplatin, cyclophosphamide >1,500 mg/m^2, and dacarbazine	Abemaciclib, cabozantinib, ceritinib, crizotinib, cyclophosphamide, imatinib, lenvatinib, lomustine, niraparib, procarbazine, ribociclib, and temozolomide
Moderately emetogenic agents	Arsenic trioxide, azacitidine, bendamustine, carboplatin, cyclophosphamide <1,500 mg/m^2, doxorubicin, epirubicin, fam-trastuzumab deruxtecan, idarubicin, ifosfamide, irinotecan, oxaliplatin, and trabectedin	
Low emetogenic agents	Bortezomib, brentuximab, cabazitaxel, carfilzomib, cetuximab, cytarabine ≤1,000 mg/m^2, decitabine, docetaxel, eribulin, etoposide, fluorouracil, gemcitabine, methotrexate, paclitaxel, pemetrexed, topotecan, and trastuzumab-emtansine	Afatinib, alectinib, alpelisib, axitinib, brigatinib, capecitabine, chlorambucil, cobimetinib, dabrafenib, dacomitinib, dasatinib, encorafenib, entrectinib, erdafitinib, erlotinib, etoposide, everolimus, gefitinib, hydroxyurea, ibrutinib, lapatinib, lenalidomide, lenvatinib, lorlatinib, methotrexate, nilotinib, olaparib, osimertinib, palbociclib, pazopanib, pomalidomide, regorafenib, ruxolitinib, sorafenib, sunitinib, tegafur-uracil, thalidomide, topotecan, trametinib, vandetanib, vemurafenib, and venetoclax
Minimal emetogenic agents	Atezolizumab, bevacizumab, bleomycin, daratumumab, durvalumab fludarabine, ipilimumab, nivolumab, pembrolizumab, ramucirumab, rituximab, trastuzumab, vinblastine, vincristine, and vinorelbine	

Pathophysiology

Chemotherapy-induced nausea and vomiting is regulated by central pattern generator (vomiting center), nucleus tractus solitarius and area postrema (chemoreceptor trigger zone), higher brainstem and cortical structures, and GI tract (via vagus and splanchnic nerves). Acute CINV is mediated mainly by peripheral pathway which is predominantly mediated via serotonin receptors located in GI tract. Delayed CINV is mediated mainly by central pathway which is predominantly mediated via substance P and neurokinin 1 (NK1) receptors located in the brain. Anticipatory emesis is mediated by higher brainstem and cortical structures.

Treatment

Drugs used in CINV are *5-HT3 receptor antagonists*: *First-generation*: Dolasetron, granisetron, and ondansetron *and second-generation*: Palonosetron. *Neurokinin-1 receptor antagonists*: Aprepitant, fosaprepitant, netupitant, and rolapitant. *Glucocorticoids:* Dexamethasone. *Atypical antipsychotic*: Olanzapine. *Dopaminergic antagonist*: Phenothiazines, metoclopramide, and butyrophenones. *Cannabinoid:* Dronabinol. *Antihistaminic*: Diphenhydramine and hydroxyzine. *Benzodiazepine:* Lorazepam. Others: Thalidomide, scopolamine, etc.

In cases of breakthrough CINV (nausea and vomiting which occurs despite optimal antiemetic prophylaxis and requires rescue therapy) and refractory CINV (nausea and vomiting which occurs despite optimal antiemetic prophylaxis and requires rescue therapy) other causes of nausea and vomiting such as GI obstruction/paresis, brains metastases, dyselectrolemia, uremia, and drugs like opioids must be ruled out. After ruling out other causes an agent from different class of antiemetic should be added. Complementary therapies acupuncture, behavioral therapy, ginger, etc., can also be used.

Chemotherapy-related Diarrhea

Diarrhea is defined as abnormal increase frequency, water content, and weight (>300 g/day) of the stool. Acute diarrhea: <2 weeks; persistent diarrhea: 2–4 weeks; and chronic diarrhea: >4 weeks.

Chemotherapy-induced diarrhea: Fluoropyrimidines (5-fluorouracil and capecitabine) and irinotecan. Targeted therapy-associated diarrhea: Gefitinib, afatinib, erlotinib, sorafenib, sunitinib, everolimus, bortezomib, cetuximab, and panitumumab. Others such as immunotherapy-associated diarrhea, radiotherapy-induced diarrhea, neutropenic colitis, *Clostridium difficile* diarrhea, enteral feeding, and celiac plexus block.

It can occur by any one of the following mechanism or combination of them: Increased secretion (fluid and electrolytes) and abnormal absorption; osmotic diarrhea; increased GI motility; infection; and inflammation. Few specific mechanisms are:

- *Fluoropyrimidine*: Diarrhea occurs due to the relative increase in number of immature crypt cells due to its mitotic arrest leading to defects in its absorption and secretion.
- *Irinotecan*: Acute diarrhea occurs due to inhibition of acetylcholine esterase leading to increase in cholinergic transmission while delayed diarrhea occurs by from deconjugation by intestinal bacteria of irinotecan metabolite, leading to its direct toxic effect on intestinal epithelium leading to defects in its absorption and secretion.
- *Targeted therapy*: Altered gut motility, colonic crypt damage, changes in the intestinal microflora, and altered colonic transport.

Diarrhea may be associated with pain abdomen. Features of infection, dehydration, and electrolyte imbalance may be present. Diarrhea can lead to dehydration, electrolyte imbalance, and malnutrition

Grading

It is graded according to National Cancer Institute-Common Terminology Criteria for Adverse Events (NCI-CTCAE) version 5.0 as below.

- Grade 1: Increase of <4 stools/day or mild increase in ostomy output over baseline
- Grade 2: Increase of 4–6 stools/day or moderate increase in ostomy output over baseline
- Grade 3: Increase of ≥7 stools/day or severe increase in ostomy output over baseline, limiting self-care activities of daily living, and requiring hospitalization
- Grade 4: Life-threatening consequences and urgent intervention required
- Grade 5: Death

Patient is said to have complicated diarrhea if any of the following risk factor is present: Grade 3/4 diarrhea or grade 1/2 diarrhea with ≥1 of the following feature: Abdominal cramps, nausea/vomiting grade ≥2, deteriorating or decreased performance status, fever, suspected sepsis, neutropenia, blood in stools, dehydration, chest pain, and history of admission for chemotherapy-induced diarrhea.

Diagnostic workup includes CBC, stool routine and culture, stool for *Clostridium difficile* toxin, comprehensive metabolic panel along with magnesium, abdominal imaging like CT if needed (fever, bloody diarrhea, or peritoneal signs), infective workup if needed (fever and suspected sepsis), and endoscopy if needed (refractory diarrhea, chronic diarrhea, or bloody diarrhea).

Treatment

Common drugs used in its management are opioids (loperamide), somatostatin analogs (octreotide), uridine triacetate, budesonide, antibiotics, and other agents.

Extravasation of Chemotherapy

Extravasation of chemotherapy refers to inadvertent leakage of chemotherapy into the tissue around it from a blood vessel or tube. Based on local toxicity chemotherapeutic agents are divided as:

- *Vesicants*: Dactinomycin, daunorubicin, doxorubicin, epirubicin, trabectedin, vinblastine, and vincristine.
- *Irritants*: Ado-trastuzumab emtansine, bendamustine, bleomycin, bortezomib, carboplatin, cisplatin, cyclophosphamide, cytarabine, dacarbazine, docetaxel, etoposide, fluorouracil, gemcitabine, ifosfamide, irinotecan, liposomal doxorubicin, oxaliplatin, paclitaxel, and topotecan.
- *Neutral***:** Arsenic trioxide, asparaginase, eribulin, monoclonal antibodies, methotrexate, and pemetrexed.

Vesicants cause tissue necrosis. Irritants cause inflammation and concentrated large volumes can also result in necrosis. Initially at the site of extravasation and surrounding tissue there may be redness, tingling, burning sensation, pain or discomfort, and swelling. Later there may be blistering, ulceration, or necrosis. *Diagnostic workup includes* peripheral extravasation clinical examination which is usually sufficient, but in selected cases ultrasound (quantify volume and determine margin) may be needed.

In central venous access device extravasation, a chest radiograph or CT scan should be obtained. Management strategy for chemotherapy extravasation is summarized in **Box 2**.

Cytokine Release Syndrome

Cytokine release syndrome (CRS) refers to an acute cytokine-mediated systemic inflammatory syndrome which is characterized by fever and multiorgan dysfunction. It is seen with chimeric antigen receptor (CAR) T-cell therapy, therapeutic antibodies, and haploidentical allogeneic transplantation mainly. It is also seen with severe viral infection.

BOX 2: Management of extravasation of chemotherapy.

Peripheral line extravasation

- Stop the injection immediately, and leave the cannula in place
- Elevate the afflicted limb
- Aspirate as much fluid as possible through the cannula and also try to draw back about 3–5 mL of blood. Then remove cannula
- Mark the extravasation area with a pen
- Identify class of agent extravasated
- In vinca alkaloids (vinblastine and vincristine): Local injection hyaluronidase, hot packs, and hydrocortisone cream
- In anthracyclines (daunorubicin, doxorubicin, and epirubicin): Cold pack, topical dimethyl sulfoxide + hydrocortisone cream, and intravenous dexrazoxane
- In dactinomycin: Cold pack, topical dimethyl sulfoxide + hydrocortisone cream
- In taxanes (docetaxel and paclitaxel): Cold pack, local injection hyaluronidase, and topical hydrocortisone cream
- In irritant drugs other than taxanes including trabectedin and neutral drugs: Cold packs and topical hydrocortisone cream
- Surgical referral may be sought in case of large volume subcutaneous extravasation

Central line extravasation

- Stop the injection immediately, but leave the catheter in place.
- Aspirate as much fluid as possible through the catheter
- Identify class of agent extravasated
- Start fluids, antibiotics, and analgesics. In extravasation into chest also start supplemental oxygen and antipyretics
- In anthracyclines: Intravenous dexrazoxane
- Urgent surgical referral (pleura—thoracentesis and chest tube; mediastinum—thoracoscopy or thoracotomy; and subcutaneous—drainage)

Pathophysiology

Supraphysiologic response to immune therapy that activates or engages T cells and/or other immune effector cells associated with increased levels of inflammatory cytokines. In the setting of T cell-engaging immunotherapies, CRS is triggered by release of interferon gamma (IFN-γ) by activated T cells or tumor cells. IFN-γ activates macrophages, which produce excessive interleukin (IL)-6, tumor necrosis factor alpha (TNF-α), and IL-10. IL-6 binds to the soluble form of the IL-6 receptor (IL-6R) that has been cleaved by metalloproteinases, and the IL-6 and IL-6R complex binds to gp130 and activates cell types that ordinarily do not express membrane-bound IL-6R. IL-1, 5, 8, and 10 and granulocyte-macrophage colony-stimulating factor are also elevated in CRS and which also contribute to the pathophysiology of CRS.

Clinical Presentation

Onset of symptoms after therapy: CAR-T-cell therapy: 1–14 days, therapeutic antibodies: minutes to hours, haploidentical allogeneic transplantation: 1–3 days. Clinical presentation can range from mild flu-like symptoms to a severe life-threatening systemic inflammatory response syndrome.

Grading

Common Terminology Criteria for Adverse Events (version 5) has classified CRS as below.

- Grade 1: Fever with or without constitutional symptoms
- Grade 2: Hypotension responding to fluids and hypoxia responding to <40% oxygen
- Grade 3: Hypotension managed with one pressor and hypoxia requiring ≥40% oxygen
- Grade 4: Life-threatening consequences and urgent intervention indicated
- Grade 5: Death

Management

- Depends on **grade, etiology, and comorbidities.**
- All patients should also undergo infectious disease workup to rule out any infection and if present/suspected, should be treated in lines of FN.
- *Supportive*: Antihistamines, antipyretics, and IV fluids with close monitoring.
- *Tocilizumab*: **Anti-IL-6**; dose: In <30 kg patient—12 mg/kg and ≥30 kg patient—8 mg/kg (maximum: 800 mg). If there is no clinical improvement after the first dose, it may be repeated after an interval of at least 8 hours and should not exceed four doses in total.
- *Steroid*: Usually hydrocortisone 100 mg q8 hourly or dexamethasone 10 mg up to q6 hourly or methylprednisolone 1 mg/kg/day.
- *Resistant CRS*: Anti-IL-6, e.g., siltuximab, clazakizumab, anti-IL-1RA, e.g., anakinra, anti-TNF alpha, e.g., etanercept, antithymocyte globulin, alemtuzumab, cyclophosphamide, ruxolitinib, and ibrutinib.

SUMMARY

With advances in therapeutics and enhanced survival of cancer patients, complications of malignancies are an increasingly common reason for admission in emergency department. Every healthcare provider should be aware and able to recognize oncologic emergencies. Emergencies in oncology can be life-threatening, complications can arise in a known malignancy or individual not previously diagnosed with cancer, or these events can happen during treatment. These life-threatening oncologic emergencies may not have characteristic signs and symptoms, so high degree of suspicion is crucial while dealing with malignancy related complications. Oncologic emergencies should be treated promptly in emergency department.

143 CHAPTER

Thrombocytopenia, Bleeding, and Coagulopathy

Ragesh Radhakrishnan Nair, Isha Gambhir

INTRODUCTION

Normal coagulation process involves the balance between procoagulant pathway (clot formation) and the anticoagulant pathway (clot dissolution). The normal clot formation starts as a cascade of events leading to activation of clotting factors and thus causing thrombus formation. The inhibitory pathway of coagulation system prevents the abnormal clot propagation. The various prothrombotic and antithrombotic factors are shown in **Table 1**. Normal coagulation system involves the initial or the primary hemostasis by platelet plug formation and then the activation of clotting factors called the clot propagation.

PRIMARY HEMOSTASIS

It is the platelet plug formation, which involves complex interactions between platelets, vessel wall, and adhesive proteins. The subendothelial layer is highly thrombogenic and contains collagen, von Willebrand factor (vWF), and other proteins such as laminin, thrombospondin, and vitronectin that are involved in platelet adhesion and once there is injury this subendothelial layer is exposed.

TABLE 1: Prothrombotic and antithrombotic factors in the body.

Site	*Prothrombotic factors*	*Antithrombotic factors*
Vessel wall	Exposed endothelium	Thrombomodulin
	Tissue factor	
	Collagen	
Circulating factors	Platelets	Heparin
	Platelet activating factors	Antithrombin
	Clotting factors	Protein C and S
	Fibrinogen	Plasminogen
	Prothrombin	Tissue plasminogen activator
	von Willebrand factor	

In contrast, the endothelial lining also has antithrombotic properties due to multiple factors such as negatively charged heparin-such as glycosaminoglycans, neutral phospholipids, synthesis and secretion of platelet inhibitors, coagulation inhibitors, and fibrinolysis activators.

Platelets are anucleate, disk-shaped cells which play an important role in initial platelet plug formation by providing the phospholipid rich plasma membrane which is an important component in activation of coagulation factors. Normally platelets do not adhere to intact endothelial surface, but after injury the subendothelial surface is exposed leading to binding platelets to collagen and vWF plays the intermediary role in this process. Platelets have these two important granules:

1. Alpha (α) *granules*: Contain P-selectin, fibrinogen, fibronectin, factor V, factor VIII, platelet factor IV, platelet-derived growth factor, and tumor growth factor-α (TGF-α)
2. *Delta* (δ) *granules or dense granules*: Contain adenosine triphosphate (ATP), adenosine diphosphate (ADP), calcium (Ca), serotonin, histamine, and epinephrine.

The platelet plug formation involves three steps:

1. *Platelet adhesion*: After vascular injury, the subendothelial layer is exposed, leading to binding of collagen to platelet surface receptors GPIb and promotes platelet adhesion to the subendothelial layer, and this binding is facilitated by vWF which acts as a bridge.
2. *Platelet secretion*: The binding of platelets to subendothelial layer causes the activation of platelets and thus the granules to release their contents and calcium which causes further aggregation of platelets. These granules are also responsible for activation of coagulation system.
3. *Platelet aggregation*: Secretion of granule content causes release of thromboxane A2 (TxA2) which leads to platelet aggregation. TxA2 along with ADP causes platelets to aggregate which leads to platelet plug formation and thus sealing the injury. ADP binding also causes a conformational change in GPIIb/IIIa receptors and thus facilitating binding to fibrinogen. Thrombin in turn converts fibrinogen to fibrin which further stabilizes the clot.

COAGULATION CASCADE

The second phase of hemostasis is the cascade of coagulation factor activation leading to conversion of soluble fibrinogen to fibrin strand which is involved in clot formation. Majority of coagulation factors are proenzymes called zymogens which becomes activated in coagulation cascade. Most of the factors are produced by liver except factor III, IV, and VIII. The various coagulation factors and their properties are mentioned in the **Table 2**. Normal coagulation cascade involves activation of factor X by the extrinsic or intrinsic pathway (tenase complex). Activated factor X with factor V forms the prothrombinase complex which in turn converts prothrombin to thrombin which converts soluble fibrinogen to fibrin monomer which polymerizes to form the firm clot [basic conceptual (**Fig. 1**)].

TABLE 2: Coagulation factors.

No.	*Name*	*Function*	*Half-life (in hours)*
I	Fibrinogen	Converted to fibrin	90
II	Prothrombin	Activates I, V, VII, VIII, XI, XIII, protein C, and platelets	60
III	Tissue factor	Cofactor of VII	-
IV	Calcium	Act as coenzyme	-
V	Proaccelerin and labile factor	Cofactor of X-prothrombinase complex	15
VI	None		
VII	Stable factor and proconvertin	Activates IX and X	4–6
VIII	Antihemophilic factor A	Cofactor of IX-tenase complex	10
IX	Antihemophilic factor B and Christmas factor	Activates X: Tenase complex with factor VIII	20–24
X	Stuart–Prower factor	Forms prothrombinase complex with factor V	40
XI	Plasma thromboplastin antecedent		45
XII	Hageman factor	Activates factor XI and prekallikrein	-
XIII	Fibrin-stabilizing factor	Fibrin polymerization	200
XIV	Prekallikrein (F Fletcher)	Serine protease	35
XV	HMWK (F Fitzgerald)	Cofactor	150
XVI	vWF	Binds to factor VIII, collagen, and mediates platelet adhesion	12
XVII	Antithrombin III	Inhibits IIa, Xa, and other proteases	72
XVIII	Heparin cofactor II	Inhibits IIa	60
XIX	Protein C	Inactivates Va and VIIIa	0.4
XX	Protein S	Cofactor of protein C	-

(HMWK: high-molecular-weight kininogen; vWF: von Willebrand factor)

Process of Coagulation Cascade

Coagulation process starts immediately once there is any injury to the vessel wall causing exposure of the endothelium to the blood coagulation system which includes platelets and coagulation factors. The normal coagulation process first involves platelet plug formation by platelet activation adhesion and aggregation as already explained and later the formation and maturation of fibrin.

Once the endothelium is damaged it leads to exposure to platelets which causes the first step of coagulation called the primary hemostasis and then simultaneously the secondary hemostasis also starts involving the release of tissue factor (TF) from the endothelium which activates the factor VII which is considered as the first step in the activation of the coagulation cascade which in turn activates the factor X. This activation of factor X through the TF pathway is also called the extrinsic tenase complex and is now considered as the primary stimulus for the activation of the secondary hemostasis. The coagulation factors circulate in the blood in inactive form called zymogens and are named as roman numerals and once activated they are added by lower case letter a. The main role of TF pathway is to produce thrombin burst.

The intrinsic pathway also called the contact activation pathway involves the formation of complex by high-molecular-weight kininogen (HMWK), factor XII, and prekallikrein when it comes in contact with the collagen. Once factor XII is activated it further activates XI to Xia which further activates factor IX which act as cofactor for factor VIIIa and act as intrinsic tenase complex which activates factor X to Xa. This division of coagulation pathway in extrinsic and intrinsic type is not absolutely clear, in fact this division was based on laboratory tests as intrinsic pathway is activated after contact with glass and extrinsic pathway is activated by adding thromboplastin which is a mixture of TF and phospholipid. The formation of tenase complex leads to activation of factor X which with the help of factor V and calcium forms the prothrombinase complex which converts prothrombin to thrombin which in turn convert the soluble fibrinogen to fibrin. This pathway is called the final common pathway.

In fact thrombin is not only generated by common pathway, it is also released by activated platelets which are involved in platelet plug formation. Thrombin also activates coagulation

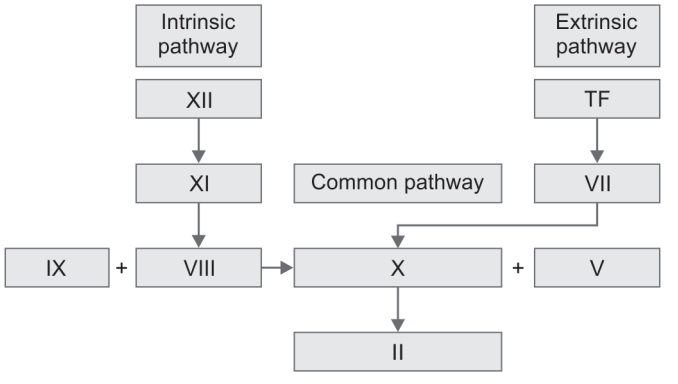

FIG. 1: Basic concepts of coagulation pathway.

factors VIII, V, and XIII and the anticoagulant protein C with the help of thrombomodulin. Role of factor XIII is to crosslink fibrin monomers and thus stabilizes the clot.

The *new model of coagulation system* involves around the cell-based coagulation system mainly the extravascular tissues providing the TFs and the platelets. It constitutes two phases; the first initiation phase which causes the release of TF leading to activation of extrinsic pathway leading to 5% of thrombin production and then the propagation phase wherein the intrinsic pathway is activated leading to 95% of thrombin generation. The other aspect is the platelet activation following tissue injury and thus causing platelet plug formation and also thrombin generation.

In fact the primary step of secondary hemostasis starts with the activation of extrinsic pathway and the intrinsic pathway further facilitates thrombin generation needed for clot propagation. *The newer model has the following steps:*

1. *Initiation*: It involves binding of TF in damaged vessel to factor VIIa which activates factor IX and factor X. This activation of factor IX by TF-VIIa complex serves as the bridge between classical extrinsic and intrinsic pathways. Factor Xa then binds to factor II to form thrombin. Thrombin generation through this reaction is not robust and can be effectively terminated by TF pathway inhibitor.
2. *Amplification*: Thrombin produced in the initiation phase further activates factor V and factor VIII, which serves as a cofactor in prothrombinase complex and augments the activation of factor II by FXa and of FXa by FIXa, respectively. This mainly involves the intrinsic pathway.
3. *Propagation*: The enzyme complexes such as tenase and prothrombinase on platelet surface produces massive amount of thrombin and platelet activation, which produces the firm clot.
4. *Stabilization*: Thrombin also activates factor XIII (fibrin stabilizing factor) which covalently links fibrin polymers and provides strength and stability to fibrin incorporated in platelet plug.

Along with the activation of coagulation cascade there is also simultaneous activation of anticoagulant pathway mainly via the antithrombin. It is serine protease inhibitor which mainly hydrolyses thrombin, factor IXa, Xa, Xia, and XIIa and thus limits abnormal propagation of thrombus. The other important anticoagulant pathway is TF pathway inhibitor which directly inhibits the TF and the tissue plasminogen activator which converts plasminogen to plasmin which degrades fibrin.

APPROACH TO THROMBOCYTOPENIA

Any patient with platelet counts $<150 \times 10^9$/L needs evaluation for thrombocytopenia. Thrombocytopenia can mild (platelet count: 100–149 $\times 10^9$/L), moderate (59–99 $\times 10^9$/L), or severe (50×10^9/L). The etiology of the thrombocytopenia can be primarily hematological or maybe the manifestation of primarily nonhematological disorder. In the emergency and critical care setting, it is important to find out the cause so as to not to miss serious hematological disorders such as acute leukemias or other thrombocytopenic emergencies like thrombotic thrombocytopenic purpura (TTP). Nonhematological illnesses like sepsis causing thrombocytopenia or disseminated intravascular coagulation (DIC) should also not be missed as they can be catastrophic. The focus of the chapter will be approach to thrombocytopenia in the critical care and emergency setting. The context of the patient's admission is very important in delineating the cause of thrombocytopenia such as sepsis or trauma which can per se lead to thrombocytopenia. It is very important to find out preexisting thrombocytopenia from the past records/history which can point out to previously existing recognized or unrecognized cause of thrombocytopenia such as immune thrombocytopenia, myelodysplastic syndrome, human immunodeficiency virus (HIV) infection, hepatitis C virus (HCV) infection, or chronic liver disease causing hypersplenism.

There are certain thrombocytopenic emergencies which have to be ruled out, especially when the thrombocytopenia is the isolated abnormality. Causes like drug-induced immune thrombocytopenia (DITP) cause severe thrombocytopenia with high risk of bleeding. The detailed review of current and past drug history including herbal medications is crucial. Common medications such as rifampicin and beta-lactam antibiotics can lead to DITP. The onset of thrombocytopenia is 1 week after the onset of drug intake. Certain drugs such as abciximab and eptifibatide can cause DITP even within 1–2 days. In DITP, platelets typically fall below 20×10^9/L. Treatment involves stopping the suspected drug (which may be sometimes essential or sometimes optional) and replacing the suspected essential drugs with a different class of drug as substitute. In case of bleeding, intravenous immunoglobulin (IVIG) may also be given.

In heparin-induced thrombocytopenia (HIT), platelet activating antibodies are formed which bind to the complex of heparin and platelet factor 4 (PF4) (present on the platelets). This phenomenon leads to drop in platelet counts by 50% classically usually after 5 days of initiating heparin. The platelet count nadir is classically $>20 \times 10^9$/L in patients with HIT. Interestingly the patient with HIT is predisposed to develop thrombosis in spite of having thrombocytopenia. The site of thrombosis can be both venous as well as arterial. The thrombosis can involve cerebral cortical veins and other unusual sites such as splanchnic vessels. The culprit heparin may be unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). The 4Ts scoring system may be helping in suspecting HIT. The 4Ts scoring system consist of the degree of platelet call and the nadir, the timing of platelet fall with relation to heparin administration, the presence of thrombosis and presence of other causes of thrombocytopenia. A low T score <4 may help in looking for other causes of thrombocytopenia in the patient. It is important to make a suspicion of HIT clinically as laboratory facilities may not be locally available at all centers to confirm the diagnosis rapidly. Laboratory diagnosis will help to confirm the clinical diagnosis or exclude the diagnosis. The tests done include PF4/heparin immunoassays [e.g., PF4/heparin enzyme-linked immunosorbent assay (ELISA)] and functional assays. The treatment consists of immediate stopping of all heparin (UFH or LMWH) in any forms including heparin intravascular catheter flushes. Patients will need immediate starting of anticoagulation to prevent thrombosis or treat thrombosis, if already present. The anticoagulants which may be used include bivalirudin, argatroban, and fondaparinux. There is emerging data for use of oral novel anticoagulant such as dabigatran and rivaroxaban preferably once the acute phase is resolved as evident by normalization of platelet counts. Warfarin also may be started after the acute

phase is resolved along with bridging with other anticoagulants as per protocol. Early use of warfarin without proper bridging can be deadly and catastrophic due to prothrombotic status due to initial depletion of protein C. When a patient presents with thrombosis in three or more vascular territories a suspicion of catastrophic antiphospholipid antibody (APLA) syndrome should always be considered. The associated thrombocytopenia may be many times mild. Appropriate diagnosis with relevant history of miscarriages, thrombosis in the past along with the identification of APLAs such as anticardiolipin antibodies, anti-beta-2-glycoprotein, and lupus anticoagulant. Patients with immune thrombocytopenic purpura (ITP) may present to the emergency with bleeding such as gastrointestinal (GI) bleeding, mucocutaneous bleeding, or intracranial bleeding and low platelet counts. Patients with ITP may also incidentally be detected of low platelets in routine check-up or for some other disorder. They may reach hospital emergency out of panic but without any symptoms. The blood tests usually depict isolated thrombocytopenia and peripheral smear shows no abnormality apart from low platelets. Bone marrow examination reveals no abnormal cells. In case of severe bleeding manifestations such as intracranial bleeding, GI bleeding, or platelets $<10 \times 10^9$/L patients would require immediate treatment with IVIG along with corticosteroids. Usually after administration of IVIG, platelets start to rise within 24–48 hours. Patients of acute leukemia such as acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL) may present to emergency or critical care department with various manifestations including bleeding manifestations due to thrombocytopenia. They may present with fever due to underlying infection (bacterial or fungal) or fever due to disease per se, fatiguability due to anemia, and bony pains due to marrow infiltration. The diagnosis is very critical as if missed can lead to mortality in a potentially curative disorder with proper treatment. Complete hemogram may show evidence of high total leukocyte count (TLC) or sometime low TLC. There may be thrombocytopenia and anemia. Peripheral smear may show evidence of blasts in the smear. Further tests such as bone marrow examination along with flow cytometry will help in confirming the diagnosis. Patients require immediate referral by a hematologist for the treatment of the acute leukemia. The most sinister of all leukemia to cause bleeding is acute promyelocytic leukemia (APL) which can lead to serious bleeding such as intracranial bleeding due to concurrent presence of thrombocytopenia and deranged coagulation parameters with DIC. Peripheral smear shows evidence of promyelocytes in the peripheral smear. Similarly patients with myelodysplastic syndrome may present to the emergency room (ER) or the intensive care unit (ICU) with bleeding due thrombocytopenia along with or without other cytopenia. Peripheral smear may show evidence of dysplasia. Aplastic anemia may have pancytopenia with severe thrombocytopenia which may be associated with catastrophic bleeding such as intracerebral bleeding or GI bleeding. Bone marrow examination will be diagnostic with evidence of hypocellularity in aplastic anemia, Patients with malignancies may present to ER with bleeding due to chemotherapy-induced thrombocytopenia or marrow infiltration by the tumor. Patients may present to critical care division with thrombocytopenia due to a potentially lethal condition known as hemophagocytic lymphohistiocytic syndrome with associated other features such as fever, hepatosplenomegaly, hemophagocytosis in the marrow, cytopenia, and high ferritin in blood.

Disorders such as TTP or hemolytic uremic syndrome (HUS) are microangiopathic hemolytic anemia which may present to the ER or the ICU with thrombocytopenia, anemia, features of hemolysis, renal dysfunction (especially in HUS), and neurological manifestation (especially in TTP). Peripheral smear shows presence of schistocytes due to the presence of microangiopathic hemolysis. Acquired TTP is due to presence of anti-ADAMTS13 antibodies, which can be demonstrated by serological testing as well as low ADAMTS13 level. TTP requires immediate plasma exchange and glucocorticoids. Any delay in administering plasma exchange may lead to fatal outcomes. HUS can be typical HUS (due to enteric infection with strains of *Escherichia coli* that produce Shiga-like toxins) or atypical HUS due to genetic mutations leading to dysregulation of the complement system. Treatment of typical HUS is typically supportive. Treatment of atypical HUS is generally with eculizumab.

Pregnancy may be associated with thrombocytopenia which can bring the patient to the ER or the ICU. This thrombocytopenia can be due to gestational thrombocytopenia which is usually mild thrombocytopenia usually occurring from second trimester onwards and usually resolves postpartum. Pregnant women also can present with thrombocytopenia related previously existent ITP. The treatment may require IVIG and or prednisolone as deemed necessary by the hematologist. Patients may present with preeclampsia or HELLP syndrome which may have thrombocytopenia. Thrombotic microangiopathy such as TTP and atypical HUS may present for the first in the course of the pregnancy. During pregnancy patients may have develop DIC due to amniotic fluid embolism, puerperal sepsis, postpartum hemorrhage, or retained products of conception. This DIC is accompanied by not only thrombocytopenia but also coagulation parameter derangement.

Patients with tropical infections such as dengue, malaria, and scrub typhus may present with concurrent thrombocytopenia. Other infections such as hepatitis C, HIV, and Epstein–Barr virus (EBV) infections may also cause thrombocytopenia.

Management of Thrombocytopenia

General management of patients with severe thrombocytopenia should avoid contact sports. Antiplatelets and anticoagulants should be used with caution to avoid bleeding in patients with thrombocytopenia on a case-to-case basis in association with the hematologist. Patients presenting to the emergency or the ICU with thrombocytopenia may sometimes need invasive procedures. It is imperative to maintain platelet count in preparation for any invasive procedure to decrease the risk of bleeding. In patients without bleeding, prophylactic platelet transfusion is used in most afebrile patients with platelet counts below 10,000/μL to prevent spontaneous bleeding. Platelets are transfused in patients with fever or sepsis and platelet counts <20,000/μL. In patients with APL, the target platelet count is >50,000/μL, especially in the presence of coexisting coagulopathy. The preferred product for transfusion is single donor apheresis product which usually contains $3–4 \times 10^{11}$ platelets. In all conditions, attempt to identify the

underlying disease process causing the thrombocytopenia and addressing that disease process is the most important step in the management of thrombocytopenia.

DISORDERS OF COAGULATION

Basic Tests of Coagulation

It is critical to have a basic understanding about the various coagulation laboratory tests for the diagnosis and management of disorders of coagulation. The basic tests are prothrombin time (PT), activated partial thromboplastin time (aPTT), Fibrinogen assays, thrombin time (TT), and lupus anticoagulant assay. Next level of tests include coagulation factor activity assays, mixing studies, and inhibitor assays. Isolated prolongation of the PT (extrinsic coagulation pathway) most often reflects a deficiency of vitamin K-dependent factors due to reasons such as warfarin, vitamin K deficiency, or decreased hepatic synthesis. Reduced quantities of factor VIII, IX, XI, and XII (intrinsic coagulation pathway) cause isolated prolongation of aPTT. Deficiency or inhibition of a factor in the common pathway (factors X, V, II, and fibrinogen) cause combined prolongation of the PT and aPTT. Fibrinogen assays are prolonged in fibrinogen deficiencies. Presence of thrombin inhibitors such as heparin and dabigatran inhibit thrombin, and prolong TT. Mixing study is used in the setting of prolonged aPTT or prolonged PT to determine whether the prolongation is due to deficiency of coagulation factors or to a presence of inhibitors. Inhibitors like certain antifactor antibodies cause inhibition of coagulation factors. Correction of PT/aPTT with mixing studies indicates factor deficiency while noncorrection suggests the presence of inhibitors. Inhibitor assay determines the presence of coagulation cascade inhibitors and its titers. Lupus anticoagulant is present in patients with APLA, in which antiphospholipid antibodies result in prolongation of aPTT and usually without bleeding manifestations, but with thrombotic manifestations.

Von Willebrand Disease

Von Willebrand disease (vWD) is one of the common disorders of bleeding presenting to the healthcare setting with symptoms of mucocutaneous bleeding such as bruising, epistaxis, menorrhagia, or GI bleeding. It is characterized by quantitative or qualitative reduction in the vWF. They may also present to the critical care unit with profuse bleeding following surgery such as dental surgery and tonsillectomy. They may also come to notice in preoperative check in the form coagulation laboratory report abnormality done as part of preoperative clearance. The cases are usually hereditary with predominantly being autosomal dominant. There is also an acquired variant of vWD due to conditions such as aortic stenosis, autoantibodies to vWF, and in other conditions like hypothyroidism. The diagnostic assays for vWD include quantitative measurement of vWF (vWF:Ag) which is reduced to 30 IU/dL, vWF activity—ristocetin cofactor assay (vWF:RCo) which is reduced in the patients and factor 8 levels which may also be reduced (as normally vWF protects factor 8 from proteolysis). Management is done in collaboration with a hematologist with the help of plasma-derived vWF concentrates or using agents like desmopressin which lead to increased release of vWF from the storage pool into the circulation.

Hemophilia

Hemophilia A and hemophilia B is due to the congenital deficiency of factor VIII and factor IX, respectively. Usually the presentation is that a child presenting to the emergency because of acute joint pain due to joint bleeding, hematomas in the muscle, intracranial bleeding, profuse bleeding following procedures such as circumcision, and later on with permanent sequelae like joint damage. Many of the patients may have family history of similar disorder in X-linked recessive pattern. Diagnosis is usually established by a prolonged aPPT and demonstration of low levels of factor VIII in hemophilia A, and low level of factor IX in hemophilia B. The treatment involves urgent replacement in case of bleeding with appropriate factor concentrate; in this era with help of recombinant factor VIII in hemophilia A and recombinant factor IX in hemophilia B. The dose and duration of treatment depends on the type of concentrate and the severity of bleeding. Preoperative doses and postoperative doses may be required in patients requiring surgery to prevent catastrophic bleeding. Some patients with hemophilia who are given exogenous factor develop antibodies which inhibit the factor (known as inhibitors). In these patients the factors may not work and patient often require other agents such as recombinant factor VII or activated prothrombin complex concentrate (aPCC)-factor eight inhibitor bypass activity (FEIBA) in case of bleeding or for purposes of surgery. Hence it is also important to send inhibitor assay in a patient who comes to the emergency with bleeding manifestations; else the factor concentrates which the medical team gives maybe of no use in patients with inhibitors. Rarely patients with pregnancy, malignancy, or connective tissue disorders can present with acquired hemophilia due to development of antibodies against endogenous factor VIII. They will be diagnosed with prolonged aPTT with positive inhibitor assay in the setting of major bleeding such as intracranial bleeding or muscle hematoma.

There are several rare disorders due to congenital deficiency of other factors such as factor II, VII, X, V, and XIII which is beyond the scope of discussion here. They may present with bleeding manifestations such as intracranial bleeding, umbilical stump bleed (factor XIII deficiency), postsurgical bleeding (factor XI), or other nonbleeding symptoms such as miscarriages (fibrinogen deficiency or factor XIII deficiency), splenic rupture, and thrombosis in fibrinogen deficiency. The clue to their existence will be by the past history of bleeding and abnormal coagulation parameters such as prolonged PT and prolonged aPTT in association with normal TT in factor II, factor X, and factor V deficiency. In factor VII deficiency there would be isolated PT prolongation. In fibrinogen deficiency there would PT, aPTT, TT prolongation along with low fibrinogen levels as per fibrinogen assay. In factor XIII deficiency there would be normal aPTT, TT, PT, and fibrinogen level but clot solubility test would be abnormal. In isolated factor XI deficiency, there would be isolated prolongation of aPTT. Treatment of these rare factor deficiencies will be to given specific factor concentrates wherever available or fresh frozen plasma (FFP) in close association with a hematologist.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation is due to abnormal activation of intravascular coagulation along with fibrinolysis

BOX 1: Major causes of disseminated intravascular coagulation (DIC).

- Sepsis
- Crush injury
- Severe head injury
- Cancer procoagulant (Trousseau's syndrome)
- Acute leukemia, especially promyelocytic
- Amniotic fluid embolism
- Abruptio placentae
- Acute hemolytic transfusion reaction (ABO incompatibility)
- Snake and viper venoms
- Heat stroke
- Burns

activation leading to DIC with concurrent fibrinolysis. This can lead to bleeding due consumption and depletion of coagulation factors along with accelerated fibrinolysis. The activation of intravascular coagulation can also lead to thrombosis. It usually occurs due to a systemic abnormal exposure of procoagulant in conditions such as sepsis, malignancy such as APL, trauma, intrauterine uterine death of fetus, and viper bite (**Box 1**). Clinically it can present with the underlying condition along with features of bleeding from cannula sites, catheters site, mucous membranes, and sometimes with organ dysfunction with renal dysfunction and liver function abnormalities. Sometimes, especially in chronic DIC as in malignancies like the DIC associated with pancreatic cancer presentation can be due to thrombosis. Laboratory abnormalities in various permutations and combinations reflect the systemic activation of coagulation along with concurrent activation of fibrinolysis as shown by prolonged PT/aPTT/low fibrinogen levels/increased D-dimer/thrombocytopenia/evidence of microangiopathic hemolysis in the peripheral smear. The treatment involves that of treating the underlying condition such as antibiotics for sepsis. Prevention of bleeding includes prophylactic platelet transfusion with target platelet counts above 20,000/μL in the absence of bleeding. In the presence of bleeding or in the preparation of an invasive procedure, it is important to keep platelets above 50,000/μL. In presence of bleeding, fibrinogen has to be maintained above 100 mg/dL with the help of cryoprecipitate and if PT/aPTT is prolonged then FFP should be transfused.

Coagulation Abnormalities in Liver Diseases

In liver, being the site of production of the procoagulant factors (except factor VIII) and most anticoagulants, there is usually reduction of the synthesis of both the procoagulant and the anticoagulant factors, thereby leading to the rebalancing of the hemostasis. The measurement of PT/aPTT/fibrinogen will reveal deficiency in these factors, but in view of reduction in anticoagulant factors such as protein C, antithrombin which is also produced in the liver is prothrombotic, hence the high PT/aPTT and low fibrinogen level may mislead the treating team to believe that patient is at increased risk of only bleeding. In fact in this rebalanced hemostasis, the risk of bleeding or thrombosis depends on the tilt of this rebalancing towards thrombosis or bleeding. Hence in a nonbleeding patient with liver disease, not planned for any invasive procedure, giving FFP just for elevated PT is pointless. For patients with nonvariceal bleed, vitamin K must be supplemented, platelets to be maintained above 50,000/μL, and cryoprecipitate to be given to maintain fibrinogen level above 100 mg/dL. In case bleeding is still persistent then FFP can be given. In case of variceal bleeding, standard treatment of variceal bleeds along with above measures are done. Preparation for invasive procedure will require platelet transfusion to maintain platelet above 50,000/μL, cryoprecipitate maintain fibrinogen level above 100 mg/dL, optimization of renal status, treatment of infection, etc. Viscoelastic testing such as thromboelastography (TEG) or rotational thromboelastometry (ROTEM) can be used to optimize management and prevention of bleeding in patients with chronic liver disease. Treatment of thrombosis is chronic liver disease has to be in close association with a liver specialist in collaboration with a hematologist in view of increased risk of bleeding, both variceal and nonvariceal. Measures such as prophylaxis with beta-blockers may be needed to reduce the bleeding risk in patients with varices who need anticoagulants to be used in thrombosis such as portal vein thrombosis, deep venous thrombosis (DVT), and other thrombotic states.

Treatment of Bleeding Due to Anticoagulants

Use of anticoagulants for various conditions like DVT may lead to bleeding complications. The treatment of the bleeding complications include stopping of the anticoagulant and use of reversal agents. The reversal agents used depends on the anticoagulant used. For heparin (UFH) and LMWH protamine is used for reversal. In case of bleeding due to warfarin FFP is used. For patients on direct oral anticoagulants with bleeding FFP/protamine is of no use. For dabigatran-related bleeding idarucizumab is the medication of choice for reversal. For anti-factor Xa, direct oral anticoagulants such as apixaban and rivaroxaban andexanet alpha or if not available prothrombin complex concentrates may be used in appropriate settings.

SUMMARY

There is large diversity in the spectrum of bleeding disorders. Thus, it is very important for the team of critical care/emergency care/hematologist to work in close collaboration for the diagnosis and immediate and long-term management of these patients. Special emphasis is to be laid on the immediate recognition of some of these medical emergencies, which without appropriate treatment can be fatal.

144 CHAPTER

Blood Transfusion Therapy and Related Complication

Aseem Kumar Tiwari, Geet Aggarwal

INTRODUCTION

The transfusion of the blood components in emergencies, if not done rationally, can increase the morbidity and mortality of patients. The immediate availability of blood components for life-threatening hemorrhages requires a rapid and focused approach as excessive bleeding threatens the survival of patients. Early recognition of major blood loss and immediate effective interventions are vital to avoid hypovolemic shock and its consequences. One of the effective interventions is the rapid provision of blood components, for which effective communication between emergency team and blood bank is a must. Transfusion support is vital for any patient in hemorrhagic shock. The transfusion of the right component to the right patient in the right quantity and at the right time has been the guiding principle for resuscitating emergency/trauma patients. The emergency team and blood bank also need disaster preparedness, presently, more than ever before. The entire chapter has been dealt with in five major sections: (1) Responsibility of emergency and blood bank team, (2) Transfusion approach in emergency and massive transfusion protocol (MTP), (3) Use of specific blood components, (4) Adverse effects of blood transfusion, and (5) Hemovigilance.

RESPONSIBILITY OF EMERGENCY AND BLOOD BANK TEAM

Responsibility of Emergency Team (Ordering Blood Component)

Every hospital should have a written protocol for ordering blood component in an emergency which should be clear and simple so that everyone understands and follows them. Simplified protocol given by the World Health Organization (WHO) in clinical use of blood is as follows:

- Insert an intravenous (IV) cannula. Use it to take the blood sample for compatibility testing, set up an IV infusion of normal saline or a balanced salt solution (e.g., Ringer's lactate or Hartmann's solution). Send the blood sample to the blood bank as quickly as possible.
- Clearly label the blood sample tube and the blood request form. If the patient is unidentified, which may happen in a disaster-like situation or road traffic accident, use some form of emergency identification system (e.g., emergency admission number). Use the patient's name, only when you are sure that you have the correct information. If you are not sure then an identifier like "*Unknown 1", "Unknown 2", and so on,* can be used. Preferably two identifiers should be used; so along with "Unknown 1" you can use patient's hospital enrollment/registration number (for example, patient id: *12345*).
- If you have to send another request for another blood component for the same patient within a short period, use the same identifiers which were used in the first request form (and blood sample) so the blood bank staff know they are dealing with the same patient. In the interim, even if the real name is identified it should not be used until the patient has stabilized clinically.
- If there are several staff members working with emergency cases, one person should take charge of ordering blood components and communicating with the blood bank about the particular patient(s). This is especially important if several injured patients are involved at the same time.
- Tell the blood bank how quickly the blood is needed for each patient. Communicate using words that have been previously agreed with the blood bank to explain how urgently blood is required. For example, we follow the terminology of immediate, urgent, and routine. Immediate, urgent, and routine denotes 5 minutes, 15 minutes, and 30 minutes, respectively.
- Make sure that emergency team and the blood bank staff know:
  - Who is going to bring the blood to the patient (e.g., General duty assistant at authors' institute)
  - Where the patient will be: Example, emergency room, operating theatre, and delivery room
- The blood bank may send group O (and possibly RhD negative) blood, especially if there is any risk of errors in patient identification. During an acute emergency, this may be the safest way to avoid a serious mismatched transfusion.

Responsibility of Blood Bank (Issuing Blood in Emergency)

In critical patients, the emergency physician may ask for O negative or group-specific uncross-matched blood. In such situations, the request may contain a signed statement from the emergency medical team indicating that clinical status of patient is too critical to wait for completion of pretransfusion compatibility testing. However, signed statement is not necessary before an immediate/urgent transfusion and does not preclude blood bank to issue blood in emergency. Every hospital needs to have a written emergency protocol. The emergency protocol at authors' institute is as follows.

Emergency Protocol

Blood bank should keep aside at least two O negative units for any exigency. Turnaround time (TAT)-based approach is suggested which matches the degree of urgency in transfusing blood components to a patient in an emergency setting. It has been divided in three categories: immediate, urgent, and routine.

Immediate Transfusion (TAT-5 Minutes)

- Issue uncross-matched group O red blood cells (RBCs) if the patient's blood group is unknown.
- Use RhD negative blood if the recipient's Rh status is unknown, especially if the patient is female (in childbearing age group).

Urgent Transfusion (TAT-15 Minutes)

Issue group-specific uncross-matched if the patient's blood group is known or can be typed, quickly.

Routine Transfusion (TAT-30 Minutes)

Issue group-specific cross-match compatible blood.

When blood is requested in emergency, blood bank should take the following steps:

- Document on the unit as "Uncross-matched" or "Compatibility testing not completed" at the time of issue of unit in the immediate and urgent protocol.
- Complete the compatibility tests promptly, even after issue. If any incompatibility is detected during the completion of compatibility tests, the emergency medical team should be notified and blood transfusion should be stopped.
- O RhD negative units should be issued only in emergency situations where the recipient blood group is unknown at the time of transfusion, up to two units; thereafter group-specific blood unit to be issued (as the patient should have had their blood group tested by this time). This is important to conserve precious O RhD negative inventory.

Blood Check at Administration

Final administration check of the blood unit must be done by trained and competent emergency physician or her/his trained team member. All patients receiving transfusion must be positively identified by last name, first name, and unique identification number and must match the details on blood component label and document(s). All blood components should be administered using standard blood administration set with an integral mesh filter (170–200 μ).

TRANSFUSION APPROACH AND MASSIVE TRANSFUSION PROTOCOL

Trauma patients generally present with varying grades of hemorrhage and shock. The approach with respect to blood component transfusion to such patients can only be understood if we understand various classes of hemorrhage which have been classified as follows:

- *Class I hemorrhage*: Blood volume loss of up to 15%. The heart rate is minimally elevated or normal, and there is no change in blood pressure, pulse pressure, or respiratory rate.
- *Class II hemorrhage*: There is a 15–30% blood volume loss and is manifested clinically as tachycardia (heart rate of 100–120 beats/min), tachypnea (respiratory rate of 20–24 breaths/min), and a decreased pulse pressure, although systolic blood pressure changes minimally if at all. The skin may be cool and clammy, and capillary refill may be delayed.
- *Class III/IV hemorrhage*: It involves a 30–40%/>40% blood volume loss, resulting in a significant drop in blood pressure and at times even changes in mental status.

While no treatment is necessary in Class I, Class II requires crystalloids; e.g., Ringer's lactate solution, which rapidly distributes between the intra- and extravascular spaces. Volume of crystalloid needed to restore intravascular volume is three times the estimated blood loss. Blood components are required only in Class III and Class IV hemorrhages. Earlier there was a traditional approach to give crystalloids and RBCs and transfuse fresh frozen plasma (FFP) only when >5–10 RBC units were transfused. However, this approach has given way to a newer approach described below.

Newer Approach—Transfusion for Severe Ongoing Hemorrhage (Class III/IV)

If the bleeding in trauma patients is unlikely or difficult to be controlled quickly, immediate transfusion of blood components in a 1:1:1 ratio of RBC, FFP, and platelets should be considered. In simple terms, if the emergency team recognizes that the patient will require four or more units of RBCs in 1 hour (or >10 units in 12–24 h), they should start transfusing four unit of RBCs, four units of FFP, and six units of random donor platelets (RDP) [or one unit of single-donor apheresis platelets (SDP) as one unit of SDP (also called apheresis platelets) is equivalent to six units of RDP]. Hypothermia must be controlled during transfusions with the help of inline warmers.

Studies supporting newer approach of 1:1:1 blood component transfusion are as follows:

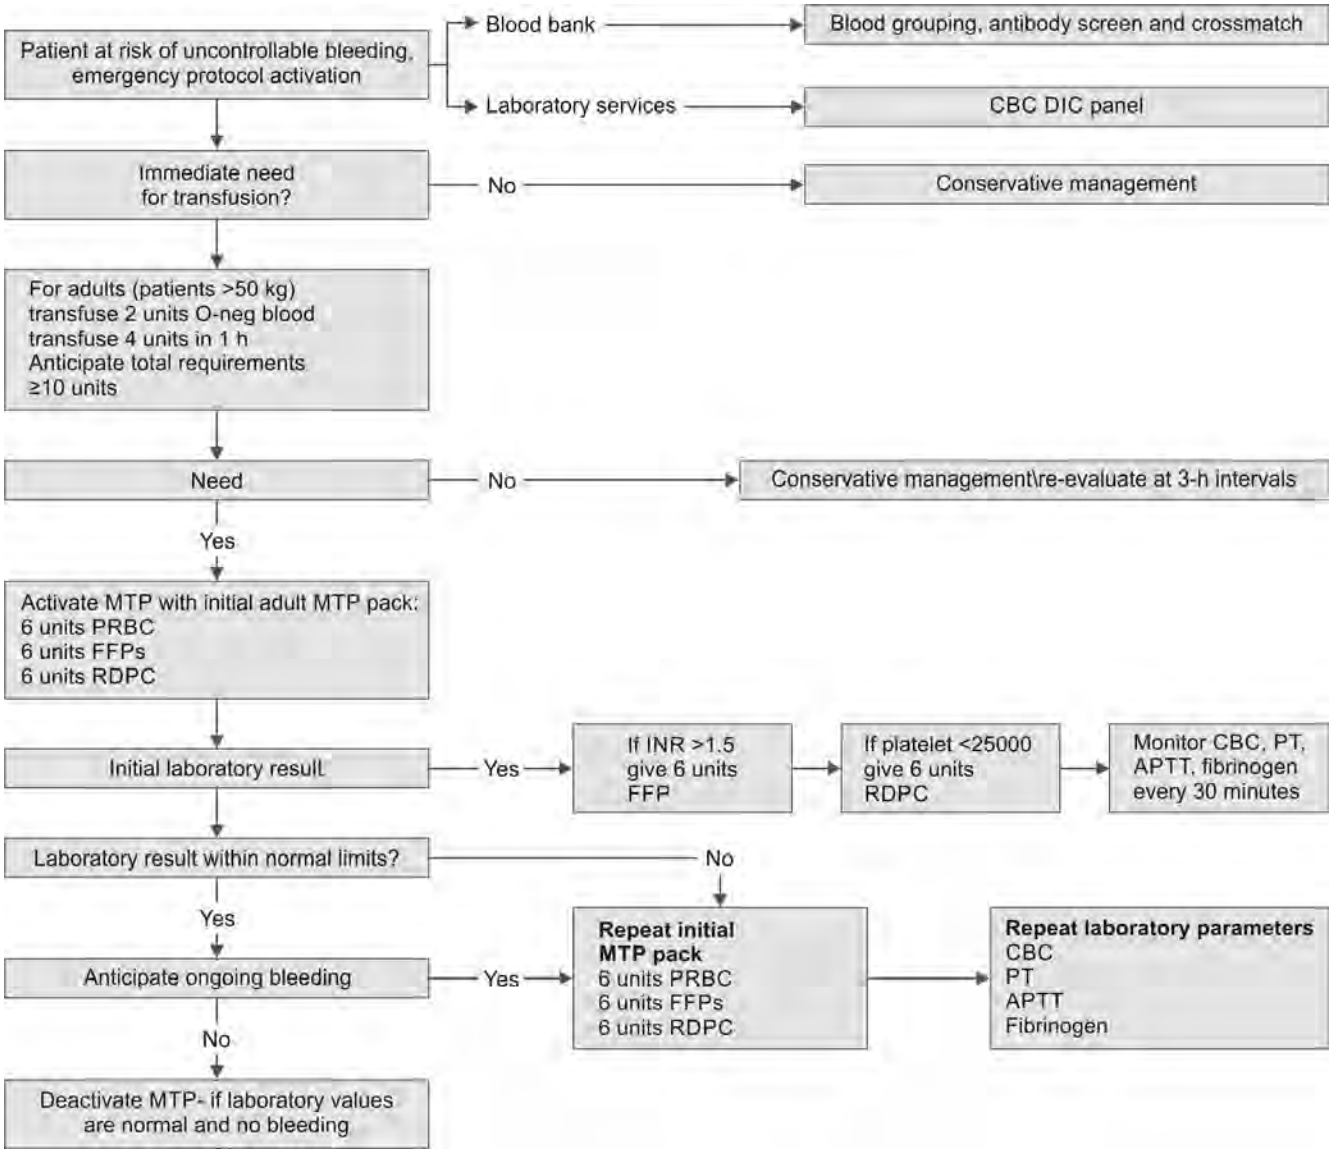
- A trial that randomly assigned 680 patients with major bleeding from severe trauma to receive transfusion of one unit versus two units of RBC for every unit of FFP and platelets (i.e., FFP to platelets to RBC of 1:1:1 vs. 1:1:2) found slightly better outcomes with the 1:1:1 approach. Patients assigned to 1:1:1 were more likely to have adequate hemostasis (86 vs. 78%) and had fewer exsanguination deaths at 24 hours (9 vs. 15%). Overall mortality at 1 day and 30 days were not different between the groups, although there was a trend favoring 1:1:1 at both time points. Adverse events were also similar between the groups.

- A retrospective study of 246 patients who presented to an army combat support hospital in Iraq has produced some data to evaluate the merits of this regimen. When patients who received massive transfusion were stratified by transfusion therapy regimen, patients who received a high ratio of FFP to RBCs (median of 1:1.4) had a survival rate of 81%, compared with 66% for those with an intermediate ratio (median 1:2.5) and 35% for those who received a low ratio of FFP to RBCs (median of 1:8).
- In a retrospective study of 467 massively transfused trauma patients, 30-day survival was increased in patients transfused at a high FFP:RBC ratio (i.e., ≥1:2) as well as in those transfused at a high platelet:RBC ratio (i.e., ≥1:2). The combination of high FFP and high platelet to RBC ratios was associated with decreased truncal hemorrhage and increased 6-hour, 24-hour, and 30-day survivals, with no change in deaths due to multiple organ failure.
- In a retrospective study of 694 massively transfused trauma patients who did not receive fresh whole blood, those receiving a high ratio of apheresis platelets (equivalent to six units of RDP) per stored RBC unit (i.e., ratio ≥1:8) had a higher 24-hour survival (95%) compared with those receiving a medium (i.e., ratio 1:16 to 1:8, 87%) or a low ratio (i.e., <1:16, 64% percent) [6]. On multivariate analysis, higher FFP:RBC ratios and higher SDP:RBC ratios were both independently associated with improved survival at both 24 hours and 30 days.

Massive transfusion protocol should be in place in every hospital and this protocol should be activated as soon as the emergency team recognizes the presence or likelihood of severe, ongoing hemorrhage. One example of MTP followed at authors' institute adapted from publication in journal of American College of Surgeons is shown in **Flowchart 1**.

ROLE OF SPECIFIC BLOOD COMPONENTS

The decision to transfuse the blood components should not depend only on transfusion triggers but should depend



(APTT: activated partial thromboplastin time; CBC: complete blood count; DIC: disseminated intravascular coagulation; FFPs: fresh frozen plasmas; INR: international normalized ratio; MTP: massive transfusion protocol; PRBC: packed red blood cell; PT: prothrombin time; RDPC; random donor platelet concentrate)

FLOWCHART 1: Massive blood transfusion protocol.

on clinical condition of patient, rate of ongoing bleeding, cardiopulmonary status, and operative intervention. The ultimate goal of blood component transfusion is to restore volume and oxygen-carrying capacity. Role of whole blood and different blood components in emergency situation are summarized in **Table 1** and described in the text below.

Transfusion of Whole Blood

Whole blood has high levels of potassium, ammonia, and hydrogen ions and has no clotting factors. With the advent of blood component therapy, the use of whole blood has become obsolete. Although it provides volume expansion along with increased oxygen-carrying capacity, it may cause volume overload and dilutional coagulopathy in patients.

Transfusion of Red Blood Cells

Red cell transfusion always remains an important unanswered question and often depends on clinical circumstances. In trauma patients if hemodynamics does not improve after administration of 2–3 L of crystalloid, two units of RBCs should be transfused. Further transfusions will depend on response to the initial transfusion.

Anti-human globulin (AHG) cross-matched compatible with antibody screen negative RBCs are best, but take considerable time. If the patient's condition warrants, emergency physician can transfuse immediately using type O RhD positive or type O RhD negative for males and type O Rh negative for girls and women of childbearing age, until group-specific uncross-matched or group-specific cross-matched blood is available.

- ABO-patients with blood type B or A may receive O RBC while type AB recipients can receive A or B RBCs. Patient should be switched back to original ABO type if blood bank inventory permits, and the patient is stable with bleeding stopped. This is important as the type B patient (or A patient) who received type O RBC, do not get too much passively transferred anti-B (or anti-A) from the donors.
- Rh negative individual may be switched to Rh positive RBCs, but should be avoided in women of childbearing potential. It can be done if RhD negative patient is likely to receive massive RBC transfusion that will deplete the existing ABO compatible and ABO inventory. Rh immunoglobulins (RhIg) prophylaxis can be given to prevent anti-D formation in childbearing females following Rh incompatible transfusion.

Transfusion of Clotting Factors: Fresh Frozen Plasma, Cryoprecipitate, and Platelets

Transfusion of intravenous crystalloid and RBC in hemorrhage increases the risk of coagulopathy due to dilution of clotting factors and platelets and also due to hypothermia. For bleeding patients (>4 units of RBCs transfused in the first few hours or chest tube continues to drain >200 mL of blood per hour) we suggest using 1:1:1 ratio approach of RBC, FFP, and RDP. This means 1 RBC:4 FFPs:6 RDP for an adult patient. If SDP is used; one SDP unit would be equivalent to six units of RDP.

When to transfuse cryoprecipitate will depend on assessment of fibrinogen levels. Fibrinogen concentration below 100 mg/dL is generally treated with 10 units of cryoprecipitate (each unit of cryoprecipitate raises the fibrinogen level by about 5 mg/dL).

TABLE 1: Use of specific blood components.

Component	*Shelf life*	*Storage condition*	*Approximate volume per unit*	*Dose*	*Trigger/indication for transfusion*	*Effect*
Red blood cell (RBC)	21–42 days (longer shelf life if suspended in additive solution)	2–8°C	• 250 mL ± 10% from 450 mL bag • 150 mL ± 10% from 350 mL bag	• 5 mL/kg (child) • 3–5 mL/kg (adult)	Hemoglobin (Hb) <8 g/dL	Raises hemoglobin by 1 g% or hematocrit by 3%
Random donor platelets (RDP)	5 days	20–24°C on flat agitator	50–70 mL	1 unit per 10 kg body weight 6 units (adult)	Platelet <20,000/μL	Raises platelet count by 30,000–50,000/mm^3, but less in many cases
Apheresis or single donor platelet (SDP)	5 days	20–24°C on flat agitator	250–350 mL	1 unit per adult	Platelet <20,000/μL	Raises platelet count by 30,000–50,000/mm^3, but less in many cases
Fresh frozen plasma (FFP)	1 year	<–30°C	• 180–220 mL from 350 mL bag • 220–300 mL from 450 mL bag	10–15 mL FFP/kg (all patients)	Used for coagulation factor replacement	Raises most coagulation factors by 25%
Cryoprecipitate	1 year	<–30°C	15–20 mL	1 unit per 5 kg 10 units (adult)	Used for replacement of fibrinogen, FXIII, FVIII, or von Willebrand factor (vWF)	Raises fibrinogen level by 50–100 mg%

Fresh frozen plasma can be transfused irrespective of Rh status of blood component, for example, A positive can be safely transfused to A negative recipient. If ABO blood group compatible FFPs are not available, use "universal plasma", group AB plasma.

Thawed plasma can be kept at 4°C for 24 hours. This plasma has decreased levels of labile factors such as FVIII and FV, but other factor levels are sufficient. It saves time in urgent transfusion settings.

Cryoprecipitate can be safely transfused across the ABO and Rh blood groups. Thawed plasma is a good alternative in emergency transfusion.

Platelets (RDP) can be safely transfused across the ABO and Rh blood group. While in apheresis transfusing O platelets to non-O blood group recipient has to be done cautiously since they may contain high titer iso-agglutinins. In such cases, it is a good idea to remove plasma to reduce transfer of iso-agglutinins.

ADVERSE EFFECT OF BLOOD TRANSFUSION

Blood transfusion can be associated with various adverse effects. These adverse effects can be either acute and arise during or shortly after the transfusion or delayed that may present after few days to months or years. Therefore, decision to transfuse blood must be based on a careful assessment of the risks and benefits to the patient, and with the knowledge and skills to recognize and treat any adverse reactions or complications that may arise. Transfusion reactions can be classified in (**Table 2**) simple categories (acute and delayed) in order to help you to recognize them, understand their underlying causes and when they may occur, and know how to prevent, manage, and record them.

Acute Complications of Blood Transfusion

Acute transfusion reactions occur during or shortly after (within 24 h) the transfusion. The WHO has broadly categorized acute transfusion reactions according to their severity and the appropriate clinical response: mild, moderate-to-severe, and life-threatening transfusion reactions.

- *Category 1: Mild reactions*
  - Mild hypersensitivity: Allergic and urticarial reactions
- *Category 2: Moderate-to-severe reactions*
  - Moderate-to-severe hypersensitivity (severe urticarial reactions)
  - Febrile nonhemolytic reactions: Antibodies to white cell or platelet antigens; antibodies to proteins, including immunoglobulin A (IgA)
- *Category 3: Life-threatening reactions*
  - Acute intravascular hemolysis
  - Bacterial contamination and septic shock
  - Fluid overload
  - Anaphylactic reactions
  - Transfusion-associated acute lung injury (TRALI)
  - Transfusion-associated circulatory overload (TACO)

Delayed Complications of Transfusion

Delayed transfusion reaction occurs days to month even years after transfusion. As with acute transfusion reactions, the consequence may be severe but often treatable. Delayed reactions can be classified into following types:

- Transfusion-transmitted infections
- Alloimmunization [against red cell or human leukocyte antigen (HLA)]
- Delayed hemolytic reaction
- Post-transfusion purpura
- Graft-versus-host disease
- Iron overload (in patients who receive repeated transfusions)

Management of Adverse Transfusion Reaction

When an acute reaction first occurs, it may be difficult to decide on its type and severity as the signs and symptoms may not initially be specific or diagnostic. However, with the exception of allergic urticarial and febrile nonhemolytic reactions, adverse reactions are potentially fatal and require urgent treatment. It is essential to monitor the transfused patient closely in order to detect the earliest clinical evidence of an acute transfusion reaction. In an unconscious or anaesthetized patient, hypotension and uncontrolled bleeding may be the only signs of an incompatible transfusion. In a conscious

TABLE 2: Guidelines for recognition of adverse transfusion reaction.

Category	*Symptoms*	*Signs*	*Possible cause*
Category 1 (mild)	Pruritus (itching)	Localized cutaneous reactions—urticaria and rash	Hypersensitivity/allergic (mild)
Category 2 (moderate-to-severe)	Anxiety; pruritus; palpitation; mild dyspnea; and headache	Flushing; urticaria; rigors; fever; restlessness; and tachycardia	• Hypersensitivity/allergic (moderate-to-severe) • Febrile nonhemolytic reaction • Possible contamination with pyrogen/bacteria
Category 3 (life-threatening)	Anxiety; chest pain; pain near infusion site; respiratory distress; pain in loin/back; headache; and dyspnea	Rigors; fever; restlessness; hypotension (>20% fall in systolic BP); tachycardia (>20% rise in heart rate); hemoglobinuria (red urine); and unexplained bleeding (DIC)	• Acute intravascular hemolysis • Bacterial contamination/septic shock • Anaphylaxis • TRALI • TACO

(BP: blood pressure; DIC: disseminated intravascular coagulation; TACO: transfusion-associated circulatory overload; TRALI: transfusion-associated acute lung injury)

patient undergoing a severe hemolytic transfusion reaction, signs and symptoms may appear very quickly—within minutes of infusing only 5–10 mL of blood. Close observation at the start of the infusion of each unit is essential. If an acute transfusion reaction is suspected, stop the transfusion immediately. Check the blood unit labels and the patient's identity. If there is any discrepancy, consult the blood bank. Management steps for blood transfusion reaction are summarized in **Box 1**.

HEMOVIGILANCE (HEMOVIGILANCE PROGRAM OF INDIA)

On December 10, 2012, a centralized hemovigilance program was launched in India. Hemovigilance Program of India (HvPI) was planned jointly by Indian Pharmacopoeia Commission (IPC) and the National Institute of Biologicals (NIB), Noida. The program was launched to assure patient safety and promote public health through a well-structured program for monitoring of adverse transfusion reactions associated with blood and blood products. The Transfusion Reaction Reporting Form (TRRF), guidance document, standardized definitions of transfusion reactions, and the Haemo-Vigil software for online reporting of transfusion reactions were approved. The key objectives outlined in the HvPI are:

- Monitor transfusion reactions,
- Create awareness among healthcare professionals,
- Generate evidence-based recommendations,
- Advise the Central Drugs Standard Control Organization (CDSCO) for safety-related regulatory decisions,
- Communicate findings to all key stakeholders, and
- Create national and international linkages.

BOX 1: Guidelines for management of acute transfusion reaction.

Category 1: Mild

- Slow the transfusion
- Administer antihistamine IM (e.g., chlorpheniramine 0.1 mg/kg or equivalent)
- If no clinical improvement within 30 min or if signs and symptoms worsen, treat as Category 2

Category 2: Moderate-to-severe

- Stop the transfusion. Replace the infusion set and keep IV line open with normal saline
- Notify the doctor responsible for the patient and the blood bank immediately
- Send blood unit with infusion set, freshly collected urine and new blood samples (one clotted and one anticoagulated) from vein opposite infusion site with appropriate request form to blood bank and laboratory for investigations
- Administer antihistamine IM (e.g., chlorpheniramine 0.1 mg/kg or equivalent) and oral or rectal antipyretic (e.g., paracetamol 10 mg/kg: 500 mg to 1 g in adults). Avoid aspirin in thrombocytopenic patients
- Give IV corticosteroids and bronchodilators if there are anaphylactoid features (e.g., bronchospasm and stridor)
- Collect urine for next 24 h for evidence of hemolysis and send to laboratory
- If clinical improvement, restart transfusion slowly with new blood unit and observe carefully
- If no clinical improvement within 15 min or if signs and symptoms worsen, treat as Category 3

Category 3: Life-threatening

- Stop the transfusion. Replace the infusion set and keep IV line open with normal saline
- Infuse normal saline (initially 20–30 mL/kg) to maintain systolic BP. If hypotensive, give over 5 min and elevate patient's legs
- Maintain airway and give high flow oxygen by mask
- Give adrenaline (as 1:1,000 solution) 0.01 mg/kg body weight by slow intramuscular injection
- Give IV corticosteroids and bronchodilators, if there are anaphylactoid features (e.g., bronchospasm and stridor)
- Give diuretic: e.g., furosemide 1 mg/kg IV or equivalent
- Notify the doctor responsible for the patient and the blood bank immediately
- Send blood unit with infusion set, fresh urine sample and new blood samples (one clotted and one anticoagulated) from vein opposite infusion site with appropriate request form to blood bank and laboratory for investigations
- Check a fresh urine specimen visually for signs of hemoglobinuria (red or pink urine)
- Start a 24-h urine collection and fluid balance chart and record all intake and output. Maintain fluid balance
- Assess for bleeding from puncture sites or wounds. If there is clinical or laboratory evidence of DIC, give platelets (adult: 5–6 units) and either cryoprecipitate (adult: 12 units) or fresh frozen plasma (adult: 3 units). Use virally-inactivated plasma coagulation products, wherever possible
- Reassess. If hypotensive: Give further saline 20–30 mL/kg over 5 min; give inotrope, if available
- If urine output falling or laboratory evidence of acute renal failure (rising K^+, urea, and creatinine): Maintain fluid balance accurately. Give further furosemide. Consider dopamine infusion, if available

  Seek expert help: The patient may need renal dialysis
- If bacteremia is suspected (rigors, fever, collapse, and no evidence of a hemolytic reaction), start broad-spectrum antibiotics IV to cover pseudomonas and gram positives

(BP: blood pressure; DIC: disseminated intravascular coagulation; IM: intramuscular; IV: intravenous)

Awareness about the hemovigilance program and its objectives was generated through hemovigilance newsletters, scientific publications, and organizations of continuing medical education (CME) programs across the country. Reporting under HvPI is voluntary. There has been a gradual increase in blood center enrolment with HvPI since its inception, and till year 2018, 716 out of 2,903 licensed blood banks (24.6%) were enrolled. Overall risk of adverse reactions, according to HvPI data, is 1 in 1,000 or 8.4 per 10,000 blood component transfusions.

SUMMARY

Safe and effective replacement of blood or one of its components in critically ill anemic or bleeding patients is main goal of transfusion therapy. The indications for transfusions in emergency department and intensive care unit should be clearly mentioned in their manual, and only the required blood components are replaced using appropriate dosages. In view of limited resources of blood products they should be given only when indicated, using the minimal dosage required and after carefully considering possible alternatives. The indications and efficacy of transfusing platelets, leukocytes, and other plasma proteins are limited although red blood cells and plasma clotting factors are crucial. By prior compatibility testing acute hemolytic transfusion reactions can be avoided; other transfusion reactions cannot be predicted by compatibility testing. By using appropriate clinical and laboratory parameters, the effectiveness and survival of transfused blood cells and plasma proteins should be monitored during and after transfusion.

145
CHAPTER

Therapeutic Plasmapheresis

Rahul Solanki, Devendra Richhariya

INTRODUCTION

Plasmapheresis, which literally means withdrawal or removal of plasma, is a procedure in which plasma is separated from the blood cells and when is replaced with fresh frozen plasma, a blood product or a plasma substitute (colloid or crystalloid such as albumin) is termed as plasma exchange. The replacement solution used depends on the severity and type of disease, tolerability of the patient, and some other factors. Saline is relatively safe for small volume exchange or even in larger quantities. The plasma protein fraction (PPF) is superior to fresh frozen plasma. The PPF is free of the risk of hepatitis. When added with albumin but supplementation with calcium and potassium is necessary as their content is low in it. A vasoactive substance bradykinin is present in PPF, which may cause severe adverse reactions. Dextran may be used for volume replacement; these solutions reduce platelets aggregation thus help in reduced clot formation. Up to 1,000 mL of this solution is usually well tolerated. Anticoagulant used in centrifugation technique is citrate while heparin is used in membrane filtration technique. Plasmapheresis is a method of treating number of diseases of frequently uncertain etiology and poorly understood pathogenesis for which there is no adequate therapy. Removal of some toxic substances or auto antibodies accumulated in the plasma can have therapeutic effect.

HISTORY

Hendon (1902s) was the first to conduct research on the therapy method of hemapheresis by withdrawing blood from animals to be washed and reinjected. Fleig (1909) after Hendon used this method for the treatment of human uremia. Abel et al. (1914) have explained the removal of plasma technique through the treatment of poisoned dogs whose kidneys had been removed. At the end of 1940s and early 1950s, simultaneously the appearance of plastic advanced blood bag and advanced refrigerated centrifuge, hemapheresis was used more broadly as a treatment method. In 1950s, Dr Edwin Cohn had established the using a continuous flow centrifuge with >60 years since it was invented by De Laval for use in the dairy industry to prepare blood products and improve the effectiveness of a therapeutic plasmapheresis during the Second World War. In 1962, Judson provided a device for separation of leukocytes from the whole blood, device consists of disposable plastic tubes that were sterile previously, and worked with a steady stream of closed system and it was the first device that enables functionality to provide the processing of large volumes of blood. This device is capable of exchanging plasma, collecting platelets, granulocytes, lymphocytes, and erythrocytes. In 1988, Cobe Company began selling a new device as SPECTRA. This type of devices is automatically equipped with computer systems that can platelet aphaeresis with minimal contamination of white blood cell. Moreover, SPECTRA have been moving for medical procedures affairs that are easily transferred to the patient's room. Subsequent development of the basic principles established by the people, eventually leading to the construction of several kinds of semiautomatic separation devices for clinical applications in blood that the wider use of plasmapheresis was followed as a method of treatment. Continuation of this trend depends on the development of consumer devices and software whatever needs to be more selective separation of blood components, and other ingredients can be returned to the donor or patient. Plasmapheresis was divided generally into two groups; plasma products by donor plasmapheresis and therapeutic plasmapheresis.

INDICATIONS

Autoimmunity is a condition in which the body produces an immune response against its own tissue constituents. It is most commonly treated with medications that suppress the immune system. Immunosuppressive drugs are like a double-edged sword, though they are most beneficial in autoimmune disease, they bring a series of adverse reactions which sometimes may become intolerable to the patient. The demand for a procedure that would cut out the adverse effects of immunosuppressants and at the same time treats autoimmune diseases. Apheresis is derived from the Greek, meaning "withdrawal". After the blood is withdrawn from the body, the blood components can be separated by either filtration or centrifugation. Filtration systems allow plasma removal (plasmapheresis) with retention of blood cells. Centrifugal systems are more versatile,

allowing plasmapheresis or selective removal of cell types (e.g., plateletpheresis). The plasma exchange involves removal of plasma and replacement of it with various fluids, whereas plasmapheresis involves only the removal of plasma.

Plasmapheresis has been used with good effect in the following disease: Myasthenia gravis, thrombocytopenic purpura, Guillain–Barré syndrome, rheumatoid arthritis, insulin-dependent diabetes mellitus, pemphigus vulgaris, bullous pemphigoid, systemic lupus erythematosus, erythema multiforme, psoriasis, multiple myeloma, hypercholesterolemia, severe sepsis and shock, and neuromyelitis of the eye. The appropriate use of therapeutic plasma exchange is based on two societies (**Tables 1** and **2**), i.e., American Association of Blood Banks (AABB) and American Society for Apheresis (ASFA).

TECHNIQUES

Techniques used in plasmapheresis are centrifugation technique and membrane filtration technique (**Figs. 1** and **2**).

Centrifugation Techniques

This technique includes continuous flow technique and intermittent flow technique.

Continuous Flow Technique

In this technique, the withdrawal of blood is fed continuously into a rapidly rotating bowl in which red cells, leukocytes, plasma, and platelets are separated in to different layers. Any of these layers are removed and the remainder is returned to the patient with the replacement fluid. The advantage of this procedure is that it is faster and completely automated. But it requires the use of a dual lumen catheter and the equipment is immobile. It is an expensive technique. The anticoagulant used in this technique is citrate.

Intermittent Technique

In this technique, blood is drawn in successive batches and separated. This cycle is repeated as often as necessary to remove the desired volume of plasma (i.e., 1–1.5 plasma volume). The equipment is portable unlike that in the continuous flow technique and a single needle peripheral venous puncture is sufficient. The limitations of this technique include the time taken, i.e., it takes >4 hours for one cycle and a large extracorporeal blood volume is required (>225 mL).

Membrane Filtration Technique

This technique is used as an alternative to centrifugation technique. The patient's blood is pumped through a parallel plate or hollow fiber filter at a continuous flow rate (50–200 mL/min). The membranes have pores of 0.2–0.6 μm diameter which is sufficient to allow passage of plasma while retaining cells. Plasma is thus collected and separated from the blood. The average time required for membrane filtration is <3 hours. In general, the plasma can be removed at a rate of 30–50 mL/min. Unlike the intermittent technique, a large vein catheter is required. The anticoagulant used in this technique is heparin.

TABLE 1: Indications of therapeutic plasmapheresis (ASFA and AABB classification) in neurologic diseases.

Disease	*Indication category*
• Guillain–Barré syndrome • Chronic inflammatory demyelinating • Polyradiculoneuropathy • Polyneuropathy with IgG/IgA monoclonal protein • Polyneuropathy with IgM monoclonal protein	I
• Stiff-person syndrome • Idiopathic inflammatory demyelinating disease • Sydenham's chorea • PANDAS	II
• Myasthenia gravis • Lambert–Eaton myasthenia syndrome • Paraneoplastic neurologic syndrome • Multiple sclerosis • Refsum's disease • Rasmussen's encephalitis	III
Polymyositis or dermatomyositis	IV

(AABB: American Association of Blood Banks; ASFA: American Society for Apheresis; Category I: standard acceptable therapy; Category II: sufficient evidence to suggest efficacy usually as adjunctive therapy; Category III: inconclusive evidence of efficacy or uncertain risk/benefit ratio; Category IV: lack of efficacy in controlled trials; IgA: immunoglobulin A; IgG: immunoglobulin G; IgM: immunoglobulin M; PANDAS: pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections)

TABLE 2: Indications of therapeutic plasmapheresis therapy (ASFA and AABB classification) in blood disease and dysproteinemia.

Disease	*Indication category*
• Post-transfusion purpura • Thrombocytopenic purpura	I
• ABO-incompatible marrow transplant • Coagulation factor inhibitors • Cryoglobulinemia • Hyperviscosity/multiple myeloma • Immune thrombocytopenia purpura	II
• Aplastic anemia • Autoimmune hemolytic anemia • Hemolytic uremic syndrome • Platelet alloimmunization • Pure red cell aplasia • Red cell alloimmunization	III

(AABB: American Association of Blood Banks; ASFA: American Society for Apheresis; Category I: standard acceptable therapy; Category II: sufficient evidence to suggest efficacy usually as adjunctive therapy; Category III: inconclusive evidence of efficacy or uncertain risk/benefit ratio; Category IV: lack of efficacy in controlled trials)

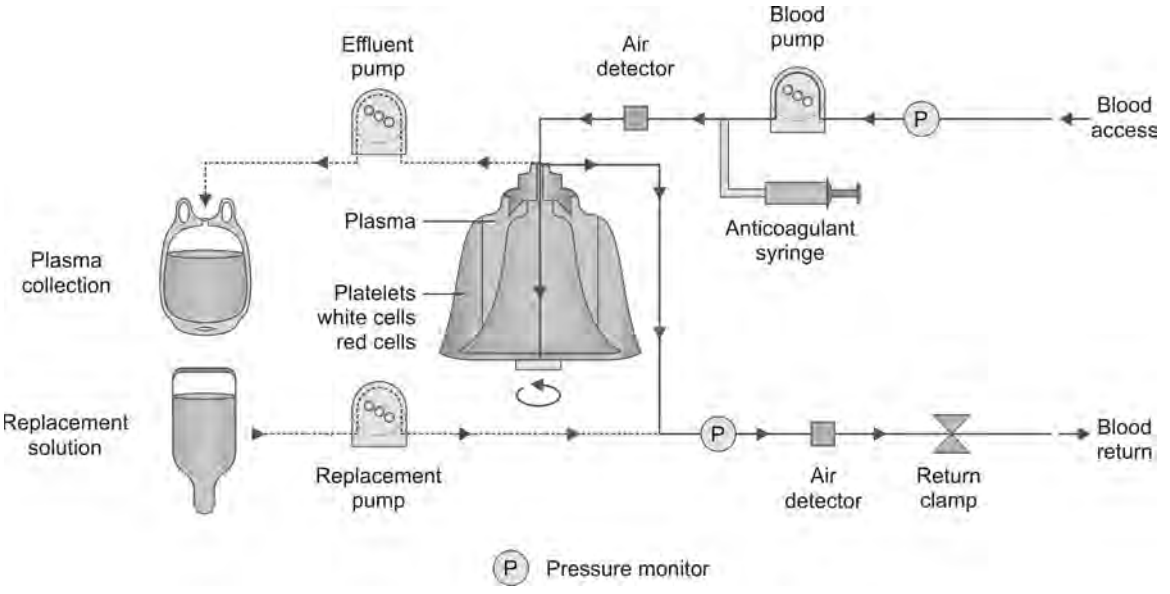

FIG. 1: Centrifugation technique.

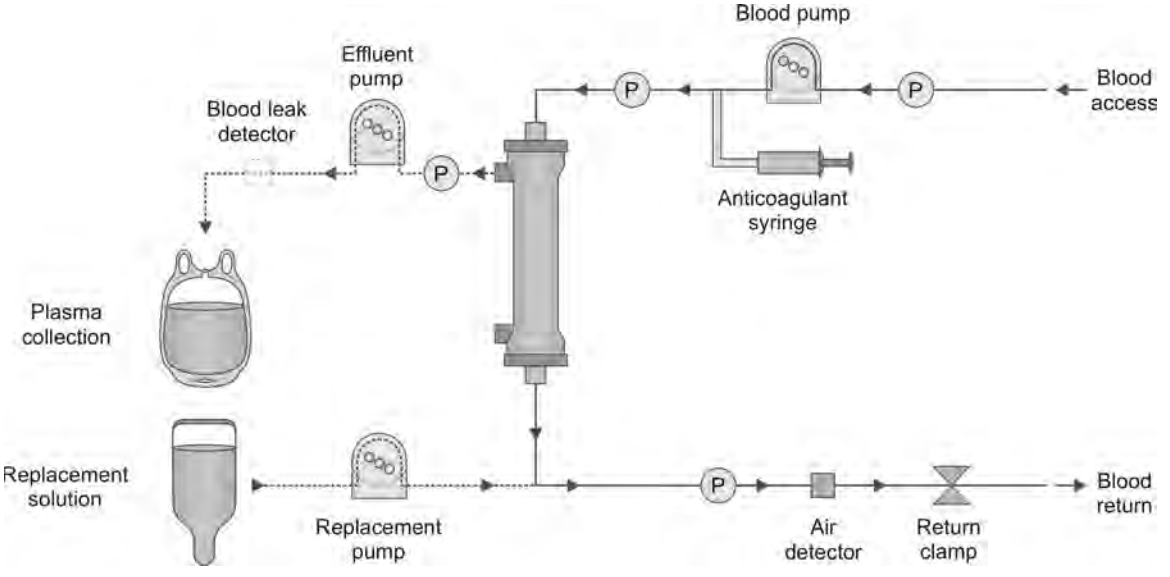

FIG. 2: Membrane filtration technique.

Patient Preparation

The patient should be asked to avoid caffeine-containing liquids 24 hours before the treatment due to their diuretic action. A balanced diet should be given before treatment. Patient should empty the bladder prior to the procedure. Comfortable clothing with loose fitting sleeves that pull easily above the elbow will make it easier to place the needle in each arm.

Procedure

A needle is inserted in to a vein in each arm; patient has to stabilize his arm during insertion of the needle. Blood is taken from one arm and circulated through cell separators following one of the previously mentioned techniques. To replace the plasma that is removed, a plasma substitute is given with returned blood cells (**Table 3**). The treatment takes several hours and it can be done on outpatient basis. The number of times the treatment is needed varies greatly depending on the disease and person's general condition (**Table 4**). An average course of plasmapheresis is 6–10 treatments over 2–10 weeks. Most patients begin to improve with in the first few days of the treatment. Patients who have received three to four exchanges over a week would remain healthy for 1–2 months.

COMPLICATIONS

The complications which may occur during or after the procedure include a drop in blood pressure, bleeding due to the use of anticoagulants, risk of infection due to placement of central venous catheter, allergic reaction to the solution, and temporary suppression of the immune system. Most of the complications are reversible and there is no major effect on vital organs.

TABLE 3: Advantages and disadvantages of any replacement fluids in therapeutic plasma exchange.

Replacement fluid	*Advantages*	*Disadvantages*
Crystalloids	• Low cost • Hypoallergenic • No viral risk	• 2–3 volumes required • Hypooncotic • No coagulation factors • No immunoglobulins
Albumin	• Iso-oncotic • No contaminating "inflammatory mediators" • No viral risk	• High cost • No coagulation factors • No immunoglobulins
Hydroxyethyl starch (HES)	• Moderate cost • Iso-oncotic • No contaminating "inflammatory mediators"	• No coagulation factors • Long-term residual levels of HES contraindicated with renal failure • Possible coagulopathy
Plasma	Maintain normal levels of immunoglobulins, complement antithrombin and other proteins	• Viral transmission risk • Citrate load • ABO incompatibility risk • Allergic reaction • Sensitization

TABLE 4: The final target of plasmapheresis therapy.

Substance to removed	*Treatment volume (mL/kg)*	*Treatment interval (hours)*	*Treatment endpoint*
Autoantibodies	40–60	24–48	Four to six treatment
Immune complexes	40–60	24–48	Treat till response
Paraproteins	40–60	24	Treat till response
Toxins	40–60	24–72	Treat till response
TTP/HUS	40	24	Treat till remission
Immunologic rebound	40–60	24–48	Two to three treatment followed by immunosuppressive medication

(HUS: hemolytic uremic syndrome; TTP: thrombotic thrombocytopenic purpura)

SUMMARY

Plasmapheresis is a valuable treatment in patients with autoimmune diseases in which all other treatment modalities have failed. Hence, it can be employed as a treatment of choice in certain autoimmune diseases involving the oral cavity in which the adverse effects of other treatment modalities outweigh the therapeutic effects. This area holds scope for further studies and trials thereby providing patients with untreatable diseases a new treatment modality with fewer side effects and faster recoveries.

146 CHAPTER

Sickle Cell Disease

Devendra Naik

INTRODUCTION

Sickle cell disease (SCD) is an inherited blood disorder which is more commonly seen among people of African, Arabian, and Indian origin. SCD occurs in heterozygous form in about 8% of American blacks and in homozygous form in 1 in 400. The disease is largely not documented in India. The sickle hemoglobin (Hb) was first described in India in the tribals of Nilgiri hills in 1952. Emergency physicians need to be familiar with SCD and its complications as this can be one of the most common causes of emergency department (ED) visits.

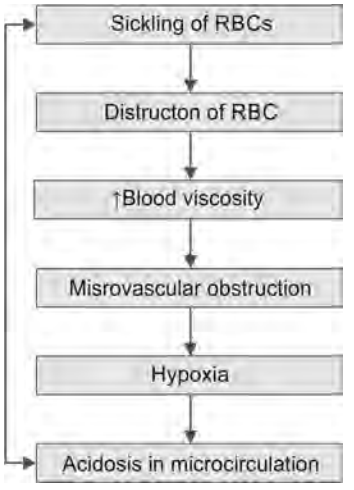
PATHOPHYSIOLOGY

The characteristic in SCD is red blood cells (RBCs) containing at least one abnormal Hb, hemoglobin S (HbS). The normal adult Hb (HbA) consists of a pair of alpha and beta chains. The Hb of sickle cell anemia (HbSS) consists of a pair of alpha chains and a pair of sickle beta chains whereas Hb of sickle cell trait (HbS) consists of a pair of alpha chains, one normal beta chain and one sickle beta chain.

The abnormal HbS results from an adenine-to-thymine deoxyribonucleic acid (DNA) substitution in the beta globin chain of Hb. Donut-shaped RBCs with normal Hb are quite flexible so that they move through arterioles and capillaries. RBCs containing HbS are stiff and sickle shaped. Sickle shape of the RBC results in premature destruction of RBC (life span of about 20 days) thereby increasing the blood viscosity which leads to microvascular obstruction. Hypoxia caused by microvascular obstruction causes acidosis in the microcirculation. This acidosis leads to further sickling (**Flowchart 1**). In the initial period, the sickling is reversible as HbS is reoxygenated. The red cell membrane will be permanently damaged due to repeated episodes of distortion and RBC remains irreversibly sickled. Many organ systems will be affected due to this chronic, ongoing hemolysis, and periods of microvascular occlusion which leads to tissue ischemia.

CLINICAL FEATURES

Sickle cell disease has been a repeated, painful, and frustrating problem for the patients. A study suggests that as many as 35% of a sickle cell population are recurrent ED visitors. SCD is characterized by *two major clinical manifestations—hemolysis and acute events of vaso-occlusions.* The hallmark and the most common reason for ED visits is *the painful vaso-occlusive crisis.* Precipitating factors are preceding infection, exposure to cold, altitude, dehydration, and trauma. Multiorgan failure is seen in a small proportion of patients with vaso-occlusive crisis. Systemic manifestations of vaso-occlusive crisis of SCD are summarized in **Table 1**.



(RBCs: red blood cells)

FLOWCHART 1: Pathophysiology of sickle cell disease.

Acute Painful Episodes

Acute pain in back and extremities is classical presentation due to vaso-occlusive crisis of SCD. Bone pain is quite common during sickle cell crisis usually involving the back and extremities. This pain would be diffuse without local signs of inflammation. Hence, if there are local signs it suggests infection. The humeral or femoral heads are most commonly affected. Managing the pain in priority basis is utmost important (**Box 1**).

Children may present with acute abdomen with acute splenic enlargement due to intrasplenic sickling and vascular obstruction. The child may be in shock. These children have increased susceptibility to infection. Most of these patients with

TABLE 1: Systemic manifestations of sickle cell disease.

Organ system	*Manifestations*
Skin	Stasis ulcers
Central nervous system	Cerebrovascular accident
Eye	Retinal hemorrhage and retinopathy
Cardiac	Congestive heart failure
Pulmonary	Pulmonary embolism, infection, and infarction
Vascular	Occlusive events at any site
Liver	Intrahepatic cholestasis, hepatic sequestration, and hepatic infarct
Gallbladder	Bilirubin gallstones due to hemolysis
Spleen	Acute sequestrations—acute abdomen
Urinary	Hematuria and urinary tract infection
Genital	Impotence, decreased fertility, and priapism
Skeletal	Bone infarcts leading to osteomyelitis and septic necrosis
Placenta	Fetal wastage
Erythrocytes	Anemia due to chronic hemolysis

BOX 1: Management of acute painful episode in sickle cell disease.

***Types of pain in sickle cell disease*:**

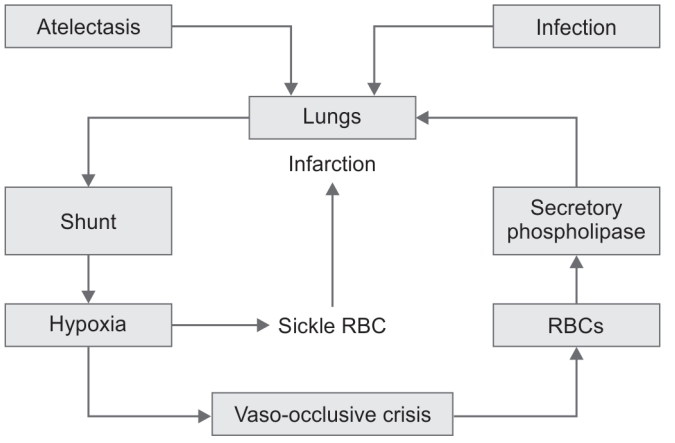
- Usually symmetric back pain and extremities pain
- Acute flare up of chronic pain—of bone and joints (chronic ulcer, osteomyelitis, and avascular necrosis of joints bone infarction)
- Neuropathic pain-burning paresthesia hyperalgesias

***Management of acute painful episodes*:**

- Triage the patient according to pain
- Opioid analgesics within 30 min, morphine 0.1 mg/kg by intravenous (IV)/oral routes avoid intramuscular route
- Adjuvant agents such as acetaminophen and nonsteroidal anti-inflammatory agents
- Other therapy; IV fluids and oxygen (in hypoxic patient, if saturation <92%)
- Laboratory—complete blood count, reticulocyte liver function test, lactate levels, and electrolytes
- Experimental therapy—steroids, nitric oxide, and possible future role of ketamine

SCD coming to ED are having a defined pain patterns. Enquiry into family history, previous pain episodes, and history of chronic anemia are very important. Adult patients commonly have a youthful appearance with long and thin extremities.

The emergency physician needs to be vigilant in differentiating uncomplicated crises from other more serious pathologic conditions. Investigations may be required to rule out other causes of acute abdomen or acute chest pains or neurological complications. The use of tissue plasminogen activator (tPA) for thrombolysis in acute nonhemorrhagic strokes is similar to acute strokes without SCD. Chronic organ system damage is common in these patients. Hence, quick review of these conditions is necessary during every ED visit. The common causes of mortality in patients with SCD are cardiopulmonary disease, chronic renal failure, acute stroke, and recurrent infections.



(RBCs: red blood cells)

FLOWCHART 2: Pathogenesis of acute chest syndrome.

Acute Chest Syndrome

It is defined as a chest X-ray (CXR) showing a new infiltrate along with one of these symptoms—fever, cough, wheezing, chest pain, or tachypnea. Acute chest syndrome (ACS) is an important cause of mortality in patients with SCD in the US. The precipitating etiology of ACS may be pulmonary infections, infarction in the ribs, pulmonary infarction, and fat emboli (**Flowchart 2**). Two most common organisms identified are *Chlamydia pneumoniae* (adults) and *Mycoplasma pneumonia* (children).

Supplemental oxygen, empirical antibiotics cephalosporin, and macrolide covering *Chlamydia* and *Mycoplasma* are initial management. Incentive spirometry and judicious use of pain control medications and IV fluids is also recommended. Improved outcomes have been reported with mechanical ventilation use. Role of anticoagulation, nitrous oxide steroid either unclear or in experimental stage can also be used. Extensive lung involvement in X-ray chest, low platelets count, and cardiac disease as comorbidity are the bad prognostic factors.

Abdominal Crisis

Constant abdominal pain is a common complaint during episodes of acute sickle cell crisis. This has to be differentiated from focal abdominal problem such as appendicitis. Jaundice and abdominal pain may be because of hepatic infarction. There may be anemia with elevated reticulocyte count, hepatomegaly, and right upper quadrant pain. Pigment-related cholelithiasis is common due to chronic hemolysis and increased bilirubin turnover. The spleen is particularly susceptible to infarction and sequestration during these vaso-occlusive episodes. The spleen might become essentially nonfunctional over time, due to microinfarction. This pushes these patients at risk for serious infections and overwhelming sepsis, especially in children.

Aplastic Crisis

These patients have a chronic hemolytic state. Aplastic crisis happens due to significant reduction in the RBC production leading to rapid drop in Hb level along with decreased reticulocytes. The Hb level will be unusually low and reticulocyte count of <0.5% (baseline Hb in SCD 6–9 g/dL and reticulocyte 5–15%). The leukocyte and platelet counts will be within normal limits. This is usually a self-limiting syndrome.

Acute Stroke

Both ischemic as well as hemorrhagic strokes are common in patients with SCD. The children with sickle cell anemia have >200 times greater risk of stroke than those without this disorder. It is unfortunate that these children are at 70–90% risk for recurrent stroke. Hence, chronic transfusion therapy is indicated in these children to prevent the recurrent strokes.

Fever and Infections

These patients are in a sort of immunocompromised state as they are functionally asplenic after their early childhood. They are susceptible to infections from *Haemophilus influenzae, Streptococcus pneumoniae, Mycoplasma pneumoniae, Salmonella typhimurium, Streptococcus aureus*, and *Escherichia coli.*

APPROACH TO SICKLE CELL DISEASE PATIENT IN EMERGENCY DEPARTMENT

Sickle cell disease patient present to ED mostly due to various complications so main challenges to emergency physician is to understand different pathophysiology. Immediate challenge is to know if any acute anemic crisis.

In Presence of Anemia

Due to increased hemolysis and RBC destruction, all patients with SCD usually are moderately anemic. A drop of 2 g/dL from baseline is considered acute. Aplastic crisis or sequestration/hemolysis need to be differentiated. Obtain the reticulocyte count. A low reticulocyte count indicates an aplastic crisis. Bone marrow production is reduced; there is a high reticulocyte count. Splenic sequestration progresses rapidly. It may manifest with left upper quadrant pain and splenomegaly and can progress to shock. These patients are critically ill. Abdominal pain is not a reliable indicator. Bedside ultrasound may be useful in assessing for splenomegaly by measuring size. This sequestration is more common in children.

Hemolysis

Hemolytic crisis will cause an elevation in lactate dehydrogenase (LDH), aspartate aminotransaminase/alanine aminotransferase, and bilirubin. This elevation will differentiate it from splenic sequestration.

In Absence of Anemia

There is presence of cardiopulmonary symptoms and ACS. Diagnostic criteria are any combination of fever, shortness of breath, hypoxia, and/or chest pain with new infiltrate on CXR.

Absence of Cardiopulmonary Symptoms—Vaso-occlusive Crisis

This condition causes ischemic pain. Bones, joints, and muscles are commonly affected. Rarely, it can cause myonecrosis. Creatine phosphokinase may be used in the appropriate setting. Ensure patients are not developing osteomyelitis, septic arthritis, avascular necrosis, or another emergent cause. Ask patients if their pain is similar or different than usual. Patients are at a higher risk for infarction because of sickling of cells. Providers must have an increased suspicion of embolic disease in patients with SCD, as they are at higher risk for: (1) stroke, (2) pulmonary thrombosis or pulmonary embolism (PE), (3) venous thromboembolism, (4) renal infarction, (5) priapism, (6) splenic infarction and chronic microvascular infarctions (often reduce or eliminate splenic function reducing immune function), and (8) hepatic infarction (may be difficult to differentiate from hepatitis or biliary disease).

MANAGEMENT

Due to availability of antenatal and neonatal screening and parental education, majority of the patients would be aware of the diagnosis. So history and clinical examination play an important role in diagnosing these conditions during the acute episodes in the ED.

Investigations

Complete blood count, reticulocyte count, LDH, serum electrolytes, renal function tests—creatinine, urea, and urine analysis, liver function tests, chest radiograph, ultrasound abdomen, blood cultures, and imaging of the brain in stroke symptoms.

General Management

Bed rest, fluids—oral or IV depending on hydration status, 5% dextrose in half normal saline, oxygen—if hypoxia present (<92%), encourage deep breathing, incentive spirometry, and hydroxyurea (10–30 mg/kg/day)—helps by increasing HbF.

Pain Management

Use analgesics as appropriate to the degree of pain, paracetamol, oral or IV for mild pain, nonsteroidal anti-inflammatory drugs (NSAIDs) for moderate pain (if no renal insufficiency), opioids for moderate-to-severe pain—titrated doses (morphine 0.1 mg/kg every 15–30 min), and intranasal fentanyl 2 μg/kg, especially in children.

Adjuvant Therapy

Antibiotics—empirical broad-spectrum antibiotics, blood transfusion—exchange transfusion is more advantageous, and surgery—splenectomy, *consider* anxiolytic antiemetic medication to prevent constipation.

Other Therapies

Considered 5-azacytidine, an antitumor drug 5-deoxyazacytidine (decitabine), IV steroids (dexamethasone), bone

marrow transplantation, gene therapy, combination of clotrimazole and magnesium, and poloxamer 188, an artificial surfactant.

Specific Treatment

- *Aplastic crisis*: Bone marrow suppression is often self-limited, but patients with SCD may not be able to tolerate an acute drop in RBC production. Packed RBC (PRBC) transfusion is indicated if Hb drops >2 g/dL from baseline. This condition is usually self-limited and resolves in 1 week.
- *Splenic sequestration*: Initially, fluid resuscitate if patients are in shock to bridge to transfusion, as fluids may help the spleen release sequestered RBCs. Perform a PRBC transfusion to goal Hb of 6–8 g/dL. Rule out precipitating pathology, such as infection. Splenectomy is not routinely indicated.
- *Hemolysis*: This condition is often self-limited. PRBC should be performed if transfusion is required, though often it is not. Rule out precipitating pathology.
- *Acute chest syndrome*: Aggressive pain treatment can be required to reduce splinting and increase tidal volume. This treatment will lead to improved respiratory mechanics and help improve oxygenation, potentially helping reduce sickling. Opioids are the preferred method of pain control. Although aggressive treatment is recommended, caution must be used to avoid over sedation causing hypoventilation. Anti-inflammatories may be used, though with caution. Patients with SCD have microvascular renal disease, even in the setting of normal creatinine due to chronic renal vasculopathy from SCD. Begin incentive spirometry on admission. It reduces splinting, increases tidal volume, and is an affective adjunct to pain medications in the treatment of ACS. Bronchodilators are indicated if wheezing is present. Supplemental oxygen is recommended only if patients are hypoxic. Administer antibiotics to cover for infection. Typically, a macrolide plus third generation cephalosporin are used. There is not, however, clear evidence for a specific antibiotic choice. Perform parenteral hydration. The goal of hydration in the treatment of ACS, or really any SCD complication, is to decrease plasma viscosity. Hypotonic solutions are preferred. Hydration is only indicated for patients with hypovolemia or examination findings suggesting dehydration. Hypotonic solutions create an osmotic gradient that allows fluid to be taken up by the RBCs, rehydrating the RBCs, and reducing sickling. D5 1/4 normal saline should be given at 1.0–1.5 times the maintenance rate. Avoid normal saline bolus, as it may precipitate ACS. Normal saline, or any normotonic/hypertonic IV fluid, can have the opposite effect, drawing fluids out of RBCs and worsening sickling, which may worsen ACS. Perform exchange transfusion. This transfusion method removes sickled cells while maintaining blood viscosity. Removing sickled cells reduces microvascular occlusion, whereas the transfusion of normal cells improves oxygen carrying capacity and reduces tissue hypoxia. It is thought to be lifesaving, but there is limited evidence on its efficacy.
- *Vaso-occlusive pain crisis*: Pain crisis is a common reason for a visit to the ED; patients are generally on outpatient pain medications and have written plans for treating pain exacerbations. Many patients may have developed a tolerance to opioids because of routine use and will require more aggressive treatment. Opioid medications are preferred. Morphine 0.1 mg/kg every 15–30 minutes. Hydromorphone 0.015 mg/kg every 15–30 minutes. Intranasal fentanyl 2 μg/kg may be a useful adjunct, especially in children. Ketamine 0.3 mg/kg may be a useful adjunct in opioid-tolerant patients. Use caution with anti-inflammatory drugs because of underlying renal dysfunction. Many patients know dosing regimens that work for them. Because of this, their requests for specific medications can be interpreted as drug seeking. Evidence has borne out that although some patients with SCD may be seeking opiates for elicit purposes, most are not. Supplemental oxygen and hydration are often not necessary. Supplemental oxygen is only needed if patients are hypoxic. IV hydration is not routinely needed. If indicated, oral hydration is preferred. Gentle IV hydration can be used if indicated. Avoid boluses if possible.

Ensure pain (i.e., chest pain, abdominal pain, and headache) is not a result of another pathologic process. Embolic disease patients are at much higher risk for embolic diseases, such as stroke, PE, and renal/splenic/hepatic infarction. Have a high index of suspicion when patients with SCD present with signs and symptoms concerning for any of these embolic pathology despite their age or lack of other risk factors. Treatment depends on the type of infarction and often involves routine care indicated for the specific condition; however, gentle hydration and exchange transfusion may be useful adjuncts in these cases as well.

SUMMARY

Sickle cell disease is one of the common genetic disorders. The most common reason for ED visits among these patients is acute painful episodes. A brief history about pattern of previous episodes is important. The emergency physician must be vigilant to look for other emergent conditions causing similar painful crisis and also conditions such as ACS, PE, and cerebrovascular accident (CVA) must be considered. Early and aggressive pain management and hydration are the key priorities in the ED (**Table 2**). Disposition has to be planned accordingly considering the individual patient's pain control and ruling out other conditions. Advice on discharge should include oral analgesics, regular ophthalmology consultation, vaccination, and antibiotic prophylaxis appropriate for splenectomies patients during invasive procedures like dental extraction. A good coordination with hematology and other outpatient teams is of utmost importance for follow-up and long-term management of patients with SCD.

TABLE 2: Summary of treatment options in sickle cell disease.

General	*Pain control*	*Adjuvants*	*Others*
• Bed rest • Hydration • Oxygen • Hydroxyurea • Deep breathing	• Paracetamol • NSAID • Morphine • Fentanyl	• Antibiotics • Transfusion • Splenectomy • Anxiolytics • Antiemetics • Laxatives	• 5-azacytidine • 5-deoxyazacytidine • IV dexamethasone • Bone marrow transplantation • Gene therapy • Combination of clotrimazole and magnesium • Poloxamer 188

(IV: intravenous; NSAID: nonsteroidal anti-inflammatory drug)

CHAPTER

Thrombotic Microangiopathies

Sirisha Kadali, Devendra Richhariya

INTRODUCTION

Thrombocytopenia can be a life-threatening condition; it may be the first presentation of the patient's primary disease or an aggravated underlying disorder. When presented to the emergency, an emergency physician should have a strong clinical suspicion for thrombocytopenia evaluation, risk assessment and should warrant early diagnostic evaluation, stabilization, and admission for further observation.

Platelet production from the megakaryocyte in the bone marrow is stimulated by thrombopoietin. A single megakaryocyte produces about 5,000–10,000/mm^3 platelets in which two-thirds enter the circulation pool and release platelet-derived growth factor and chemotactic agents stimulating extracellular matrix formation and clot propagation in their 7–10-day lifespan. Clearance of platelets occurs in the liver and spleen.

Thrombocytopenia is defined as a platelet count of <150,000/mm^3. Clinically significant thrombocytopenia occurs when there is a drop in the platelet count to <100,000/mm^3 and bleeding occurs when the platelet count drops below 30,000/mm^3.

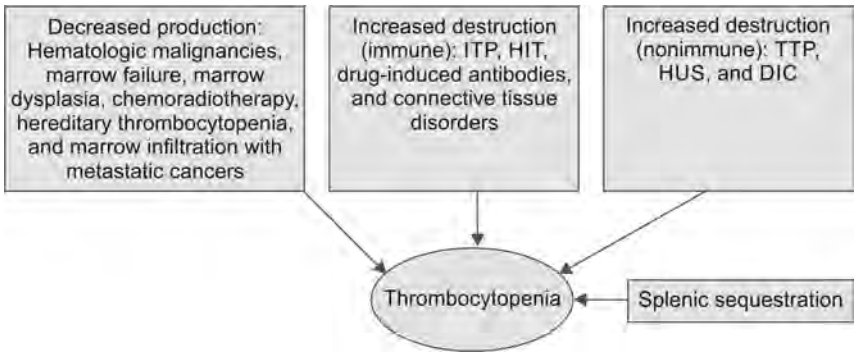
A sudden drop in the platelet count >50% even within the normal range should raise clinical suspicion and requires further evaluation.

Thrombocytopenia can result from three mechanisms; decreased production, splenic sequestration, and increased destruction as described in **Figure 1**. It is important for the emergency physician to be aware about important diagnostic clues (**Table 1**) for evaluation of the thrombocytopenia (**Flowchart 1**).

This chapter focuses on life-threatening diseases with thrombocytopenia as the underlying pathophysiology resulting predominantly from platelet destruction such as thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), idiopathic thrombocytopenic purpura (ITP), disseminated intravascular coagulation (DIC), hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome, heparin-induced thrombocytopenia (HIT) evaluating their clinical presentations, differentials, stabilizations, management, and also approach to thrombocytopenia.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura is a systemic disease characterized by platelet aggregation into thrombi leading to occlusion of body's microvasculature. Both TTP and HUS



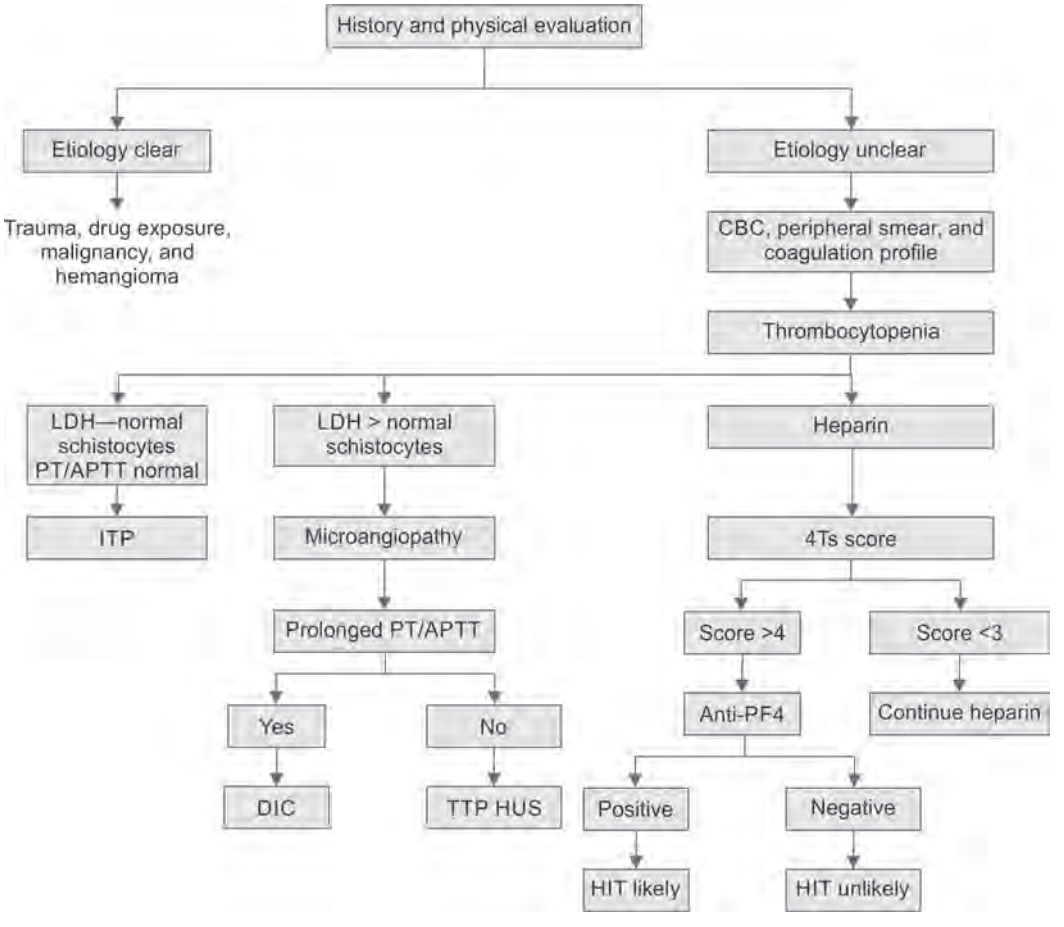
Decreased production: Hematologic malignancies, marrow failure, marrow dysplasia, chemoradiotherapy, hereditary thrombocytopenia, and marrow infiltration with metastatic cancers
Increased destruction (immune): ITP, HIT, drug-induced antibodies, and connective tissue disorders
Increased destruction (nonimmune): TTP, HUS, and DIC
Thrombocytopenia
Splenic sequestration

(DIC: disseminated intravascular coagulation; HIT: heparin-induced thrombocytopenia; HUS: hemolytic uremic syndrome; ITP: idiopathic thrombocytopenic purpura)

FIG. 1: Causes of thrombocytopenia.

TABLE 1: Diagnostic clues to thrombocytopenia.	
Clinical setting	***Differential diagnosis***
Cardiac surgery	CABG, HIT, TTP, and dilutional thrombocytopenia
Sepsis syndrome	DIC, pulmonary artery catheters, Sepsis, Hemophagocytic syndrome, and mechanical ventilation
Pulmonary failure	DIC, H1N1 infection, Hantavirus, Pulmonary Syndrome, and mechanical ventilation
Mental status changes	Seizures and ehrlichiosis
Renal failure	TTP, dengue, HIT, and DIC
Cardiac failure	HIT, drug induced, and pulmonary artery catheter
Postsurgery	Dilutional, drug induced, HIT, and TTP
Pregnancy	HELLP syndrome, fatty liver of pregnancy, and TTP/HUS
Acute liver failure	Splenic sequestration, HIT, drug induced, and DIC

(CABG: coronary artery bypass graft; DIC: disseminated intravascular coagulation; HELLP: hemolysis, elevated liver enzymes, and low platelet count; HIT: heparin-induced thrombocytopenia; HUS: hemolytic uremic syndrome; TTP: thrombotic thrombocytopenic purpura)



(APTT: activated partial thromboplastin time; CBC: complete blood count; DIC: disseminated intravascular coagulation; HIT: heparin-induced thrombocytopenia; HUS: hemolytic uremic syndrome; ITP: idiopathic thrombocytopenic purpura; LDH: lactate dehydrogenase; PF4: platelet factor 4; PT: prothrombin time; TTP: thrombotic thrombocytopenic purpura)

FLOWCHART 1: Thrombocytopenia evaluation.

are associated with platelet aggregation in the microvascular circulation mediated by von Willebrand factor (vWF) and microangiopathic hemolytic anemia which occurs from red blood cell (RBC) fragmentation during travel through the partially occluded arterioles and capillaries. TTP predominantly affects females over 40 years of age.

Causes

Idiopathic (most common), infections—human immunodeficiency virus (HIV), pregnancy, malignancy, bone marrow transplantation, drug therapy *[quinine, oral contraceptive (OC) pills, clopidogrel, ticlopidine, trimethoprim, pegylated*

interferon, and simvastatin], chemotherapy, Pancreatitis, Autoimmune disease *[systemic lupus erythematosus (SLE) and antiphospholipid syndrome].*

Pathophysiology

There are three pathophysiology processes give rise to TTP.

1. *Deficiency of ADAMTS-13*: ADAMTS-13 is produced by the hepatic stellate cells, glomerular podocytes and vascular endothelial cells. Normally regulates the cleaving of large vWF multimers into smaller proteins, the deficiency of which leads to accumulation of vWF which attracts and binds platelets.
2. *Accumulation of vWF,* which is an ultra-large multimers that can spontaneously aggregate platelets.
3. *Widespread platelet aggregation* leads to subsequent thrombi in the microvasculature and ultimately end-organ damage.

Clinical Features

Any patient presenting with a classic pentad of fever, hemolytic anemia, thrombocytopenia, renal impairment, and neurologic manifestations should be suspected for TTP.

- *Central nervous system (CNS)*: Headache, seizures, visual changes, and aphasia
- *Gastrointestinal (GI) symptoms*: Pain abdomen, nausea, vomiting, and diarrhea
- *Cardiovascular/respiratory*: Chest pain, dyspnea, and fever
- *Bleeding*: Hematuria, epistaxis, bruising, ecchymosis, petechiae, purpura, menorrhagia, and bleeding gum
- *End-organ damage*: Shearing of RBCs across the microthrombi produces the microangiopathic hemolytic anemia causing jaundice and dark-colored urine. Accumulation of microthrombi in the CNS, renal arterioles, and capillaries promotes tissue ischemia and necrosis with resultant end-organ damage such as seizures, stroke, focal neurological deficits, coma, and acute renal injury.

Diagnosis

Diagnosis is based mostly on the clinical presentation. Laboratory testing is aimed at assessing the degree of end-organ damage, ruling out other causes of thrombocytopenia and identifying an infectious or immune inciting event.

- *Complete blood count with peripheral smear*: Microangiopathic hemolytic anemia, thrombocytopenia, decreased hematocrit, and elevated reticulocyte count. Peripheral smear reveals schistocytes (fragmented RBCs due to the shear mechanism).
- *Complete metabolic panel with liver function tests*: Elevations in lactate dehydrogenase (LDH), serum K^+, and total bilirubin raises suspicions of hemolytic anemia due to release from fragmented RBCs. HUS presents with more severe renal impairment than TTP.
- *Coagulation profile [prothrombin time/partial thromboplastin time/international normalized ratio (PT/PTT/INR)]*: TTP can be distinguished from DIC by a normal coagulation profile.
- *Lactate dehydrogenase level*: Elevations in LDH should raise suspicions of hemolytic anemia and is a prognostic factor in TTP.
- *Decreased haptoglobin, increased free hemoglobin, and hemoglobinuria are suggestive of intravascular hemolysis.*
- Elevated troponin levels in acute idiopathic TTP are due to end-organ damage caused by thrombosis of coronary vasculature.
- *Other tests*: Direct Coombs test, urine pregnancy test, complete urine examination, HIV, hepatitis (A, B, and C), thyroid function tests, autoimmune screening, blood cultures, and type and screen for plasma exchange therapy (PET).

Management of Thrombotic Thrombocytopenic Purpura

Primary Treatment is Plasma Exchange Therapy

Plasma exchange therapy replaces the ADAMTS-13, removes the causative antibody and achieves a normal platelet count. Plasmapheresis is performed daily at 40 mL/kg or 1–1.5 times a patient's plasma volume and then either tapered to an alternate day plasmapheresis or stopped once normal counts are reached for 2–3 consecutive days and LDH levels are normalized. PET is more effective than PIT due to its ability to give very large volumes of fresh frozen plasma (FFP) and removal of inhibitory antibodies, disease remission, and all-cause mortality.

First-line Therapy

PET with FFP: 1–1.5 plasma volume exchanges per day with FFP (2 plasma volume exchanges in refractory cases).

Second-line Therapy

Fresh frozen PIT: FFP can be infused at 15–30 mL/kg.

Adjunctive Therapies to PET

Glucocorticoids**,** methylprednisolone 1 g/day, or prednisone 1 mg/kg/day. Rituximab in consultation with hematology at 375 mg/m^2 every week for 4 weeks.

Plasma Infusion Therapy

When PET is not available immediately, then plasma infusion therapy (PIT) can be used as a stop-gap measure and provides the required ADAMTS-13 activity, start plasma infusions at a rate of one unit every 4 hours. PIT leads to fluid overload and must be used with caution in renal and heart diseases. In patients with plasma allergy, consider factor VIII concentrates infusion containing ADAMTS-13 activity.

Cases of malignancy-induced TTP should be aimed at treating the underlying cause as PET/PIT is not beneficial. Discontinue the inciting drug in cases of drug-associated TTP. Platelet transfusions are considered only in cases of life-threatening bleeding as platelet transfusions may worsen the disease by causing accumulation of raw material leading to thrombosis in the microvasculature. Consider corticosteroids, rituximab, and cyclosporine in cases of autoimmune TTP with the advantage of reduction in relapses and refractory cases. If there are cases of TTP in pregnancy then consider early delivery in consultation with gynaecologist. Timely diagnosis and initiation of therapy is paramount to a favorable prognosis. Mortality is as high as 90% in untreated TTP whereas prompt recognition and initiation of treatment reduces the mortality

to as low as 20%. TTP relapse is defined as onset of a new case >30 days after completion of remission and seen in 20–50% of cases, most often within 2 years of the initial episode. Patients with ADAMTS-13 activity levels <10% are at increased risk for relapse.

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is characterized by microangiopathic hemolytic anemia, thrombocytopenia due to microvascular thrombosis, and renal failure. HUS is divided into typical and atypical HUS.

Typical HUS usually effects 1 week to 4 years age group and causative agents being Shiga toxin-producing *Escherichia coli* O157:H7 (most common), *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter*. Manifests as infectious bloody diarrhea and comes to medical attention with renal failure. Extrarenal manifestations include thrombocytopenia, neurological involvement as seizures, deranged liver function tests, and pancreatitis. Supportive treatment and dialysis are helpful. Recurrence is uncommon.

Atypical HUS effects older children and adults and is due to defective complement system activation. Causative agents include *Streptococcus pneumoniae*, Epstein–Barr virus (EBV), bone marrow transplantation, and chemotherapeutic agents and have a prominent extrarenal symptomatology without bloody diarrhea. Prognosis is worse for atypical HUS. Supportive treatment dialysis ± plasmapheresis is required. Recurrence is common.

Pathophysiology

Predominantly transmitted via food or water. Once ingested the virulent factors associated with Shiga toxin-producing *E. coli* O157:H7 allow invasion of intestinal epithelial cells, subsequent transmural migration, and produce the characteristic hemorrhagic colitis. Toxin-mediated microvascular injury promotes platelet aggregation and thrombus formation at the injury site.

Once absorbed into the systemic circulation, the Shiga toxin binds with receptors on the epithelial and endothelial cells of the glomerulus, renal tubules, colon, cerebrum, and the pancreas creating a vicious cycle of thrombosis and microangiopathic hemolytic anemia via shearing of RBCs over the microthrombi contributing to tissue ischemia and necrosis.

Clinical Features

Hemolytic uremic syndrome typically sets in 2–14 days after the diarrhea develops, so the patients present during the diarrheal phase of illness with abdominal cramps with or without bloody diarrhea and often without fever.

Laboratory Evaluation

For patients with bloody and nonbloody diarrhea, stool testing reveals inflammatory colitis. Electrolytes, urinalysis (RBC casts and protein), and renal function panels to detect nephropathy and associated dyselectrolytemia.

Management

Typical HUS is treated with supportive care and pain management with careful maintenance of fluid and electrolytes.

TABLE 2: Differentiating features between TTP and HUS.

	TTP	*HUS*
Clinical features	• Mostly nonspecific symptoms • Neurological features are common—aphasia, diplopia, and clumsiness • Minor purpura related to thrombocytopenia	• Bloody diarrhea, abdominal pain, nausea, and vomiting • Kidney injury is more common than TTP • Neurologic symptoms are less common than TTP
Lab findings	• Anemia, thrombocytopenia, and schistocytes on smear • Low ADAMTS-13 activity	Anemia, thrombocytopenia, schistocytes on smear, and inflammatory colitis
Treatment	Urgent plasma exchange	• Typical HUS (Shiga toxin associated) supportive care Atypical HUS (complement associated), PET, and eculizumab (anticomplement therapy) • PET, and eculizumab (anticomplement therapy)

(HUS: hemolytic uremic syndrome; PET: positron emission tomography; TTP: thrombotic thrombocytopenic purpura)

Control the hypertension with nifedipine and nicardipine. RBC or platelet transfusion is required in cases of significant anemia or profound thrombocytopenia. Hemodialysis when clinically indicated. Severe extrarenal manifestations can be treated with plasma exchange. Antimotility agents and antibiotics are contraindicated as they increase the risk of HUS by increasing Shiga toxin expression from the bacteria. Atypical HUS is often hard to distinguish from TTP and should be treated as a close TTP variant with PET therapy. Eculizumab (C5 inhibitor) is being used in atypical HUS and reduces the incidence of renal failure. Typical HUS is associated with acute renal failure in 55–70% of patients and almost 85% of the patients have recovered kidney function. Mortality in typical HUS is about 5–15%. Atypical HUS has a poor outcome and is associated with permanent renal failure and neurologic damage.

It is often difficult to differentiate atypical HUS from TTP (**Table 2**) in emergency setting. If any one of diagnoses is considered a team of hematologist, nephrologist, neurologist critical care blood bank team should be involved in managing the critically ill patient.

IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura is an acquired immune-mediated syndrome characterized by thrombocytopenia and bleeding tendencies, despite which the circulating platelets are functional. ITP is characterized by antiplatelet antibodies to platelet surface glycoprotein IIb/IIIa ultimately resulting in

peripheral platelet destruction. Idiopathic with no underlying cause termed as *primary ITP* while *secondary ITP* is associated with underlying cause or medication induced. Primary ITP further subdivide to acute ITP (duration of illness 3 months) and chronic illness (>12 months). This process is likely to be multifactorial whereby a genetic predisposition causes an alteration in the immune response and peripheral tolerance. The immunoglobulin G (IgG) autoantibodies from the patient's B-lymphocytes directed against the platelet membrane glycoprotein IIb/IIIa cause peripheral platelet destruction and inhibition of megakaryocyte platelet production ultimately leading to thrombocytopenia.

Causes

Causes of ITP are as follows:

- *Medications*: Acetaminophen, acetazolamide, allopurinol, amiodarone, ampicillin, aspirin, carbamazepine, cephalexin, chlorothiazide, chlorpheniramine, cimetidine, diazepam, digoxin, diphenylhydantoin, furosemide, gentamicin, heparin, lidocaine, methicillin, methyldopa, minoxidil, morphine, penicillin, phenylbutazone, procainamide, quinidine, quinine, ranitidine, rifampin, spironolactone, tricyclic, antidepressants, trimethoprim-sulfamethoxazole, valproic acid, and vancomycin
- *Underlying conditions*: Live vaccinations (i.e., mumps, measles, and rubella), *Helicobacter pylori*, *Cytomegalovirus*, hepatitis C virus (HCV), HIV, antiphospholipid syndrome, SLE, Evans syndrome, posthematopoietic cell transplantation, chronic lymphocytic leukemia, and low-grade lymphoproliferative disorders

Clinical Presentation

Mucocutaneous bleeding is the most common clinical presentation. Epistaxis and gingival bleeding and menorrhagia in childbearing women are other presentations. Petechial or purpuric rashes in the dependent lower extremities and areas of constriction, receding in crops over days. Chronic ITP patients present as paradoxical thrombosis. Otherwise normal physical examination except for bruises and petechiae.

Laboratory Workup

Complete blood count reveals anemia, thrombocytopenia, and large well-granulated platelets on peripheral smear. Rh testing for treatment with anti-Rh(D). Direct Coombs test to exclude concurrent autoimmune hemolytic anemia. Hepatitis C and HIV testing to rule out secondary causes of ITP. Bone marrow evaluation in complex/atypical cases/elderly (>60 years)/those with diagnostic uncertainty.

Diagnosis

No definitive diagnostic test for ITP exists and the diagnosis is primarily by exclusion of an underlying cause and is characterized by isolated thrombocytopenia.

Management

Goal of therapy is to treat symptomatic bleeding and maintain platelet count >30,000/mm^3. Life-threatening bleeding with a platelet count <30,000/mm^3 where there is an urgent need to achieve hemostasis, administer IV corticosteroids and IV immunoglobulins concomitantly and repeat platelet transfusions until hemostasis is achieved. Consider emergent splenectomy when other treatment options have exhausted. Treatment strategies are summarized in **Table 3**.

Complications

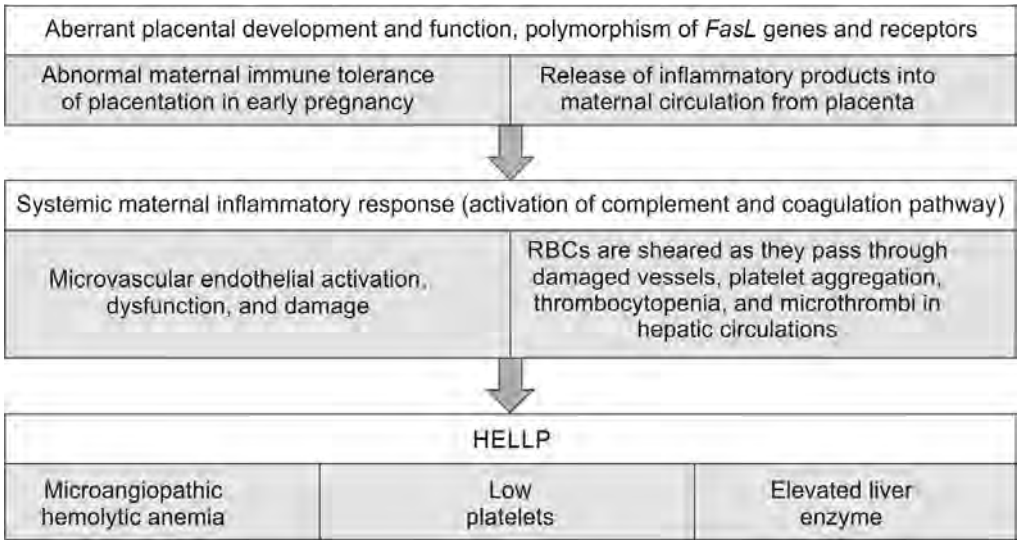
Life-threatening spontaneous bleeding [intracerebral (IC) bleed and GI bleed] are more significant with a platelet count <10,000/mm^3. Hypotension, transfusion reactions, transient neutropenia, acute kidney injury, infection, and aseptic meningitis with intravenous immunoglobulin (IVIG) infusion are other complications. Mortality from hemorrhage is approximately 1% in children and 5% in adults. Patients with bleeding tendencies and with moderate-to-severe thrombocytopenia need to be admitted for close monitoring and initiation of therapy. Patients with new-onset thrombocytopenia and those with poor patient follow-up need to be considered for admission to determine the clinical course and platelet trends. Asymptomatic patients with platelet counts >30,000/mm^3 can be considered for outpatient management.

HELLP SYNDROME

HELLP stands for hemolysis, elevated liver enzymes, and low platelet count and describes a variant of preeclampsia. Presents in pregnancy after 20 weeks of gestation and can be life-threatening. Family history, advanced maternal age, and

TABLE 3: Treatment of idiopathic thrombocytopenic purpura (ITP) with life-threatening bleed and thrombocytopenia.

First line: Corticosteroids are the first line of treatment for primary ITP	*Second line: Monoclonal antibodies*	*Third line: Thrombopoiesis stimulating agents*
• Prednisolone 1 mg/kg daily for 4–6 weeks and taper after obtaining response (or) • Dexamethasone 40 mg/day PO/IV for 4 days (or) • Methylprednisolone 30 mg/kg IV with rapid taper every third day to 1 mg/kg daily • Response to corticosteroids occurs in 4–14 days and peaks at 7–28 days • IVIG 1 g/kg daily for 1–2 days, response occurs at 1–3 days and peaks at 2–7 days • Single dose anti-Rh(D) 50–75 µg/kg IV in Rh(+)ve patients and have not undergone splenectomy • Platelet transfusion if bleeding actively	• Rituximab 375 mg/m^2/week for 4 weeks, which acts by blunting the autoimmune destruction of platelets • Splenectomy	• Thrombopoietin mimetics and thrombopoietin receptor agonists such as romiplostim and eltrombopag to stimulate platelet production • Cyclophosphamide, cyclosporine, azathioprine, eltrombopag, romiplostim, and vincristine



Aberrant placental development and function, polymorphism of FasL genes and receptors
Abnormal maternal immune tolerance of placentation in early pregnancy
Release of inflammatory products into maternal circulation from placenta
Systemic maternal inflammatory response (activation of complement and coagulation pathway)
Microvascular endothelial activation, dysfunction, and damage
RBCs are sheared as they pass through damaged vessels, platelet aggregation, thrombocytopenia, and microthrombi in hepatic circulations
HELLP
Microangiopathic hemolytic anemia
Low platelets
Elevated liver enzyme

(HELLP: hemolysis, elevated liver enzymes, and low platelet count; RBCs: red blood cells)

FIG. 2: Pathophysiologic mechanism of HELLP.

past pregnancy with preeclampsia are few risk factors for HELLP syndrome. Pathophysiologic mechanism of HELLP is summarized in **Figure 2**.

Patient presents with complaints of right upper quadrant abdominal pain, headache, blurred vision, nausea, vomiting, malaise, and flu-like symptoms. On examination, weight gain, edema, hypertension, mucosal bleeding, hematuria, and petechiae/purpura are the findings. Since HELLP syndrome is common in pregnancy and gives rise to various complications as follows:

- *Maternal complication:* Placental abruption, DIC, renal failure, pulmonary edema, liver hematoma, liver failure, severe ascites, cerebral edema, and cerebral hemorrhage.
- *Neonatal complications:* Perinatal death, preterm delivery, thrombocytopenia, intraventricular hemorrhage, respiratory distress syndrome (RDS), patent ductus arteriosus, and bronchopulmonary dysplasia.

HELLP syndrome should be differentiated from *conditions related to pregnancy* such as acute fatty liver of pregnancy and benign thrombocytopenia of pregnancy; *hepatobiliary conditions* such as hepatitis, cholangitis, cholecystitis, pancreatitis; and *other platelets disorders* such as ITP, TTP, HUS, SLE, antiphospholipid antibody (APLA), hemorrhagic, or septic shock.

Diagnostic Workup

The first sign of HELLP is a decrease in the platelet count followed by abnormal liver function test. *Complete blood count* reveals anemia, decrease in hematocrit, platelets <100,000 µL/mL, increased reticulocyte count, decreased haptoglobin due to marrow release of immature cells, and hemolysis.

- *Peripheral smear:* Hemolysis, schistocytes, and burr cells
- *Liver function test*: Unconjugated bilirubin > 1.2 mg/dL, aspartate aminotransferase (AST) >70 IU/L, LDH > 600 IU/L or more than two times the upper limit of the normal
- *Renal function test*: Increased serum levels of creatinine and uric acid due to glomerular endotheliosis and impaired renal tubular secretion
- *Imaging:* Subcapsular liver hematoma or frank liver rupture

Management

Definitive treatment of HELLP syndrome is the delivery of the baby. Seizure prophylaxis and blood pressure (BP) control are among the first-line agents in the management of HELLP syndrome.

Seizure management—$MgSO_4$: Loading dose 4–6 g IV over 20 minutes followed by continuous infusion of 2 g/h to be continued for 24 hours after delivery. *BP control*: Target systolic blood pressure (SBP) < 160 mm Hg or diastolic blood pressure (DBP) < 105 mm Hg. *Hydralazine*: 5 mg IV every 15 minutes up to a maximum dose of 20 mg/h (or) labetalol 20–40 mg IV every 15 minutes up to a maximum dose of 240 mg/h.

Corticosteroids are considered beneficial in thrombocytopenia as they decrease the inflammatory response that leads to platelet activation, aggregation, destruction, and improve neonatal outcomes accelerating fetal lung maturity. Betamethasone: 12 mg IM every 12th hourly (or) dexamethasone: 12 mg IV every 12th hourly. Any patient seen in the emergency department suspected of HELLP syndrome requires consultation with obstetrics and admission for an extended period of observation with repeated laboratory evaluation and fetal monitoring and delivery.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation is an acquired, systemic process of overstimulation of the coagulation pathway resulting in thrombosis followed by consumption of platelets and coagulation factors with concomitant activation of fibrinolytic system resulting in breakdown of fibrin clots and subsequent bleeding. DIC can be classified into acute and chronic. Acute and decompensated DIC when the generation of clotting factors cannot match the excessive consumption. Chronic and compensated DIC when the generation of clotting factors matches the consumption. Precipitating factors which may give rise to DIC are summarized in **Table 4**.

TABLE 4: Precipitating factors of DIC.

Conditions	*Comments*
Infection (bacterial, viral, and fungal)	Most common cause, endotoxins stimulate monocytes and endothelial cells to express tissue factor
Carcinoma, adenocarcinoma, and lymphoma	Malignant cells cause endothelial damage and allow expression of tissue factor
Acute leukemia	DIC is common with promyelocytic leukemia, blast cells release procoagulant enzymes
Trauma	DIC with brain injury, crush injury, burns, hypothermia, hyperthermia, rhabdomyolysis, fat embolism, and hypoxia
Organ injury: Liver disease and pancreatitis	• Acute DIC can occur in setting of acute hepatic failure, tissue factor is released from the injured hepatocytes • Pancreatitis can activate the coagulation cascade
Pregnancy	Placental abruption, amniotic fluid embolus, septic abortion, and IUFD
Vascular disease	Large aortic aneurysms, giant hemangiomas, vasculitis, and multiple telangiectasias
Envenomation	Venom damages the endothelial cells
Acute lung injury (ALI) or ARDS	Microthrombi are deposited in the small pulmonary vessels and patients develop acute lung injury
Transfusion reactions, such as acute hemolytic reaction	DIC with severe bleeding, shock, and acute renal failure

(ARDS: acute respiratory distress syndrome; DIC: disseminated intravascular coagulation; IUFD: intrauterine fetal demise)

Pathophysiology

The precipitating factors causing widespread activation of intrinsic coagulant pathway lead to marked imbalance between procoagulant and anticoagulant processes resulting in unopposed thrombin generation and diffuse fibrin clot formation and intravascular deposition with subsequent microvascular occlusion and tissue hypoxia ultimately leading to multiple organ death syndromes as described in **Flowchart 2**. Production of thrombin and fibrin indirectly activates tissue plasminogen activator and counter-regulatory fibrinolytic system. When hyperfibrinolysis occurs, the hemostatic clots dissolve and bleeding ensues. Bleeding is due to a combination of factor depletion, platelet dysfunction, thrombocytopenia, and excessive fibrinolysis.

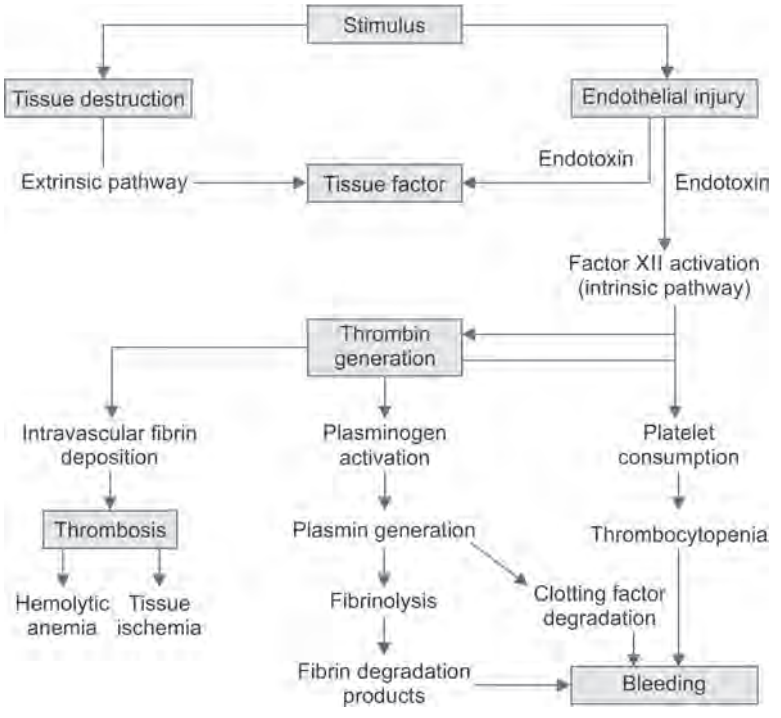
Clinical Presentation

A clinical suspicion for DIC is paramount in establishing the diagnosis. Rapid onset of bleeding from more than three unrelated sites is highly suggestive of DIC.

- *End-organ damage*: Cutaneous gangrene, thrombotic purpura, and purpura fulminans
- *Bleeding*: Petechiae, ecchymosis, GI bleed, and intracranial bleed
- *Nervous system*: Headache, delirium, neurologic deficits, and coma
- *Multiorgan involvement*: Acute renal failure, acute RDS, liver failure, and shock
- *Thromboembolism:* Venous, arterial, and nonbacterial thrombotic endocarditis

Laboratory Evaluation

A compatible underlying condition and laboratory studies (**Table 5**) consistent with increased activation of coagulation and thrombin generation [elevated PT, activated partial thromboplastin time (APTT), fibrin degradation product (FDP),



FLOWCHART 2: Pathophysiology of disseminated intravascular coagulation (DIC).

TABLE 5: Laboratory abnormalities in DIC.

Platelet count	*Usually low or dropping*
Prothrombin time	Prolonged
Fibrinogen < 100 mg/dL	Correlates with severe DIC
FDPs and D-dimer	Elevated
APTT	Usually prolonged
Thrombin clotting time	Prolonged
Fragmented blood cells	Should be present
Factor II, V, VII, and IX	Low

(APTT: activated partial thromboplastin time; DIC: disseminated intravascular coagulation; FDPs: fibrin degradation products)

and D-dimer] and excessive fibrinolysis (decreased fibrinogen, antithrombin III, and platelets). International scoring system (**Table 6**) is helpful for the diagnosis and severity of DIC. Patient must be screened with a DIC screening panel composed of PT, APTT, platelet count, fibrinogen, and D-dimer.

Differential Diagnosis

Disseminated intravascular coagulation should be differentiated from *primary fibrinolysis*—a rare syndrome where fibrinolysis occurs without the production of thrombin and *severe liver disease.* D-dimer assay is normal or minimally elevated in both primary fibrinolysis and liver disease but significantly elevated in DIC.

Treatment

Identification and treatment of underlying disorder that is driving the thrombin generation is the hallmark for the management of DIC. Treat the precipitating disorder: volume resuscitation, antibiotics, and external cooling. Guidelines for transfusion of various blood products described in **Box 1**. Acute DIC requires admission, aggressive resuscitation, and treatment of underlying cause. DIC from sepsis has a significantly higher death rate than DIC associated with trauma.

Prognosis is poor and mortality is 50%. Approach to DIC is summarized in **Flowchart 3**.

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia is a syndrome that occurs due to the formation of IgG or IgM autoantibodies directed against the heparin-platelet factor 4 complex that activates platelets producing thrombocytopenia and a tendency for thrombosis. Type I is a benign nonimmune mediated and Type II is a life-threatening. Incidence of HIT is influenced by the heparin preparation used, dose, patient characteristics, and increases with the duration of heparin exposure (heparin treatment for >4 days, incidence is 15% and treatment <4 days, incidence is 0.2%). Frequency of HIT is less with low-molecular-weight heparin (LMWH) (1%) when compared to unfractionated heparin (UFH) (1–5%). HIT can be predicted by using the 4Ts score described in **Table 7**.

TABLE 6: International Society on Thrombosis and Hemostasis scoring system for diagnosis of DIC.

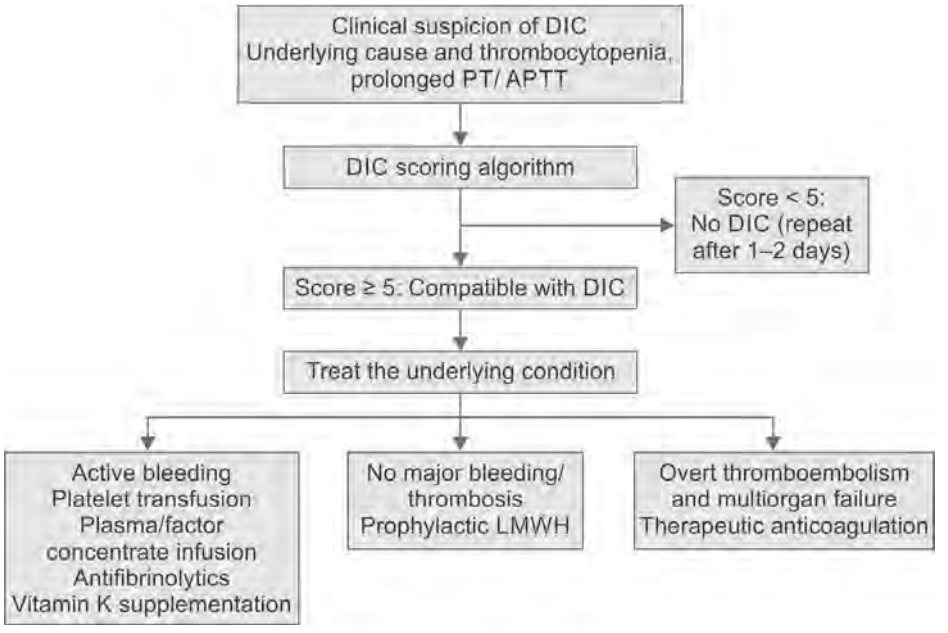
Tests	*Points*
Platelet count	
• >100,000/mm^3	0
• 50,000–100,000/mm^3	1
• <50,000/mm^3	2
Fibrin markers (D-dimer and FDPs)	
• Normal	0
• Mildly elevated	2
• Markedly elevated	3
Prothrombin time prolongation	
• <3 seconds	0
• 3–6 seconds	1
• >6 seconds	2
Fibrinogen level	
• >100 mg/dL	0
• <100 mg/dL	1
• A score of ≥ 5 is compatible with overt DIC	
• A score of <5 is suggestive of nonovert DIC	
• Higher scores correlate with a higher 28-day mortality	

(DIC: disseminated intravascular coagulation; FDPs: fibrin degradation products)

BOX 1: Guidelines for transfusion of various blood products in patients at high risk of bleeding.

- Consider platelet transfusion when there is a high risk of spontaneous bleeding (platelet count <20,000/mm^3) or active bleeding. Platelets <50,000/μL, give platelet concentrates or one unit of SDPs
- Fibrinogen 80–100 mg/dL, give 10 units of cryoprecipitate. Transfuse FFP/cryoprecipitate when fibrinogen level < 100 mg/dL
- Hematocrit below 30%, give red cells
- Prothrombin time more than twofold the upper limit of normal and APTT abnormal, give two to four units of FFP. Vitamin K for prolonged PT
- When risk of hypervolemia due to FFP administration, consider prothrombin complex concentrates
- In case of thromboembolic disease, retained products of conception, purpura fulminans consider heparin/LMWH as it augments antithrombin III activity and prevents conversion of fibrinogen to fibrin
- Consider tranexamic acid for trauma-related DIC

(APTT: activated partial thromboplastin time; DIC: disseminated intravascular coagulation; FFP: fresh frozen plasma; LMWH: low-molecular-weight heparin; PT: prothrombin time; SDPs: single donor platelets)



(DIC: disseminated intravascular coagulation; LMWH: low-molecular-weight heparin)

FLOWCHART 3: Approach to DIC.

TABLE 7: Prediction (4Ts score) for heparin-induced thrombocytopenia (HIT).

Points	***2***	***1***	***0***
Thrombo-cytopenia	>50% fall from the baseline and 20–100 × 10^9/L	30–50% fall or 10–19 × 10^9/L	<30% fall or <10 × 10^9/L
Timing of platelet fall	Onset within 10 days of heparin	Counts fall after day 10	Counts fall <5 days and no recent heparin
Thrombosis	New thrombosis or skin necrosis	Progressive or recurrent thrombosis	None
Other cause for thrombo-cytopenia	None	Possible	Definite

Test score high probability: score 6–8; intermediate probability: score 4–5; low probability: score 0–3. Patients with a low probability score are very unlikely to have HIT and can forgo PF4-heparin antibody testing and empiric therapy. Patients with intermediate and high scores should receive empiric therapy until definitive testing can be obtained.

Patients are often asymptomatic with unexplained thrombocytopenia. One of the earliest clues is an anaphylactoid reaction such as fever, chills, hypertension, tachycardia, dyspnea, and chest pain within 30 minutes of receiving an IV bolus of heparin and should be evaluated for HIT. Paradoxical venous thrombosis with thrombocytopenia involving the skin (cutaneous necrosis), major arteries (ischemic limbs), and veins (recurrent venous thrombosis or pulmonary embolism).

Diagnosis is confirmed by history of heparin exposure and unexplained thrombocytopenia. HIT should be suspected when there is a sudden onset of thrombocytopenia with either at least 50% drop in the platelet count from the baseline or platelet count falling to < 100 × 10^9/L in patients receiving heparin in any form. Baseline platelet count to be obtained, repeated at 24 hours and every 2–3 days during treatment with heparin. Serotonin release assay is gold standard which is a platelet aggregation assay. Enzyme-linked immunosorbent assay (ELISA) immunoassay detects anti-heparin PF4 antibodies.

Treatment

First step in the therapy of HIT consists of discontinuing all forms of heparin including heparin-bonded catheters, heparin IV locks, and heparin flushes. Consider platelet transfusion only in case of life-threatening bleeding due to risk of perpetuating thrombus. Transition to warfarin or thrombin specific inhibitors such as dabigatran (Pradaxa) or rivaroxaban (Xarelto) should be made once the patient is stabilized and the platelet counts are >150,000/mm^3.

The platelet counts return to normal within 4–6 days of discontinuing heparin. Protamine is not effective against the immune mediated response. Treatment of HIT is summarized in **Box 2**.

SUMMARY

Thrombotic microangiopathies (TTP, HUS, HELLP, ITP, HIT, and DIC) are life-threatening conditions and emergency physician should be aware of their clinical feature and management strategies to recognize these conditions in early stage so that life-saving treatment can be initiated in emergency department. Thrombotic microangiopathies are summarized in **Table 8.**

BOX 2: Treatment of heparin-induced thrombocytopenia (HIT).

***Argatroban*:**

A synthetic thrombin inhibitor

- Initial dose of 2 µg/kg/min adjusted to an APTT of 1.5–3 times normal
- In severe liver disease at 0.5 µg/kg/min adjusted to an APTT of 1.5–3 times normal
- In MODS at 1 µg/kg/min adjusted to an APTT of 1.5–3 times normal
- Post-CABG 0.5–1 µg/kg/min adjusted to an APTT of 1.5–3 times normal
- Indications: Prevention and treatment of thrombosis in HIT

***Bivalirudin*:**

Semisynthetic direct thrombin inhibitor

- Bolus: 1 mg/kg
- Infusion: 2.5 mg/kg/h for 4 hours and then 0.2 mg/kg/h for 14–20 hours
- Renal adjustments:
  - For creatinine clearance of 30–59 mL/min, decrease dose by 20%
  - For creatinine clearance of 10–29 mL/min, decrease dose by 60%
  - For creatinine clearance of <10 mg/min, decrease dose by 90%

Indications: Percutaneous coronary intervention in patients with or without HIT

***Lepirudin*:**

Direct inhibitor of thrombin: Initial IV bolus of 0.4 mg/kg IV bolus

- Continuous infusion: Initial rate determined by renal function
- GFR > 60 mL/min: 0.10 mg/kg/h, GFR 45–60 mL/min: 0.075 mg/kg/h
- GFR < 45 mL/min: Lepirudin not recommended (consider argatroban)

***Fondaparinux*:**

Indirect anti-Xa inhibitor

- 7.5 mg every 24 hours (consider 5 mg in patients under 50 kg and 10 mg in patients over 100 kg)
- *Perform APTT at 4-hour interval until steady state within the therapeutic range (1.5–2 times patient baseline APTT is achieved)*

(APTT: activated partial thromboplastin time; CABG: coronary artery bypass graft; GFR: glomerular filtration rate; MODS: multiple organ dysfunction syndrome)

TABLE 8: Summary of thrombotic microangiopathies.

	TTP	*HUS*	*ITP*	*DIC*	*HELLP*	*HIT*
Pathogenesis	ADAMTS-13 deficiency	• Typical HUS: Shiga toxin-producing bacteria • Atypical HUS: Defective complement activation and regulation	Immune-mediated platelet destruction and inhibition of production	Activation of coagulation cascade with thrombin production	Unknown	Antibodies destroy heparin platelet factor 4 complex
Features	MAHA with thrombocytopenia No other cause	Same as TTP + renal failure, predominantly effects children with diarrhea, and renal failure	Isolated thrombocytopenia with normal smear	Consumptive coagulopathy due to an underlying pathologic abnormality	MAHA with elevated liver enzymes and low platelets associated with pregnancy	Drug exposure, immune-mediated thrombocytopenia, and thrombosis
Laboratory	• CBC with peripheral smear: Thrombocytopenia, anemia, and red cell fragmentation • LDH: Elevated	Stool: Shiga toxin-producing *Escherichia coli*	• CBC with smear: Isolated thrombocytopenia, no red cell fragmentation • Diagnosis of exclusion	CBC with smear: Thrombocytopenia, anemia, red cell fragmentation, elevated PT and APTT, D-dimer, decreased fibrinogen	• CBC with smear: Thrombocytopenia, anemia, red cell fragmentation • Increased AST or ALT • Positive UPT	CBC with smear: Isolated thrombocytopenia with a >50% decrease in the platelet count in first 5–10 days of initiation of heparin

Continued

Continued

	TTP	*HUS*	*ITP*	*DIC*	*HELLP*	*HIT*
Treatment	• Plasma exchange therapy • Glucocorticoids • Prednisolone or methyl-prednisolone	• Typical HUS: Supportive care • Atypical HUS: Treat like TTP	• Methylpred-nisolone or prednisone • IVIG • Platelet transfusion or splenectomy	• Treat underlying cause • Administer platelets/FFP/ cryoprecipitate in serious bleeding	• BP control (labetalol or hydralazine) • Prevent seizures ($MgSO_4$) • Definitive care is delivery of fetus	Discontinuation of heparin and anticoagulation with nonheparin containing anticoagulant

(APTT: activated partial thromboplastin time; ALT: alanine aminotransferase; AST: aspartate aminotransferase; BP: blood pressure; CBC: complete blood count; DIC: disseminated intravascular coagulation; FFP: fresh frozen plasma; HELLP: hemolysis, elevated liver enzymes, and low platelet count; HIT: heparin-induced thrombocytopenia; HUS: hemolytic uremic syndrome; ITP: idiopathic thrombocytopenic purpura; IVIG: intravenous immunoglobulin; LDH: lactate dehydrogenase; MAHA: microangiopathic hemolytic anemia; PT: prothrombin time; TTP: Thrombotic thrombocytopenic purpura; UPT: urine pregnancy test)

148
CHAPTER

Approach to Skin Diseases in Emergency

Ramanjit Singh, Nidhi R Sharma

INTRODUCTION

Dermatology is considered to be primarily an outpatient specialty. Dermatological diseases account for 8–20% of the patients visiting emergency outpatient department globally. This chapter will help in recognizing dermatological emergencies because recognition of specific skin signs, early diagnosis, hospitalization, monitoring, and multidisciplinary care can reduce associated morbidity and mortality. Proper history taking and examination is an important part to start while approaching a dermatology patient in an emergency department (ED).

HISTORY TAKING

- Onset and duration of the disease
- *Nature of spread*: Generalized or is it localized
- Asymptomatic or associated with symptoms such as pain, itching, and burning sensation
- Associated complaints such as fever, joint pain, and oral ulcers
- First episode or recurrence nature of it
- Any aggravating or relieving factor
- Similar complaints in family or close contacts
- *Triggering factors*: Drug intake, vaccination, excessive sunlight exposure, food, and chemical exposure
- Prior history of travel
- Previous history of drug or food allergies or any chronic disease
- Treatment history or any investigations done specifically skin biopsy of the skin condition patient has landed into ED

EXAMINATION OF THE PATIENT

It can be divided into two parts—general and systemic examination and dermatological examination.

General and Systemic Examination

It is similar to general and systemic examination like in other patients presenting in ED. Check for patient's vital signs and symptoms to rule out sepsis or anaphylaxis. Systemic examination should be done to rule out respiratory disease/cardiovascular/neurological/gastrointestinal involvement, involvement of lymph nodes along with pallor, icterus, clubbing, and cyanosis should be checked, and check for joint involvement.

Dermatological Examination

The clinical diagnosis of skin diseases is accomplished by understanding the morphology of the lesion along with distribution, color, arrangement, and body site. Thorough examination of rash should be done after undressing the patient in a proper light. A small magnifying lens can be used for better visualization. Inspect all skin and mucous membranes including hair, nail, scalp, and mucous membranes. Palpation of the skin augments the visual clues. Lesions should be palpated after wearing the gloves to see the texture of the lesion, if it is blanching or it bleeds on touch. Skin lesions can be classified into two types:

1. *Primary skin lesion*: It is the initial lesion, occurring early in a disease that has not been altered by trauma, manipulation, medication, secondary infection, or natural regression.
2. *Secondary skin lesion*: This is a lesion that arises later during the course of a disease or is created by scratching or secondary infection.

Tables 1 to **3** depict the basic morphology of primary, secondary, and special lesions. **Table 1** summarizes the primary skin lesions and **Table 2** summarizes secondary skin lesion.

DIAGNOSTIC TESTS

Simple diagnostic tests and cytology can aid in the rapid and reliable diagnosis or to rule the disease:

- KOH mount can diagnose fungus and molluscum contagiosum.
- Gram stain can aid in diagnosis of the type of bacterial infection.
- Tzanck smear will diagnose herpes or acantholytic cells (in case of blistering disease).

- Skin scrapings can help in diagnosing of mites such as scabies and pediculosis.
- Woods light or lamp produces invisible long wave ultraviolet radiation. It is a quickest technique for diagnosing erythrasma due to *Corynebacterium* infection (coral red fluorescence), fungal infection due to *Malassezia* infection (dull yellow fluorescence), *Pseudomonas* infection (yellow/green fluorescence), and porphyria cutanea tarda (orange/red color and urine fluorescence).
- Serological test to rule out syphilis [venereal disease research laboratory/treponema pallidum hemagglutination (VDRL/TPHA)], systemic lupus erythematous, and acquired human immune deficiency virus.

TABLE 1: Primary skin lesions. ***(For color version, see plate 19 to 21)***

S. No.	*Type of lesion*	*Description*	*Example*
1.	Macule	A circumscribed area of skin or mucous membrane different in color or texture from its neighboring tissue, measuring <1 cm in diameter.	
2.	Patch	A circumscribed area of skin or mucous membrane different in color or texture from its neighboring tissue, measuring >1 cm in diameter.	
3.	Papule	A small solid, elevation of the skin <1 cm in diameter.	

Continued

Continued

S. No.	Type of lesion	Description	Example
4.	Plaque	A solid elevated area of skin >1 cm in diameter, where the horizontal dimensions are more than vertical.	
5.	Nodule	A solid elevated area of skin >1 cm in diameter, which can be observed as an elevation or can be palpated.	
6.	Vesicle	A circumscribed elevated area of skin <1 cm in diameter, containing fluid other than pus.	
7.	Bulla	A circumscribed elevated lesion of >1 cm in diameter containing free fluid other than pus.	

Continued

Continued

S. No.	Type of lesion	Description	Example
8.	Pustule	A circumscribed area of the skin of any size containing visible purulent exudate.	
9.	Cyst	A closed cavity or sac with an epithelial, endothelial, or membranous lining, containing fluid or semisolid material.	
10.	Wheal	An elevated, evanescent compressible area due to dermal edema. It is pale and often surrounded by a dermal flare.	

- Skin biopsy is indicated in case of doubtful cases which cannot be confirmed by clinical examination.
- Complete panel of relevant investigations need to be performed to rule out systemic involvement.

Few pointers to aid in diagnosis: Fever with leukocytosis is mostly seen in cases of infection or autoimmune disease. Drug rashes may have elevated transaminases along with eosinophilia in drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome. Thrombocytopenia along with disseminated intravascular coagulation (DIC) and acute kidney disease may be indicative of bacteremia/toxic shock syndrome.

TABLE 2: Secondary skin lesion. ***(For color version, see plate 22 and 23)***

S. No.	*Type of lesion*	*Description*	*Example*
1.	Erosion	Loss of whole or part of the epidermis, but with the dermis left intact, and which heals without scarring.	
2.	Ulcer	A breach in continuity of the epidermis and at least a part of dermis, associated with necrosis of tissue and which heals with scarring.	3.	Excoriation	Loss of substance of skin produced by scratching (linear erosions).	4.	Scale	Visible exfoliation of skin.	

Continued

Continued

S. No.	Type of lesion	Description	Example
5.	Crust	Accumulation of dried up exudate, secretion, or hemorrhage on the skin surface as a result of its disruption.	
6.	Scar	A visible alteration in the appearance of the skin due to fibrous tissue replacing normal tissues destroyed by disease or injury.	
7.	Lichenification	Thickening of the skin with exaggeration of its normal marking often as a result of chronic scratching or rubbing.	
8.	Sclerosis	Circumscribed or diffuse hardening of skin usually due to fibrosis.	
BEDSIDE TESTS IN DERMATOLOGY

Few bedsides tests that are specific to the dermatological conditions can be done by the physician while examining the patient, as they can help in confirmation of the disease or help in differentiating from other skin disease.

- *Asboe-Hansen Sign*: There is enlargement of bulla by applying finger pressure to small, intact, and tense bulla. It is seen in pemphigus and bullous pemphigoid.
- *Auspitz sign*: There is pinpoint bleeding on removal of scales from the lesions of psoriasis by using blunt end of

TABLE 3: Special lesions. ***(For color version, see plate 24 and 25)***

Special lesions		
Burrow	A passage or a tunnel in the skin that houses a parasite, e.g., scabies.	
Comedones	A plug of keratin or a sebum in a dilated pilosebaceous orifice, e.g., acne vulgaris.	Purpura	Discoloration of skin due to extravasation of blood. • If >2 cm in diameter—ecchymosis • If <2 cm (pin point)—petechiae • If linear, it is called vibex	Telangiectasias	Permanent dilatation of capillaries.	
Continued

Continued

Special lesions		
Fissure	A small linear gap or slit in the skin surface.	
Sinus	A closed cavity or channel that permits the escape of pus or fluid.	
Milium	A tiny white superficial cyst with an epidermal lining containing keratin.	

pin or glass slide. It is more specific to psoriasis, but it can also be seen in Darier disease and actinic keratosis.

- *Carpet tag sign*: The adherent scale is removed from the lesions of discoid lupus erythematosus, the under-surface of the scale shows horny plugs that have occupied patulous hair follicles.
- *Cullen's sign*: It is seen as periumbilical ecchymosis in cases of acute hemorrhagic pancreatitis and ruptured ectopic pregnancy.
- *Dermographism*: When normal skin is stroked with a dull object, it becomes raised and inflamed to assume the shape of the stroke. It is commonly seen in physical urticaria.
- *Diascopy*: It is a refinement in which a piece of clear glass or plastic is pressed against the skin while the observer looks directly at the lesion under pressure. It is to determine if skin redness is due to blood within vessels (erythema) or extravasated into the skin (petechiae and purpura). The former will blanch with pressure, the latter will not.

- *Forchheimer sign*: It presents as dull red macules or petechiae seen on the soft palate during the prodromal period. It is seen in 20% cases of rubella and can also be seen in infectious mononucleosis.
- *Nikolsky sign*: It refers to easy peeling of skin on applying tangential pressure over a bony prominence and is classically seen in pemphigus, toxic epidermal necrolysis (TEN), and staphylococcal-scalded skin syndrome.
- *Nose sign*: It is seen in exfoliative dermatitis in which there is complete absence of erythema and scaling of the nose and perinasal areas.

EVALUATION OF THE NATURE OF DISEASES

- Dermatological diseases without systemic involvement or complications
- Dermatological diseases with systemic involvement or complications
- Primary systemic diseases with related cutaneous disorders
- Systemic diseases with unrelated cutaneous disorders

Studying in detail on each topic or disease is beyond the scope of this chapter. Hence, we will discuss common rashes seen in pediatric and adult patient presenting in ED. Major groups of dermatologic emergencies include:

- Vesiculobullous disorder and drug reaction
- Infections
- Autoimmune disorders
- Inflammatory cutaneous disorders
- Environmental disorder

VESICULOBULLOUS DISORDERS

- Erythema multiforme (EM) major
- *Stevens–Johnson syndrome (SJS)*: It is considered to be a severe form of EM
- *TEN*: It is considered to be more severe form of SJS
- Generalized bullous fixed drug eruption
- Pemphigus vulgaris
- Bullous pemphigoid
- DRESS syndrome

Table 4 depicts differentiation between EM, SJS/TEN, and bullous fixed drug eruption while **Table 5** presents differentiation between pemphigus vulgaris and bullous pemphigoid.

DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS/DRUG-INDUCED DELAYED MULTIORGAN HYPERSENSITIVITY

It is a severe idiosyncratic drug reaction, usually occurs 2–8 weeks after initiating the offending drug. Clinical manifestations include fever, rash, lymphadenopathy, hematological findings (eosinophilia, leukocytosis, etc.), and visceral involvement mainly abnormal liver function tests, which can mimic viral hepatitis. The cutaneous manifestations typically consist of an urticarial, maculopapular eruption and, in some instances, vesicles, bullae, pustules, purpura, target lesions, facial edema, cheilitis, and erythroderma.

INFECTIOUS DISEASES

Major cutaneous patterns of presentation include:

- *Petechial/purpuric lesions*: Chronic gonococcal septicemia, meningococcemia, subacute and acute bacterial endocarditis, Rocky Mountain spotted fever, and dengue hemorrhagic fever
- *Vesicular*: Herpes zoster, varicella zoster (chickenpox), neonatal herpes simplex virus, hand, foot, mouth disease, and Kaposi varicelliform eruption
- *Pustular*: Sepsis (staphylococcal endocarditis) and disseminated candidiasis
- *Maculopapular*: Viral infections, pityriasis rosea, scabies, hepatitis B, and rickettsial infections
- *Diffusely erythematous*: Staphylococcal scalded skin syndrome and toxic shock syndrome
- *Violaceous skin discoloration*: Necrotizing fasciitis and infectious gangrene
- *Annular erythema*: Lyme disease
- *Hansen's disease*: Usually mycobacterial infections do not constitute emergencies. But in few cases patients may

TABLE 4: Differentiation between EM, SJS/TEN, and bullous fixed drug eruption.

	EM major	***SJS/TEN***	***Generalized bullous fixed drug eruption***
Lesion pattern	Typical target lesion present	Flat/atypical target lesion present	Absence of target lesions/bullous lesions with surrounding rim of erythema
Mucosal involvement	Yes	Yes	Yes/no
Distribution	Mainly acral involvement/limbs	Widespread	Widespread
Blister/erosions	Yes at the center of target lesions	Yes <10%: SJS 10–30%: SJS/TEN overlap >30%: TEN	Yes
Recurrence history	Occasional	Rare	Common
Prognosis	Excellent	Mortality depends on risk factors (SCORTEN)	Generally favorable if <20% body surface area is involved

(EM: erythema multiforme; SCORTEN: SCORe of Toxic Epidermal Necrolysis; SJS: Stevens–Johnson syndrome; TEN: toxic epidermal necrolysis)

TABLE 5: Differentiation between pemphigus vulgaris and bullous pemphigoid.

	Pemphigus vulgaris	*Bullous pemphigoid*
Age	Middle aged	Elderly
Clinical features	Monomorphic lesions	Polymorphic lesions
Blisters	Flaccid blisters and ruptures easily	Tense blisters
Content of blisters	Fluid filled	Often hemorrhagic
Mucosal involvement	Common	Rare
Nikolsky sign	Positive	Negative
Tzanck smear	Acantholysis	No acantholysis

undergo "reversal reaction" after starting the treatment. This may produce erythema of skin along with swelling of subcutaneous tissues and nerve involvement.

NONINFECTIOUS CAUSES OF HEMORRHAGIC LESIONS

- *Coagulation abnormalities*: Idiopathic thrombocytopenia, DIC, and clotting factor deficiencies
- *TEN*: Initial lesion presents as petechial lesions
- *Vasculitides*: Leukocytoclastic vasculitis
- Raynaud's syndrome or disease

Usually it is difficult to differentiate maculopapular eruption caused due to drug and viral infection. **Table 6** demonstrates maculopapular drug rash and maculopapular viral exanthema.

TABLE 6: Maculopapular drug rash and maculopapular viral exanthema.

	Maculopapular drug rash	*Maculopapular viral exanthema*
History of drug rash	Present	Absent
Onset or rash	7–10 days after drug intake	Prodromal symptoms such as fever, conjunctivitis, headache, rhinorrhea, cough, sore throat, and myalgia present before onset of the rash
Temperature	Low to moderate	Low grade to high grade
Type of rash	Erythematous maculopapular rash on trunk, extremities, and folds. Progresses cephalocaudally. It is symmetrical.	Cephalocaudal distribution of maculopapular eruption and usually associated with lymphadenopathy
Pruritus	Mostly pruritic	Usually nonpruritic
Palms and soles involvement	Present	Spared
Laboratory investigations	Occasionally derangement of liver function test and raised eosinophil count	Usually shows elevated blood counts and lymphocytosis/ lymphocytopenia/ thrombocytopenia

NECROTIZING FASCIITIS

It is a bacterial infection that is rapidly progressive, often over hours, destroying muscle, and subcutaneous tissues. It is commonly associated with beta-hemolytic streptococci. The bacteria usually enter through surgical or traumatic wound and move quickly along facial planes destroying vessels and tissues.

URTICARIA AND ANGIOEDEMA

Urticaria is characterized by appearance of pruritic, evanescent, erythematous, and edematous lesions on skin called as wheals. Approximately 40% of patients with urticaria also experience angioedema. Acute urticaria (disease duration of <6 weeks) occurs usually from secondary causes such as allergic reaction to food, drugs, infections, or insect stings. Chronic urticaria is characterized by symptoms >6 weeks.

Urticarial lesions can sometimes be difficult to differentiate from urticarial vasculitis. However urticarial vasculitic lesions generally last longer than 24 hours and leave some hyperpigmentation as they resolve. Also urticarial vasculitic lesions tend to be painful and to burn rather than itch. When there is difficulty in differentiating urticaria from vasculitis, a skin biopsy may give a definite answer.

Angioedema manifests as sudden localized, nonpitting swelling of certain body parts including skin and mucous membranes. Acute episodes of angioedema can be life-threatening if it involves the larynx leading to the obstruction of upper airways and it is a major cause of death. Angioedema involving the lips, cheek, and tongue are common with bizarre presentations. Angioedema of the gastrointestinal tract frequently mimic an acute abdomen resulting in unnecessary surgical intervention and increased morbidity. Drug-induced angioedema, like other cutaneous drug reactions, is most frequently elicited by beta-lactam antibiotics and nonsteroidal anti-inflammatory drugs.

ERYTHRODERMA

It is also known as generalized exfoliative dermatitis. There is generalized skin redness and scaling. It is a potential presentation of a variety of diseases. It is an emergency in certain due to the fluid and electrolyte imbalances, tachycardia, disturbances in thermoregulation, and risk of cardiac failure. It can be due to underlying skin conditions such as staphylococcal scalded skin syndrome, contact or allergic dermatitis, atopic dermatitis, leukemia/lymphoma/ paraneoplastic, drug induced (includes DRESS), psoriasis, idiopathic, mycosis fungoides (cutaneous T-cell lymphoma/ Sézary syndrome), and pityriasis rubra pilaris.

INFLAMMATORY CUTANEOUS DISORDERS

- *Pyoderma gangrenosum*: It is one of a neutrophilic dermatoses. It is a dermatologic emergency because it is rapidly progressive, causing severe local tissue destruction. It is frequently misdiagnosed as an infectious process or a brown recluse spider bite and is treated by debridement.
- *Childhood vascular anomalies*: The most common vascular anomalies (about 3% of birth) that have potential to become dermatologic emergencies are infantile capillary hemangioma. When they occur around eye and oral cavity can cause significant morbidity and mortality. Some ophthalmologists suggest that even few days of obstructed vision in newborn can inhibit normal visual development so treated aggressively. Likewise enlarging infantile hemangioma of upper respiratory tract and oral cavity can result in acute emergent situation.
- *Acne fulminant*: Although acne is not usually considered an emergency condition, if not treated acutely, can lead to severe cutaneous scarring and psychological problem. The eruption is characterized by rapid suppuration of large, highly inflamed nodules and plaque resulting in ragged ulceration and scarring of chest, back and less commonly face. Often attendant with the cutaneous symptoms are fever, leukocytosis, arthralgia, and myalgia suggesting a systemic upregulation of the immune system.
- *Drug eruption*: On occasion, drug eruption can present as diffuse exfoliative erythroderma or red man syndrome. In addition to drugs, other causes of exfoliative erythroderma that must be ruled out include psoriasis, lymphoma, and flare of seborrheic or atopic dermatitis. Other that can cause dermatologic emergencies include toxic epidermal necrolysis, leukocytoclastic vasculitis, and severe urticarial or angioedema.
- *Kawasaki disease*: The mucocutaneous findings include conjunctival congestion, oropharyngeal lesion (mucosal inflammation), strawberry tongue, fissure lips, hand and foot erythema, and exanthema (generalized macular erythema). These findings along with lymphadenopathy, constitute the minor criteria for Kawasaki disease. Four of five minor plus one major criterion fever >38.3°C.

ENVIRONMENTAL DISORDERS

- *Heat stroke*: It is not a typical skin problem but in heat stroke patient's skin is erythematous, hot, and dry. These findings in association with unconsciousness should alert one to diagnosis.
- *Cutaneous sign of child abuse*: e.g., bruising and abrasion, burn with unusual pattern, e.g., cigarette burn that appears randomly over body, dunking scald injury which have distinct border or sometimes have doughnut pattern.
  - Generalized wastage and dermatitis
  - Traumatic alopecia
  - Bite mark of adult usually >4 cm
- *Lightning strike*: These patients have characteristic skin finding in addition to entry and exit wound skin can often exhibit whirled or fern-like erythema.
- *Scleroderma neonatorum*: It is typically seen in newborns but may occur up to 3 months of age. Clinically, it presents as a hardening of skin with decreased temperature, vascular mottling, and yellow white discoloration in a symmetric distribution usually over thigh and trunk.
- *Cholesterol emboli*: They can be present anywhere in body but cutaneous manifestation commonly occurs in lower extremities. This condition commonly occurs after angiography when trauma to aortic plaque dislodges cholesterol into circulation. Clinically patient presents acutely with fairly well demarcated areas of cyanosis or livedo reticularis on feet and lower leg, these areas can undergo necrosis or ulceration.

ACUTE SKIN FAILURE

It is a dermatological emergency where total dysfunction of the skin occurs due to different dermatological conditions. Acute skin failure is associated with hemodynamic changes, impaired thermoregulatory control, and metabolic complications. In addition, fluid and electrolyte imbalance and loss of essential nutrients affecting patient's survival. It requires multidisciplinary and intensive care approach. Adequate knowledge about monitoring these patients and hospitalization in specialized units can reduce the high morbidity and mortality associated with this condition.

Disposition of the Patient

- Patient requiring aggressive resuscitation should be treated in intensive care unit (ICU).
- *Admission for further assessment and treatment*: For patients who are ill but not toxic necessitate in patient care.
- *Observation in ED*: For patients such as anaphylaxis, angioedema, or urticaria, who respond to treatment quickly.
- Can be treated at home, after patients in ED have been thoroughly evaluated and are stable to be managed at home with proper instructions.
- *Referral to the dermatologist*: In patients when diagnosis is unknown or unclear.

SUMMARY

Skin diseases are one of the most common types of health issue faced by all age groups. The diagnosis of skin disease mostly depends on the expertise of the physician and result of skin biopsy, which is a time-consuming process. Skin disease identification and classification through automated computer-based system images identification is needed to improve for diagnostic accuracy as well as to handle the scarcity of skin specialist. Diagnosis and classification of skin disease from an image is challenging because many skin diseases have highly similar visual characteristics and highly depend on the features of the diseases. Better and cost-effective treatment can be delivered to the patient with accurate analysis of any skin diseases and improvement of the diagnosis techniques.

149 CHAPTER

Generalized Dermatologic Emergencies

Tejas D Patel

INTRODUCTION

An emergency physician may be the first to see a patient with life-threatening dermatologic conditions. Early recognition and treatment of the conditions help in reducing the mortality and mortality. Interruption of the normal anatomy and physiology of skin is caused by varied dermatological emergencies leading to a number of complications collectively known as acute skin failure. Acute skin failure has been defined as loss of normal temperature control and inability to maintain core body temperature; barrier mechanism against foreign material is also compromised. Fluid, electrolyte, and protein loss along with other serious complications such as sepsis, multiorgan failure, and pulmonary embolism can also happen. Understanding the pathogenesis and systemic complications of acute skin failure and aggressive management in intensive care unit significantly reduces the fatality rate due to dermatologic emergencies. For better understanding of the chapter dermatological emergencies are classified as shown in **Table 1**.

STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Synonyms: Lyell syndrome

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are blistering diseases of the skin. In 1922, Steven and Johnson described a condition which was characterized by disseminated cutaneous eruption with central necrosis, febrile erosive stomatitis, and severe purulent conjunctivitis. Adverse reactions of drugs are the common cause of these complex conditions (SJS and TEN). Adverse drug reaction is the cause in about >80% of the TEN and 50% cases in SJS. Condition is associated with widespread erythema, necrosis, and bullous detachment of extensive areas of epidermis. SJS is considered as erythema multiform major. Epidermal detachment in SJS is <10% while epidermal detachment in TEN is >30%. 10–30% cases overlap between SJS and TEN. Diagnosis is mostly clinical (**Figs. 1A** to **C**).

Clinical Presentation

The patient with SJS/TEN presents with fever, malaise, muscle and joint pain with purpuric lesions which occur on the face, upper torso, and proximal limbs. Lesions gradually involve other body parts eventually turning into fluid-filled blisters. Hemorrhagic crust on lips is characteristic. Ocular manifestations include conjunctivitis, clouding, symblepharon, corneal erosions, and photophobia. Erosion can spread to gastrointestinal (GI) tract and respiratory tract giving rise to symptoms such as dysphagia, diarrhea, pulmonary edema, and bronchopneumonia. Glomerulonephritis represents renal involvement. Evaluation of patient needs medication history and management of complications (**Table 2**).

TABLE 1: Etiologic classification of dermatologic emergencies.

Noninfectious	*Infectious*	*Autoimmune causes*	*Others*
• Stevens–Johnson syndrome (SJS) • Toxic epidermal necrolysis (TEN) • Pyoderma gangrenosum	• Staphylococcal scalded skin syndrome • Necrotizing fasciitis • Fournier's gangrene • Herpes zoster • Meningococcemia • Rocky mountain spotted fever • Febrile viral exanthems	• Type I (immunoglobulin E dependent) • Anaphylaxis and urticaria angioedema • Type II (cytotoxic) • Pemphigus group of diseases • Type III (immune complex) • Vasculitis • Lepra reaction type 2 • Type IV (delayed) • Lepra reaction type 1 • Graft-versus-host disease	• Psoriasis • Dermatitis (atopic, contact, and seborrheic) • Disorders of keratinization (lamellar ichthyosis, bullous, and nonbullous ichthyosiform erythroderma) • Cutaneous T-cell lymphoma

FIGS. 1A TO C: (A and B) Epidermal involvement in Stevens–Johnson syndrome (SJS); (C) Toxic epidermal necrolysis (TEN). ***(For color version, see plate 26)***

TABLE 2: Complications of SJS and TEN.

Acute complications	*Long-term complications*
• Thermoregulatory dysfunction • Fluid and electrolytes dysfunction (if >50% BSA involvement) • Anemia and leukopenia • Hypalbuminemia • Hyperglycemia • Life-threatening complication—septicemia	• Postinflammatory dyspigmentation • Onychomadesis (shedding of nails) • Abnormal photosensitivity and sweating • Ocular: Corneal and conjunctival scarring, dry eye, trichiasis, and entropion • Oral mobility limitation due to gingival synechiae • Lung: Bronchiolitis obliterans • GIT: Esophageal stricture • Urogenital: Vaginal and introital adhesions
Most common drugs associated with SJS and TEN are allopurinol, carbamazepine, lamotrigine, nevirapine, sulfamethoxazole and other sulfa antibiotics, sulfasalazine, nonsteroidal anti-inflammatory drugs, phenobarbital, and phenytoin	

(BSA: body surface area; GIT: gastrointestinal tract; SJS: Stevens–Johnson syndrome; TEN: toxic epidermal necrolysis)

Management

Indian Association of Dermatologist, Venereologist, and Leprologist (IADVL) consensus treatment guidelines for SJS/TEN.

Immediate Management

- Stop all drugs
- Fluid replacement
- Nutritional support
- Sterile Vaseline or Paraffin Gauze Dressing
- Temperature regulation
- Antacids and analgesics
- Initiation of disease-specific therapy—corticosteroids, cyclosporine, intravenous (IV) immunoglobulin, and plasmapheresis
- Other drugs—cyclophosphamide, thalidomide, N-acetyl cysteine, and pentoxifylline

Continued Management

- Ophthalmic and oral care
- Pulmonary care
- Antibiotics

Prognosis

Stevens–Johnson syndrome (5% mortality) has better prognosis than TEN (30–40% mortality) SCORe of Toxic Epidermal Necrosis (SCORTEN) score for probability of death (%) (**Table 3**).

PYODERMA GANGRENOSUM

Pyoderma gangrenosum is an uncommon, chronic and recurrent, idiopathic, and ulcerative condition (**Fig. 2**) predominantly involving the skin, with distinctive morphologic characteristics and frequent association with few systemic diseases.

Diagnostic Criteria for Pyoderma Gangrenosum

- *Major*:
  - Rapid progression of painful necrolytic cutaneous ulcer with an irregular, violaceous, and undermined border
  - Exclusion of other causes of ulceration

TABLE 3: SCORTEN score for probability of death (%).	
Parameters	***Points***
Age > 40 years	1
Presence of a malignancy	1
Epidermal detachment >30%	1
Heart rate >120 beats/min	1
Bicarbonate <20 mmol/L	1
Urea >10 mmol/L (28 mg/dL)	1
Glycemia >14 mmol/L (252 mg/dL)	1
Score and % mortality correlation (score 0: 1–3%) (score 2: 12%) (score 3: 35%) (score 4: 58%) (score >5: 90%)	

(SCORTEN: SCORe of Toxic Epidermal Necrosis)

FIG. 2: Pyoderma gangrenosum. ***(For color version, see plate 26)***

- *Minor*:
  - History suggestive of ulcer development at sites of trauma or clinical finding of cribriform scarring
  - Systemic diseases associated with pyoderma gangrenosum
  - Histopathological findings (sterile dermal neutrophilia ± mixed inflammation ± lymphocytic vasculitis)
  - Rapid response to systemic corticosteroid therapy (50% decrease in size within 1 month in response to a dose of 1–2 mg/kg/day)

In adults, the most frequent association is rheumatoid arthritis and in children it is ulcerative colitis.

Topical steroid or tacrolimus 0.1% ointment used for mild cases and severe cases respond to oral corticosteroid (1–2 mg/kg). Cyclosporine acts rapidly in corticosteroid resistant cases.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

It is commonly seen in infants and children due to exotoxin released by *Staphylococcus aureus* group 2 phage 71. Exotoxin is an epidermolytic toxin also called exfoliating toxin or epidermolysin. Clinically, intense erythematous cutaneous eruptions occur following an upper respiratory tract infection or purulent conjunctivitis. Painful erosions appear when

FIGS. 3A AND B: Necrotizing fasciitis. ***(For color version, see plate 26)***

erythematous sheets of skin are shed which is referred to as potato chip desquamation. Patient should be admitted and treated promptly with antibiotics covering *S. aureus*.

NECROTIZING FASCIITIS

Necrotizing soft tissue infections are divided into three categories according to their depth of involvement:

1. Necrotizing cellulitis
2. Necrotizing fasciitis (NF)
3. Myonecrosis (MN)

Necrotizing cellulitis progressing to involve fascia is considered to be NF (**Figs. 3A** and **B**); further extension of NF to muscle is MN.

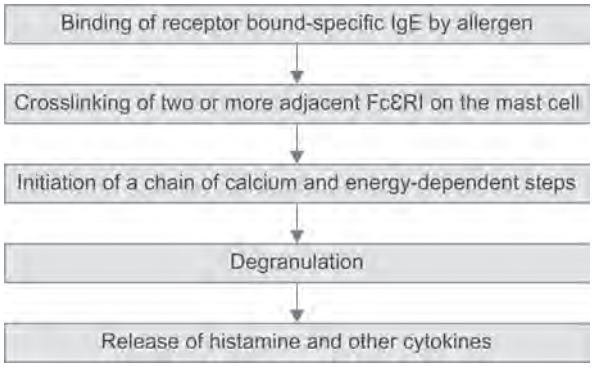
Predisposing factors include trauma, diabetes, drug injection, and burns. The most common sites of involvement are the extremities, trunk, perineum, head, and neck.

Necrotizing fasciitis of perineum and genitals is known as *Fournier gangrene*. Patient of NF usually have history of surgery wound and trauma. Type 1 NF is due to polymicrobial involvement and associated pathogens are streptococci, *Bacteroides,* or Enterobacteriaceae. Type 2 NF is caused by single pathogens such as beta-hemolytic streptococci and *S. aureus*. Fever, chills, erythema, edema, and pain over involved skin are common features. Erythematous skin gets a blue discoloration and vesicular and bullous lesions develop over erythematous skin with serosanguinous discharge. After that gangrene develops in next 4–5 days and black eschar by 10 days.

There is no specific diagnostic test for NF. Routine blood tests should be done. Radiology is used to detect gas within soft tissue and muscle. Hospitalization, surgical debridement, fluid resuscitation, and broad-spectrum antibiotic therapy are the main steps in the management.

URTICARIA (HIVES), ANGIOEDEMA, AND ANAPHYLAXIS

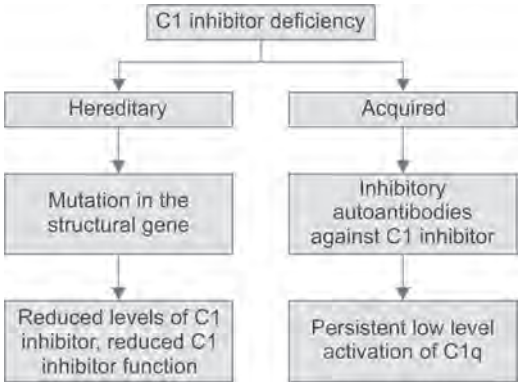
Urticaria is a common skin reaction that may be transient for 12–24 hours or last long for 6–8 weeks. Urticaria and angioedema have similar mechanism of action; histamine and other mediators (anaphylatoxins, C3a, and C5a) are released from mast cell and basophils (**Flowcharts 1** and **2**).



Binding of receptor bound-specific IgE by allergen
Crosslinking of two or more adjacent FcεRI on the mast cell
Initiation of a chain of calcium and energy-dependent steps
Degranulation
Release of histamine and other cytokines

(IgE: immunoglobulin E)

FLOWCHART 1: Mast cell-dependent urticaria and angioedema.



C1 inhibitor deficiency
Hereditary
Acquired
Mutation in the structural gene
Inhibitory autoantibodies against C1 inhibitor
Reduced levels of C1 inhibitor, reduced C1 inhibitor function
Persistent low level activation of C1q

FLOWCHART 2: Mast cell-independent urticaria.

Mostly these are type I hypersensitivity reaction mediated by immunoglobulin E (IgE) antibodies.

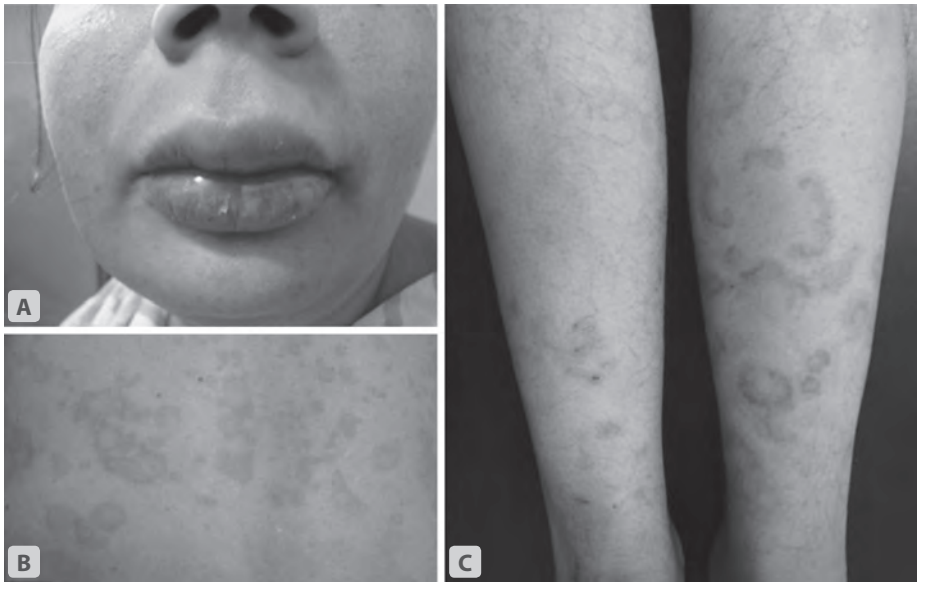
In urticaria, mast cells are present in superficial dermis while in angioedema mast cells are present in dermis and subcutaneous tissues. Both conditions are self-limiting but when respiratory mucus membranes are involved producing laryngeal edema it indicates a medical emergency (**Figs. 4A** to **C**). Differentiating features of urticaria angioedema and anaphylaxis are shown in **Table 4**.

Common trigger factors are allergens, insect envenomation, and physical stimuli such as heat, cold, vibration, or pressure. Patient on angiotensin-converting enzyme (ACE) inhibitors may develop angioedema. Slightly elevated pruritic, erythematous papules, and plaques are the common presenting clinical features. Relevant history taking and physical examination should be performed to determine cause. Laboratory workup is not helpful unless history and examination suggest some specific cause.

Investigations in chronic or recurrent urticaria—complete blood count (CBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), antinuclear antibody (ANA), rheumatoid factor (RF) testing, examination of stool for ova and parasites, serum complement assays, serum cryoglobulin, thyroid function test, and C1 esterase inhibitor functional assays.

Management

According to the European Academy of Allergy and Clinical Immunology (EAACI)/World Allergy Organization (WAO) guidelines if angioedema persists with urticaria, parenteral



FIGS. 4A TO C: (A) Angioedema; (B and C) Urticaria. ***(For color version, see plate 27)***

TABLE 4: Differentiating features of urticaria, angioedema, and anaphylaxis.

Urticaria	*Angioedema*	*Anaphylaxis*
(Synonyms: Hives and nettle rash)	(Synonyms: Quincke's edema and angioneurotic edema)	
• Itching • Edema in dermis • Well defined • Only skin involved	Painful rather than itchy, edema in deeper dermis, subcutaneous fat, and submucosal tissues. Ill defined, skin, mucous membrane, lips, larynx, gastrointestinal mucosa, causing upper airway obstruction, and angioedema is emergency	• Type I hypersensitivity urticaria and/or angioedema plus hypotension and tachycardia • Treatment: Epinephrine and corticosteroids

corticosteroid and epinephrine 0.3–0.5 mg should be given (**Table 5**).

PEMPHIGUS GROUP OF DISEASES

The word pemphigus is derived from a Greek word "pemphix" meaning blister or bubble. Pemphigus is a group of autoimmune blistering disorders characterized by intraepidermal split. Pemphigus can be classified into pemphigus vulgaris, pemphigus foliaceus, paraneoplastic pemphigus, immunoglobulin A (IgA) pemphigus, and drug-induced pemphigus. From the above-mentioned diseases pemphigus vulgaris and pemphigus foliaceus are the most common diseases to present to the emergency department in the form of acute skin failure (**Figs. 5A** and **B**).

Pemphigus vulgaris presents with vesicles, bulla, erosions or crusted plaques on skin, and oral erosions and ulcers. Antibodies (IgG class) are directed against desmoglein-1 (Dsg1) and desmoglein-3 (Dsg3). Pemphigus foliaceus presents with small flaccid bullae with crusting and scaling. Here target antigen is Dsg1. Bullae readily rupture, resulting in moist erosions and cornflake-like crusts.

TABLE 5: Stepwise approach for management of urticaria.

Basic treatment	*Step 1*	*Step 2*	*Step 3*	*Step 4*
• Avoidance of triggers and relevant physical factors if physical urticaria/angioedema is present	• Monotherapy with second-generation antihistamine (sgAH) • If inadequate control: After 2–4 weeks or earlier, if symptoms are intolerable	• Increase sgAH dose (up to four times) • If inadequate control: After 2–4 weeks or earlier, if symptoms are intolerable	• Add on to sgAH: Omalizumab [monoclonal antibody against immunoglobulin E (IgE) • If inadequate control: With in 6 months or earlier, if symptoms are intolerable	• Add on to sgAH: Cyclosporin

FIGS. 5A AND B: (A) Pemphigus vulgaris; (B) Pemphigus fallacious. ***(For color version, see plate 27)***

Most common complications are septicemia or secondary bacterial infections, hypoproteinemia resulting from decreased oral intake and iatrogenic side effects of corticosteroids such as hyperglycemia and osteoporosis.

Mainstay of treatment for pemphigus is systemic corticosteroids and prednisolone is the most preferred agent started at a dose of 0.5–1 mg/kg. It is tapered off by 50% every 2 weeks after 80–90% of lesions have healed. In recent times, rituximab (IgG type chimeric monoclonal antibody against CD20) has emerged as a popular therapy due to its advantages of long-term remission and lesser steroid induced side effects.

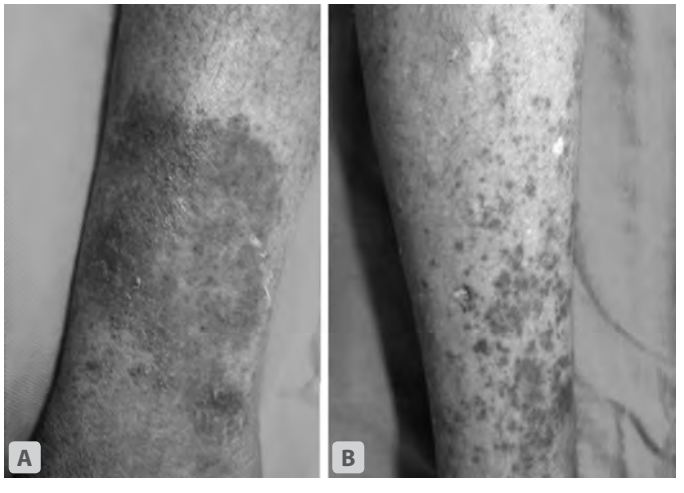
Other treatment modalities include dexamethasone-cyclophosphamide pulse, azathioprine (2–4 mg/kg/day), mycophenolate mofetil (2 g/day), cyclosporine (3–6 mg/kg/day), and IV immunoglobulin (2 g/kg/cycle divided over 3–5 days, minimum of three cycles).

VASCULITIS

Systemic vasculitis primarily classified in to primary vasculitis syndrome and secondary vasculitis syndrome. Primary vasculitis syndrome is a type of vasculitis caused by inflammation of blood vessels while secondary vasculitis syndrome is caused by underlying connective tissue disease, tumor, infections and drug allergies. The etiology of both vasculitis syndrome is not clear. Primary vasculitis syndrome and secondary vasculitis syndrome are included within the systemic autoimmune disease (**Figs. 6A** and **B**).

Conditions where vasculitis should be suspected:
- Fever of unknown origin
- Multisystem disease
- Active glomerulonephritis
- Ischemic symptoms in young patients
- Palpable purpura
- Mononeuritis multiplex

Pathogenetic factors in vasculitis:
- Immune complex deposition
- Complement activation
- Antineutrophilic cytoplasmic antibodies
- Cell-mediated immunity:
  - *Three types*: Small vessel, medium vessel, and large vessel vasculitis
  - *Most common type*: Leukocytoclastic vasculitis
  - *History is important*: Medications [penicillin (PCN), nonsteroidal anti-inflammatory drugs (NSAIDs), sulfas, and cephalosporins]
  - Workup for systemic involvement
  - *Treatment*: Eliminate cause, treat infection, steroids, colchicine, and immunosuppressants



FIGS. 6A AND B: Vasculitis. ***(For color version, see plate 28)***

LEPRA REACTION

Lepra reaction occurs during the treatment course of leprosy. Lepra reactions are treated as emergencies because they may lead to permanent damage to nerves, limbs, or may cause blindness. There are two types of lepra reaction (**Table 6**).

PSORIASIS (ERYTHRODERMIC PSORIASIS)

It is a generalized form of psoriasis involving >90% body surface area (BSA) with erythema, induration, and superficial scaling (**Figs. 7A** to **D**).

Precipitants are infections, alcohol, drugs, and sudden withdrawal of corticosteroids. It is diagnosed by histopathological and clinical features. Erythrodermic psoriasis is a kind of acute skin failure so main focus of management is directed to skin barrier repair, fluid and electrolyte balance, cyclosporine for short period to manage acute flare up, and then addition of methotrexate for maintenance, if not contraindicated.

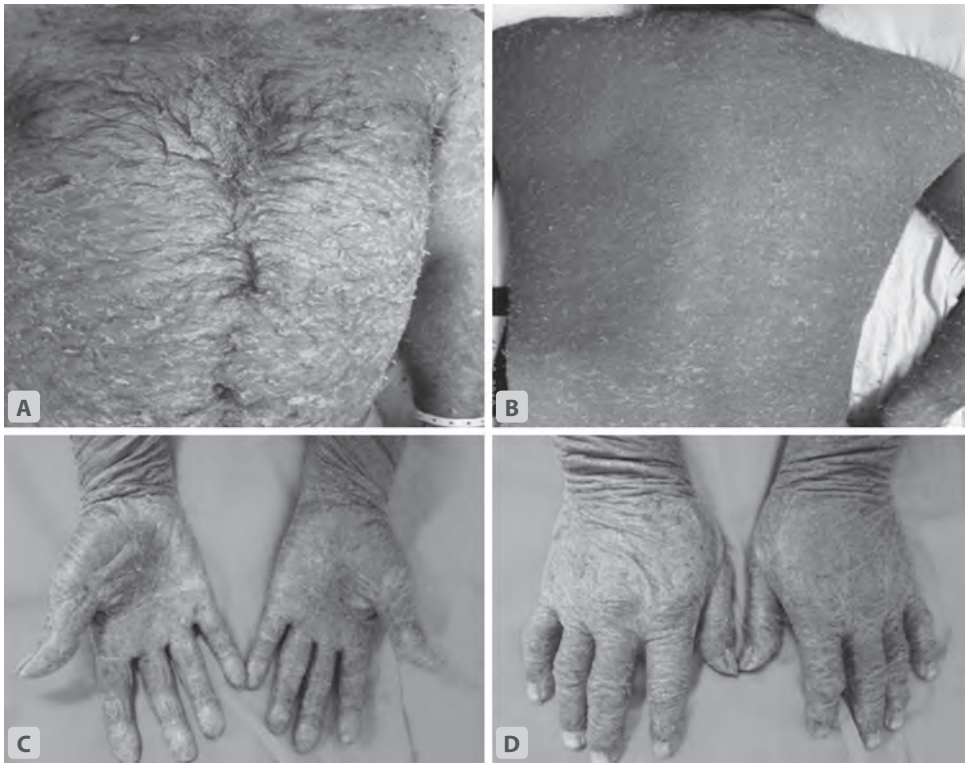
ACUTE SKIN FAILURE

Acute skin failure is a state of total failure of skin functions due to various dermatological conditions requiring a multidisciplinary and intensive care approach for management. The major consequences of acute skin failure are:
- *Fluid and electrolyte imbalance*: In normal circumstances, water loss through the skin is 1 mL/cm^2/h. In patients with acute skin failure, the daily water loss through skin increases to 40 times more than the normal range. This is due to the destruction of skin layer stratum corneum responsible for the barrier function of the skin. If about 50% BSA is affected, estimated daily fluid loss is up to 4–5 L, loss of protein (40 g/L), Na (120–150 mmol/L), Cl (10–90 mmol/L), and K (5–10 mmol/L). The manifestations are dehydration and decreased urinary output, electrolyte imbalance (low Na^+ and high K^+) and raised serum levels of urea and creatinine.
- *Infection*: Damaged barrier function of the skin supports growth of endogenous and exogenous organisms resulting in systemic infection and increases the incidence of septic complications.
- *Hemodynamic alteration*: Persistent inflammation of the skin leads to marked peripheral vasodilatation and increased cutaneous blood flow nearly doubles the cardiac output resulting in high-output cardiac failure in compromised cardiovascular system (elderly, hypertensive, ischemic, or valvular heart disease).
- *Thermoregulatory dysfunction*: Either hypothermia or hyperthermia can occur depending on surrounding environment.
  - *Hypothermia*: It manifests as sign of septic shock. Compensatory mechanisms against hypothermia are shivering [due to increased interleukin-1 (IL-1)] and raised basal metabolic rate (BMR).

TABLE 6: Differentiating features of lepra reactions.

Features	*Type 1*	*Type 2*
Type of immunological reaction	Delayed type hypersensitivity reaction (type 4)	Antigen antibody immune complex reaction (type 3)
Type of patients affected	Borderline type (BT, BB, and BL)	LL rarely BL
Constitutional signs and symptoms	Rare (fever, malaise, arthralgia, and myalgia)	Common (fever, malaise, arthralgia, and myalgia)
Type of the skin lesions	Existing skin lesions suddenly become reddish, swollen, warm, painful, and tender	• Fresh red, painful, tender, cutaneous nodules, and plaques • The existing lesions remain unchanged
Nerve involvement	Nerves close to skin lesions may be enlarged, painful, and tender due to acute neuritis with loss of nerve functions (loss of sensation and muscle weakness). Neuritis may also appear suddenly	Nerves may be affected but not as common or as severe as in type 1 reaction
Eye involvement	Corneal anesthesia and lagophthalmos may occur due to nerve involvement (5th and 7th CN)	Internal eye disease such as iritis, iridocyclitis, glaucoma, and cataract are common
Other organs	Not affected	May be affected: Lymphadenitis, epididymo-orchitis, painful dactylitis, periosteal pain, myositis, arthritis, and glomerulonephritis are common
Treatment	NSAIDs and corticosteroids	NSAIDs, corticosteroids, clofazimine, thalidomide, and Biologics

(BB: midborderline; BL: borderline lepromatous; BT: borderline tuberculoid; CN: cranial nerve; LL: lepromatous leprosy; NSAIDs: nonsteroidal anti-inflammatory drugs)



FIGS. 7A TO D: Psoriasis. ***(For color version, see plate 28)***

  - *Hyperthermia*: It is seen in conditions like erythroderma due to psoriasis as skin is already hypohidrotic or anhidrotic as a result of intraepidermal occlusion of the sweat duct.
- *Metabolic abnormalities*: Hypercatabolic state leads to increased energy expenditure. Further worsening of hypercatabolic state is caused by amino acid breakdown from hyperglycemia and glycosuria which results from relative insulin resistance and decreased insulin secretion.

Management

The management of patients with acute skin failure requires well-coordinated teamwork. Care should focus on double

barrier nursing care; monitoring hemodynamic changes; fluid, electrolyte balance, and nutrition; prevention of complications (e.g., sepsis); prompt identification of risk factors; and topical therapy.

Monitoring Hemodynamic Changes

Due to disruption of barrier mechanism of the skin, continuous loss of water occurs through the body surface and it is thus important to monitor hourly hemodynamic status via pulse rate, heart rate, urine output (50–100 mL/h). Temperature, blood glucose, and gastric content to be monitored every 3 hourly.

Fluid, Electrolyte, and Nutrition

Fluid and electrolyte administration to correct and maintain hemodynamic and electrolyte equlibrium is a necessity. In the initial 24 hours, the IV fluid administered contains human albumin 1 mL/kg/%BSA and isotonic saline 0.7 mL/kg/BSA. Though TEN is often compared with burn injury, the fluid requirement is three-fourths of that of patients with burns covering the same area. This is because the depth of tissue destruction and underlying vascular injury is less in case of TEN. 1,500–2,000 mL of nasogastric feed is required. Start with total 1,500–2,000 kcal/day then daily increment of 500 kcal up to 3,500–4,000 kcal/day and 2–3 g/kg/day protein intake in adults can be added (3–4 g/kg/day in children).

Nursing Care and General Measures

The environmental temperature should be maintained at 30–32°C. Use of air fluidized beds and burn cage ensures patient comfort and easy handling. Regular cleaning and removal of crusts from the oral and nasal cavities and care of the eyes, genitalia, and perianal region is essential to prevent infections.

Topical Management

Various topical agents such as silver sulfadiazine, nonphysiologic lipids (petrolatum jelly and lanolin), and physiologic lipids (component mixture of cholesterol, ceramide, and free fatty acids in an optimized ratio of 3:1:1) should be used as barrier repair agents and to accelerate the barrier repair after cleaning.

Antibiotics

Prophylactic antibiotic use in absence of strong evidence of infection is not recommended by many authors. Indications of antibiotic use are as follows:

- Culture from skin and urine shows high bacteria count
- Sudden hypothermia in a relatively stabilized patient
- An altered sensorium (first sign of sepsis)
- Signs and symptoms of infection related to particular system, e.g., increased respiratory rate due to hypoxia resulting from pneumonia

SUMMARY

Sudden alteration in the anatomy and physiology of skin results from certain generalized dermatoses can lead to life-threatening syndrome of acute skin failure. Understanding of etiopathogenesis and their prompt and early management in emergency department itself can salvage many lives.

150
CHAPTER

Approach to Joint Pain

Sourabh Malviya

INTRODUCTION

Joint pain is one of the most common presentations in emergency ward. Thorough initial assessment always helps to differentiate and characterize joint pain. All emergency practitioners should be well versed in the evaluation of the "red hot joint". Rarely it can be life-threatening and may be sole manifestation of serious systemic diseases and infections. So "red flags" of joints should be in the mind of every emergency department (ED) clinician if he/she encounters any patient of acute joint pain. These "red flags" are septic arthritis, acute gout, and fracture. On the other hand, inflammatory arthritis can present with acute joint pain and swelling and if not diagnosed and treated on time can lead to long-term deformity and disability. So through clinical examination and then evaluation should be done for any joint pain.

EVALUATION OF JOINT PAIN

Clinical History

Detail clinical history and physical examination (**Table 1**) may help in evaluation whether patient has articular or periarticular disease. If articular, then type, number, and areas of joints involved can give information of probable disease.

Location of Pain

Articular pain may be described as generalized sensation of joint pain. On the other hand, periarticular pain is localized to a specific site of inflammation.

Acute or Chronic

Injury, infection or inflammatory process, or acute exacerbation of a chronic arthritis can give rise to acute joint pain. History of recurrent acute pain could be due to chronic arthritis.

Worsening Factor

Joint pain is often exacerbated by both active and passive motion of the join, can also occur at rest, as seen in acute inflamed joint (inflammatory or infective arthritis). If muscles or tendons are actively or passively moved then periarticular pain can be exacerbated, commonly seen with overuse conditions.

TABLE 1: Evaluation (history and physical examination) of joint pain.

History	***Probable diagnosis***
Fever and history of infection recently	Septic arthritis
History of immunosuppression	Septic arthritis
Elderly and diabetic	Septic arthritis
IV drug abuser	Septic arthritis
History of hyperuricemia	Gout
History of trauma	Fracture
Cancer	Pathologic fracture
History of inflammatory back pain	Spondyloarthritis
History of uveitis/psoriasis/IBD	Spondyloarthritis
Physical examination	
Examination clues	***Probable diagnosis***
Sick look or toxic	Septic arthritis
Limited range of motion	Fracture or septic arthritis
Single red hot swollen joint	Septic arthritis
Pustular skin lesion	Gonococcal arthritis
Heart murmur	Endocarditis
Urethritis/cervicitis/conjunctivitis	Reiter's syndrome
Firm hepatosplenomegaly	Malignancy
Multiple joints involved	Inflammatory arthritis
Malar rash and Raynaud's phenomenon	SLE
Psoriasiform rash	Psoriatic arthritis
Tophi	Gouty arthritis

(IBD: inflammatory bowel disease; IV: intravenous; SLE: systemic lupus erythematosus)

Number of Joints Involved

Bursitis/tendinitis or any periarticular problem usually involve single joint. Arthritis should be differentiated into monoarticular (septic and gouty arthritis), oligoarticular [juvenile idiopathic arthritis (JIA), sarcoidosis, and

seronegative spondyloarthritis (SpA)] or polyarticular [Acute: Viral arthritis or gonococcemia; Chronic: Rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), psoriatic arthritis, or dermatomyositis] (**Table 2**).

Symmetric or Asymmetric

If it is polyarthritis then it should be looked whether it is symmetric (e.g., drug-induced arthritis, RA, and SLE) or asymmetric (e.g., psoriatic arthritis, gonococcal arthritis, and acute rheumatic fever).

Distribution of Joints

Location of joint pain may be characteristic of some arthritis. Proximal interphalangeal (PIP) commonly involved in RA, SLE, osteoarthritis (OA), and distal interphalangeal (DIP) joints of the hand in psoriatic arthritis, OA, or sarcoidosis. Metacarpophalangeal (MCP) commonly affected in RA. Gout commonly affects the great toe metatarsophalangeal (MTP) joint (known as podagra). Ankle and knee commonly affects in OA or seronegative SpA. Hip joint is usually involved in JIA, OA, or SpA.

Associated Clinical Findings

Extra-articular signs and symptoms should be elicited in a patient of joint pain to reach proper diagnosis. High-grade fever can be a symptom of septic arthritis whilst low-grade of inflammatory arthritis or connective tissue diseases (CTDs). Other constitutional features such as Raynaud's phenomenon, malar rash, erythematous skin rash, recurrent hair fall, and recurrent oral ulcer may suggest SLE while dryness of mouth or eyes more likely of Sjögren's syndrome. Track marks in skin may be of injection drug users in endocarditis. Ocular findings can also give some clues like episcleritis may points towards RA or anterior uveitis for ankylosing spondylitis. Tophi in the skin or uric acid stones in kidneys may be associated with gouty arthritis. Purulent urethritis suggests infective etiology like gonococcal disease. The combination of palmoplantar skin lesions, conjunctivitis, and urethritis suggests Reiter's syndrome.

Past Medical History

One should always enquire about past history of chronic inflammatory arthritis other autoimmune disease, gout, hemophilia, and malignancy. Drug history should be taken as few drugs do have joint or skin manifestations. Thiazide diuretics increase uric acid levels and may precipitate gout. Isoniazid, procainamide, and hydralazine therapy may lead to a lupus-like syndrome. Family history is important in diagnosing few arthritis, especially seronegative SpA. Inquiries about overuse activities, sports, injection drug use, and sexual history should also be made. History of infections like tuberculosis (TB) or leprosy should be elicited to look for infective arthritis related to said diseases.

Physical Examination

To reach into differential diagnosis of joint pain in ED after history thorough physical examination should be conducted.

General Examination

With mere general appearance sometimes clinician can make out what patient could be having, like if infective or septic arthritis patient will have sick look. Abrasions or contusions may be there in case of traumatic joint.

Infective or traumatic conditions may give rise to tachycardia or hypotension. Inflammatory arthritis or CTD typically present with a normal temperature or low-grade fever, and possibly mild tachycardia or tachypnea due to pain.

Examination of Joints

Joint swelling may be secondary to hemorrhagic fluid from an injury, infection (purulent fluid), or due to synovitis, excessive amounts of synovial fluid. Initial look to be given to number of joints involved. If monoarticular, predominantly large joints of the the lower limb, then it could be be crystal arthritis. If nearby skin is indurated and some signs of cellulitis is there along with red swollen joint then infection will be more likely. In case of knee pain if both joints are involved, looks swollen, may be one more than other then one should think of OA. OA of hands commonly involves first carpometacarpal (CMC) and DIP joints. While in inflammatory arthritis like RA mainly small joints of hands (PIP/MCP) are affected. Joints will be swollen in RA and are mostly symmetrical. In RA there can be deformities of hands involved, but in CTD like lupus there may not be the same. Tophi anywhere in the skin or joint line can suggest gouty arthritis.

Typical signs of inflammation would be there in case of inflammatory arthritis or infective arthritis or crystal arthritis such as redness, warmth, tenderness, and range of motion will be reduced. These findings should always be compared to opposite joint. These palpatory examination findings can also take examiner towards diagnosis, can delineate if its particular joint structure (ligament or tendon), or whole joint. Swelling,

TABLE 2: Differential diagnosis as per number of joint involved.

Monoarticular	*Oligoarticular*	*Polyarticular*	*Periarticular*
Septic arthritis	Reiter's syndrome	Acute rheumatic fever	Bursitis
Hemarthrosis	Sarcoidosis	Drug-induced arthritis	Cellulitis
Osteoarthritis	Juvenile idiopathic arthritis	Gonococcal arthritis	Tendonitis
Gout/pseudogout	Lymphoreticular malignancy	Systemic lupus erythematosus (SLE)	
Trauma	Oligoarticular onset polyarthritis	Rheumatoid arthritis	
Monoarticular onset polyarthritis	Seronegative spondyloarthropathies	Seronegative spondyloarthropathies	
	Reiter's syndrome	Viral arthritis	

particularly due to a joint effusion, may be palpable if not easily visualized on inspection.

Range of motion may be decreased secondary to pain from degenerative joint disease, inflammation, infection, or injury or with increasing age. Hypermobile joints may occur with joints that are unstable from ligamentous injury, or in association with joint hypermobility syndrome such as benign hypermobile joint syndrome and Ehlers–Danlos syndrome. Few tests can help examiner to look for subtle effusion in joint such as patellar tap test or wave test in the knee joint.

Patellar Tap Test

The patient is lying in supine with the leg extended. Examiner puts pressure on the proximal side of the knee in an effort to squeeze the fluid out of the suprapatellar pouch. The fluid can be moved under the patella while maintaining the pressure on the suprapatellar pouch; the examiner uses his/her other hand to press up on the medial and lateral recesses forcing the fluid under the patella. Tapping down the patella with the index to create an upward and downward movement and a palpable "click" as the patella hits the underlying femur. If the test is negative, the femur and the patella are already in contact. A positive test is when the patella can be felt to move down through the fluid and rebounds on the patella. The test can be false positive, therefore we must always test both sides to compare.

Fluid Wave Test

It is used when the effusion is <30–50 cc. The patient lies supine and examiner presses his/her fingers in both parapatellar gutters. Because there is a pressure from below upward, the gutters are emptied. The patient is asked to stand while the examiner keeps his/her fingers in the parapatellar gutters. If examiner releases his/her fingers and the fluid comes back in the parapatellar gutters, it is a positive sign. Pain in weight bearing joint suggest arthritis. Periarticular structural problem commonly results in pain during active range of motion.

Detail General and Systemic Examination

Detail general and systemic examination should be done in presence of other patient complaints, signs, or symptoms (**Table 3**). A detailed examination will be helpful in identifying an underlying systemic disease, like skin tightening in scleroderma, heart murmur of endocarditis, pharyngitis or eye findings of associated arthritides, or skin rashes of SLE or of dermatomyositis. Reduced salivary pool in oral cavity or reduced tear secretion points towards Sjögren's syndrome. Hypoesthetic patch with dactylitis may suggest leprosy. Chronic cough with chest findings like localized crepitations with history of TB can guide to us diagnosing Poncet's arthritis.

LABORATORY TESTS

Evaluation through blood tests is not of very much significance in reaching diagnosis, but clinical examination. Leukocytosis may suggest infective etiology of joint pain, while anemia may point towards chronic arthritis like RA. Inflammatory markers [erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)] may be elevated in infection or inflammatory arthritis but may be nonspecific sometimes. Hyperuricemia can be there in up to 5% patient in normal individual but in case of acute gout, serum uric acid levels are often normal. Any patient presented to ED if has polyarthritis, few tests to be done, routine tests such as complete blood count (CBC), liver function tests (LFTs), kidney function tests, and also subjected to rheumatoid factor (RF) if symptoms are >6 weeks duration. In RA, RF has sensitivity of around 80–95% but specificity 55–60%. Anti-cyclic citrullinated peptide (CCP) antibody can also be done if RF is negative or for prognostication and in some cases of diagnostic dilemma if clinical profile suggests RA. Anti-CCP has 50–60% sensitivity and 95–98% specificity in RA. If some other features are there apart from joint pain which are mentioned for CTD then antinuclear antibody (ANA) can be ordered. Gold standard method of ANA is by indirect immunofluorescence rather than enzyme-linked immunosorbent assay (ELISA). For further characterization of CTD, extractable nuclear antigen (ENA) profile may help in further delineating diagnosis. In case of acute onset polyarthritis associated with fever, viral etiology like chikungunya fever should be suspected, especially if it is of short duration of <6 weeks. Routine blood tests should be done such as CBC, LFT, and parvovirus and so few viral markers such as human immunodeficiency virus (HIV), hepatitis B surface antigen (HBsAg), and anti-hepatitis C virus (HCV). If clinical possibility of infection is there than blood culture do guide us if there is hematogenous spread. In case of trauma hemarthrosis can be suspected but if not, then coagulation disorders should be ruled out with routine coagulation profile such as prothrombin time (PT), partial thromboplastin time (PTT), bleeding time, and platelet count.

SYNOVIAL FLUID ANALYSIS

Synovial fluid analysis (**Table 4**) is a very useful tests to march towards diagnosis, especially in case of septic arthritis, crystal arthritis, or to differentiate between inflammatory versus infective arthritis and also in a case of joint effusion if diagnostic dilemma. These can be done through arthrocentesis. Synovial fluid analysis includes routine such as cell count and differential, sugars, or glucose and microscopy such as Gram stain and culture. Also crystal analysis should be done. Gram stain and cultures should send to microbiology laboratory once aspirated. Crystal analysis is performed using polarizing microscopy, with monosodium urate crystals in gout appearing as, needle-shaped crystals that are negatively birefringent. In contrast, calcium pyrophosphate crystals in pseudogout appear as polymorphic (often rhomboid) positively birefringent crystals.

IMAGING

In ED setting, X-rays are indicated for patients with a history of significant trauma looking for fractures, deformities, neoplasm, osteomyelitis, avascular necrosis, or other bone disease or foreign bodies. Radiographs may show loss of joint space, periarticular osteopenia, or erosions. In infective or septic arthritis, one may find subchondral bone destruction, erosions, or periosteal new bone formation. Ultrasonography may be useful in confirming a joint effusion, tendinitis, or tenosynovitis and can also be used to guide joint aspiration. For further confirmation of findings, computed tomography can be done for better bony anatomy, whereas magnetic resonance imaging (MRI) is extremely useful for defining soft tissue pathology.

TABLE 3: Causes of joint pain and characteristic features.

Diagnosis	*Symptoms*	*Signs*	*Evaluation*
Osteoarthritis	Monoarticular acute flares with chronic arthritis without any systemic findings. First CMC, DIP, PIP, joint and knees and first MTP joints are most commonly affected	Generally elderly age groups are affected. Joint examinations have crepitus and swelling in the affected joints. Bouchard's nodes (PIP) and Heberden's nodes (DIP) often present in the hands	CBC and biochemistry is often normal; inflammatory markers (ESR/CRP) typically normal. Plain radiographs demonstrate formation of osteophytes and joint space narrowing
Gout	Monoarticular symptoms, with MTP joint of the great toe. At onset pain may be severe. Systemic symptoms are uncommon. Tophi can be there on examination in few cases, mostly in polyarticular involvement	Patients are generally afebrile. Affected joints are erythematous, warm, and painful on movement	• Serum uric acid may be normal in acute attacks. Synovial fluid analysis demonstrates negatively birefringent, needle-shaped crystals and high WBC counts in the fluid • If turbid or purulent fluid then associated septic arthritis must be ruled out by joint fluid Gram stain and culture
Pseudogout	Can be seen in osteoarthritic joint. Monoarticular arthritis usually occurring in the knee, wrist, ankle, and elbow. More than one joint maybe involved. Typically less acute and less severe than gout	Affected joints are erythematous, warm and painful to touch, or movement. Systemic systems typically absent	CBC and biochemistry is often normal; inflammatory markers (ESR/CRP) typically normal. Radiographs sometimes show calcifications (chondrocalcinosis) in joints, tendon insertions, ligaments, and bursae. Synovial fluid examination under polarized microscopy will reveal rhomboidal, weakly positive birefringent crystals of calcium pyrophosphate dehydrate
Septic arthritis	Mostly monoarthritis, erythema, warmth, and swelling. More than 70% of cases involve large joints. Associated symptoms may be fever with chills, loss of appetite, and malaise	Affected joints are erythematous, warm, and exquisitely sensitive to touch or movement. Fever may be present	Leukocytosis may be there. ESR is commonly elevated. CRP may be disproportionately higher than ESR. Blood cultures may grow etiologic agents (about half). Synovial fluid analysis shows marked polymorphonuclear leukocytosis. Gram stain may demonstrate organisms (50–70%), although synovial culture is the gold standard. Plain radiographs could suggest soft tissue swelling only
Rheumatoid arthritis	Polyarticular, usually symmetric, arthritis with acute flare-ups occurring in the context of chronic disease. The hands (MCP and PIP joints), wrists, elbows, and feet (MTP joints) are most often affected. Constitutional/extra-articular symptoms may be there with joint pain lasting months	Joints are warm, tender, and swollen. Deformities such as *swan neck and boutonniere* deformities in the hand, and muscle atrophy and subcutaneous nodules maybe present	• Synovial fluid is typically inflammatory. ESR/CRP is often elevated • Hemoglobin may be low due to anemia of chronic disease. Rheumatoid factor, an antibody against IgG, is positive in 70–80% of patients but is nonspecific. Radiographs demonstrate soft tissue swelling, periarticular osteopenia, erosions in joints or joint space narrowing
Seronegative spondyloarthropathies	Polyarticular and symmetric arthritis often associated with other symptoms such as psoriatic rash, low back pain from sacroiliitis, urethritis, or uveitis. Family history of similar illnesses (ankylosing spondylitis, psoriatic arthritis, arthropathy of IBD, Reiter's syndrome, and other reactive arthritides) often present. Onset is subacute (may occur over several months). Morning stiffness may be a component of all of these	In addition to polyarticular and symmetric arthritis, a variety of clinical signs related to the underlying condition (psoriatic rash or uveitis) may be present	Laboratory analysis shows a negative rheumatoid factor, although CBC may show mild anemia with elevated WBC. ESR is often elevated. Up to 80% of patients have HLA-B27 marker. Radiographs may demonstrate sacroiliitis and "bamboo spine" in ankylosing spondylitis. Synovial fluid is typically inflammatory

Continued

Continued

Diagnosis	*Symptoms*	*Signs*	*Evaluation*
Trauma/ hemarthrosis	Monoarticular joint pain and swelling, with history of known trauma. In the case of coagulopathy, a history of trauma may be absent. Systemic symptoms are absent, although a personal or family history of bleeding diatheses may be present in patients with coagulopathy	Pain and swelling in the affected joint. Signs of inflammation are minimal acutely. Systemic signs, such as fever are typically absent	Laboratory testing (PT, PTT, bleeding time, and platelet count) may demonstrate evidence of coagulopathy if the hemarthrosis is atraumatic. Radiographs may demonstrate fracture if traumatic etiology. The synovial fluid is bloody, with <10,000 WBC presence of marrow elements possible in trauma
Viral arthritis (immune complex disease)	• Polyarticular (symmetric or asymmetric) concomitantly or following viral syndrome, typically rubella, hepatitis B, parvovirus, mumps, or adenovirus. Typically, the PIP, knee, ankle, and MCP joints are most commonly affected • Other symptoms dependent on the temporal relationship of the arthritis to the primary viral infection; fever with swollen lymph nodes may be the only other symptoms	Fever may be present, and signs of hepatitis or other specific viral illness may be noted. The arthritis is typically severe	Elevated WBC count may be noted. Liver function tests may be abnormal in hepatitis, and should be followed with serologies for specific viral etiologies. The synovial fluid is typically noninflammatory, with cell counts—2,000 cells/mm^3. May develop inflammatory characteristics as the disease progresses

(CBC: complete blood count; CMC: carpometacarpal; CRP: C-reactive protein; DIP: distal interphalangeal; ESR: erythrocyte sedimentation rate; HLA-B27: human leukocyte antigen B27; IBD: inflammatory bowel disease; IgG: immunoglobulin G; MCP: metacarpophalangeal; MTP: metatarsophalangeal; PIP: proximal interphalangeal; PT: prothrombin time; PTT: partial thromboplastin time; WBC: white blood cell)

TABLE 4: Synovial fluid analysis.

Characteristics	*Normal*	*Noninflammatory*	*Inflammatory*	*Septic*	*Traumatic*
Color	Colorless	Yellow	Yellow	Yellow	Red
Appearance	Clear	Clear	Cloudy	Cloudy	Cloudy
WBC/mL	<200	<2,000	2,000–100,000	>100,000	
% PMNs	<25	<25	>50	>95	
Crystals	None	None	May be present	None	None
Cultures	Negative	Negative	Negative	Positive	Negative
Conditions		Trauma, osteoarthritis, and viral infections	Inflammatory arthritis such as, RA, spondyloarthritis, SLE, acute rheumatic fever, reactive arthritis, and crystal-induced arthritis	Bacterial arthritis and tubercular arthritis	Fractures and coagulopathies

(PMNs: polymorphonuclear leukocytes; RA: rheumatoid arthritis; SLE: systemic lupus erythematosus; WBC: white blood cell)

TREATMENT

Treatment should be based on differential diagnosis of any patient presenting with joint pain. But few general principles should be followed immediate immobilization of joint, adequate analgesia, joint aspiration in case of septic arthritis, appropriate antibiotics as per suspected antibiotics, and proper referral to concerned specialty as per differential diagnosis.

When to give analgesia?

Step ladder approach should be followed for analgesia like if suspected of degenerative arthritis then begin with paracetamol first, maximum 1 g 6 hourly can be given. If no response than opioid analgesia might help like codeine, tramadol, or morphine in severe cases if no contraindication.

In cases of inflammatory arthritis paracetamol or opioids may give mild relief. Nonsteroidal anti-inflammatory drugs (NSAIDs) are often helpful in relieving pain in inflamed joint. Steroids can be added judiciously if pain does not get relieved with NSAIDs as former can reduce synovitis and thereby pain.

In cases of crystal arthropathies like gouty arthritis, first line of treatment is NSAIDS in adequate dosages. Secondly colchicine (a microtubular inhibitor to reduce inflammation) may be added to reduce synovitis. In resistant cases or in patients where NSAIDS are contraindicated, steroids can be given in tapering schedule. Sometimes intra-articular steroids can also be given if there is large synovitis which reduces joint inflammation significantly. There is no role of urate-lowering therapy (ULT) (uric acid lowering agent) in acute setting. If patient is already on ULT then it should be continued.

Is there any role of immobilization?

Immobilization of affected joint might help in reducing pain by not stimulating stretch receptors in synovium. Measures like

rest, ice fomentation, compression, and elevation of affected joint can reduce pain. Patients should be encouraged to begin range-of-motion exercises to avoid the loss of function, stiffness, and muscle atrophy once pain relief with all measures (both pharmacologic and nonpharmacologic).

Arthrocentesis: Is it important?
In case of acute onset arthritis, especially monoarthritis, joint aspiration and drainage with lavage help for diagnostic and therapeutic purposes. In cases of septic or infective arthritis, this is most important if large joint like knee or hip is involved. If large joint even have moderate effusion than aspiration and drainage is always better than medical management.

Do antibiotics have any role?
In case of septic arthritis, antibiotic should be started as soon as diagnosis is being made. It could be life-threatening if not treated on time and patient improves with administration of appropriate intravenous (IV) antibiotics and should be broad-spectrum covering major organism such as *Staphylococcus aureus*, *Streptococcus*, and *Escherichia coli*. If organism is methicillin-resistant *Staphylococcus aureus* (MRSA) then IV vancomycin is the drug of choice. In case of gonococcal infection, IV ceftriaxone could be ideal. Acute rheumatic fever is best treated with injectable benzathine penicillin G or oral penicillin V for 10 days. In case if suspicion is of TB, then joint fluid should be sent for demonstration of acid-fast bacillus (AFB) and culture, appropriate drugs should be started as soon as diagnosis is made.

Steroids: Where does it stand in ED for a patient with Joint Pain?
It is very tricky situation regarding usage of corticosteroids in ED. On one hand it can worsen septic arthritis but on the other hand it helps in improving patients of inflammatory or crystal arthritis. It should be used if one has ruled out infective cause. Because of its beautiful anti-inflammatory action steroids does improves synovitis although temporarily. It can be given either intramuscular, IV, or even high-dose pulse therapy in very severe cases. In cases of diabetes mellitus, it should be used with caution or with strict glucose monitoring or control.

When to start disease modifying antirheumatic drugs?
Disease modifying antirheumatic drugs (DMARDs) are the main stay and anchor-sheet drugs in case of inflammatory arthritis like RA. But it may take few weeks to show its action so sometimes steroids can be used as a bridging therapy. Different DMARDs are methotrexate, sulfasalazine, leflunomide, hydroxychloroquine, azathioprine, cyclosporine, etc. These drugs should be used for long-term but needs frequent monitoring of laboratory tests such as complete blood count, LFTs, and renal function tests for its side effects. If a patient of inflammatory arthritis is already on this drug then it should be continued in ED. DMARDs are true disease modifiers, control long-term disease activity, and complications of primary disease.

What is the role of surgery?
In cases of traumatic or fracture in the joint or joint line or septic arthritis then urgent orthopedic consultation should be sought. Septic arthritis may need lavage of joint or debridement and fracture may need corrective surgery.

SUMMARY

Joint pain is one of the most common presentations in ED. Thorough initial assessment always helps to differentiate and characterize joint pain. All emergency physicians should be well versed in the evaluation of the joint pain. Rarely it can be life-threatening and may be sole manifestation of serious systemic diseases and infections. So "red flags" of joints should be in the mind of every ED clinician if he/she encounters any patient of acute joint pain. These "red flags" are septic arthritis, acute gout, and fracture. On the other hand, inflammatory arthritis can present with acute joint pain and swelling and if not diagnosed and treated on time can lead to long-term deformity and disability. So through clinical examination and then evaluation should be done for any joint pain.

Overview of Rheumatological Disorders

151
CHAPTER

Neeraj Jain, Amit Dua

INTRODUCTION

Rheumatic disorders are a heterogeneous class of chronic autoimmune disorders. They are among the most common chronic diseases. They can affect a wide range of age groups. The spectrum of rheumatic diseases is showed in **Table 1**. About 5% of the population suffer from a chronic inflammatory rheumatic disease. In recent studies it was reported that, in America, a higher number of disabilities are due to inflammatory rheumatic diseases with arthritis than by heart disease, cancer, or diabetes. The Chopra et al. rural community survey in India reported 746 (18.5%) out of 4,092 adults were identified with rheumatological complaints.

CLASSIFICATION AND DEFINITION

Most of the rheumatic diseases can be grouped into 10 major categories. More than 150 rheumatic diseases were classified with specific pathogenesis, clinical features, therapy, and prognosis (**Table 2**).

1. Systemic connective tissue diseases
2. Vasculitides and related disorders
3. Seronegative spondyloarthropathies
4. Arthritis associated with infectious agents
5. Rheumatic disorders associated with metabolic, endocrine, and hematologic disease
6. Bone and cartilage disorders
7. Hereditary, congenital, and inborn errors of metabolism associated with rheumatic syndromes
8. Nonarticular and regional musculoskeletal disorders
9. Neoplasms and tumor-like lesions
10. Miscellaneous rheumatic disorders

ETIOLOGY

Rheumatic diseases are caused by a combination of genes and environmental factors. In general, having certain gene variants can increase a person's susceptibility to rheumatic diseases, and factors in the environment may trigger the onset of the disease. A single gene mutation or a single environmental trigger, most occur as a consequence of a complex interaction of genetic factors and environmental triggers. Some of the environmental predictive and protective factors for rheumatic diseases are depicted in the **Table 3**. Given an overwhelming genetic influence by the human leukocyte antigen (HLA) locus, which include major histocompatibility complex (MHC) and complement genes, individualized recognition and processing of antigens remain a leading pathway to pathogenesis of autoimmunity. Rheumatic disease associations with the MHC are shown in **Table 4**.

EVALUATION

The cardinal manifestations in rheumatology are joint pain and swelling. It is important to recognize the most appropriate cause of joint pain to make proper diagnosis. Detailed history and examination is the cornerstone in diagnosing rheumatic diseases. Rheumatic diseases are multisystem disorders so looking beyond the joints is important to clinch the diagnosis. One must look for rashes, oral and genital ulcers, Reynaud's

TABLE 1: Spectrum of various rheumatic diseases.

Disease	*Type of organ involvement*	*Autoimmune features*	*Examples*
Inflammatory joint diseases	Musculoskeletal	Few	Spondyloarthropathies and reactive arthritis
Inflammation of joints + systemic disease	Musculoskeletal and internal organs	Several	Rheumatoid arthritis
Systemic rheumatic diseases	Multi-organ disease	Many	Systemic lupus erythematosus, scleroderma, and antiphospholipid syndrome

TABLE 2: Definition of common rheumatic disorders.

Disease	*Definition*
Osteoarthritis	Osteoarthritis is the most common form of arthritis which primarily affects and destroys cartilage, the soft tissue that cushions the ends of bones within joints.
Rheumatoid arthritis	Rheumatoid arthritis is known to be one of the most severe and common chronic inflammatory disease with progressive course affecting articular and extra-articular structure resulting in pain, disability, and mortality.
Psoriatic arthritis	Psoriatic arthritis is a complicated disease, characterized by pain, swelling, stiffness, and joints tenderness as well as the surrounding ligaments and tendons.
Juvenile idiopathic arthritis	Juvenile idiopathic arthritis is the most common chronic rheumatic disease in childhood and which may be accompanied by fevers and rashes.
Ankylosing spondylitis	Ankylosing spondylitis is the most common of seronegative spondyloarthropathies and is a chronic progressive inflammatory disease, which primarily affects sacroiliac joints and axial skeleton.
Gout	Gout is the most common inflammatory arthritis caused by deposition of monosodium urate (MSU) crystals formation, which forms due to the presence of increased urate concentration.
Systemic lupus erythematosus	Systemic lupus erythematosus is a systemic autoimmune disease, with multisystemic involvement.
Vasculitis	Vasculitis is a broad term encompassing a group of disorders characterized by blood vessel inflammation and necrosis.
Fibromyalgia	Fibromyalgia a chronic condition marked by tender points and localized pain throughout the musculoskeletal system.
Reactive arthritis	Reactive arthritis, or Reiter's syndrome, a spondyloarthropathy that develops after an infection of the urinary tract, bowels, or other organs.
Polymyalgia rheumatic	Polymyalgia rheumatica which causes pain and stiffness in tendons, muscles, ligaments, and tissues around joints.
Scleroderma	Scleroderma or systemic sclerosis, an autoimmune rheumatic disease that leads to a thickening and tightening of the skin and inflammation and scarring in various other parts of the body, including the blood vessels, joints, and certain organs.
Polymyositis	Polymyositis which affects the muscles and can affect the entire body.

TABLE 3: Some of the environmental predictive and protective factors for rheumatic diseases.

Musculoskeletal condition	*Environmental risk factor*	*Protective factor*	*Risk factors for a poor*
Rheumatoid arthritis	• Female gender • Smoking • Obesity • Silica exposure • Nulliparity	Oral contraceptive use, high fruit intake, and moderate alcohol intake	Rheumatoid factor and anti-citrullinated peptide antibodies
Ankylosing spondylitis	• Male gender • Certain infections	Smoking	
Psoriatic arthritis	• Psoriasis • Trauma		
Gout	• Alcohol (especially beer and spirits) • Dietary factors (e.g., meat, seafood, sugary drinks, and fructose) • Early menopause • Thiazide and loop diuretics • Chemotherapy for cancer • Components of the metabolic syndrome	Dietary factors (e.g., dairy produce, cherries, and coffee)

TAP2	Systemic lupus erythematosus

phenomenon, digital ulcers, thickening of skin, and eye involvement.

Stepwise Approach to the Patient with Musculoskeletal Pain

There are numerous causes of arthritis or musculoskeletal complaints. This stepwise approach to arthritis is important to narrow down the diagnostic possibilities to only few conditions.

The *first step in the approach* is to identify whether the pain is arising from the joints, i.e., from joint capsule, synovium, synovial fluid (SF), cartilage intra-articular ligaments and adjacent bones (articular origin) or from the periarticular structures (bursa, tendon, muscle, bone, and ligaments). Rheumatoid arthritis (RA) is a disease of synovium and osteoarthritis involves cartilage. These are the examples of true arthritis. Achilles tendonitis causing ankle pain, carpal tunnel syndrome causing wrist pain, frozen shoulder, etc., are all not true arthritis but are examples of periarticular pain. In arthritis, pain emerges with virtually all movements of the joints but periarticular pain is selective and localized to the structure affected. **Table 5** enumerates the difference between articular and periarticular pain. *As a second step*, we should look for the number of joints involved (**Table 6**). *Third step* is to identify the duration of joint pain. Conventionally arthritis duration of <6 weeks is acute arthritis, and ≥6 weeks is chronic arthritis. *Fourth step* is to differentiate whether the arthritis is inflammatory or noninflammatory in nature. This is the most important step as it determines the management and prognosis of the patient. This is because if the inflammatory arthritis is not diagnosed

TABLE 5: Difference between articular and periarticular pain.

Articular	*Periarticular*
Pain is deep and diffuse	Pain is localized
Painful and limited range of movement in both active and passive movement of the involved joints	Pain is more in active movement
Swelling and tenderness over joints	Local tenderness and swelling in region away from joint line
Deformity, crepitus, instability, and contractures are seen	Rare

TABLE 6: Number of joints involved.

Number of joints	*Types of arthritis*
1	Monoarthritis
2–4	Oligoarthritis
>4	Polyarthritis

and treated timely can cause deformities, e.g., as in RA and psoriasis, and even can cause life-threatening complications if major organs are involved as in systemic lupus erythematosus (SLE), vasculitis, etc. The classical sign of inflammation (namely red, hot, tender, swallow, and nonfunctional) may not always be used to classify arthritis as inflammatory and noninflammatory, as these signs may not be easily recognizable in all cases of inflammatory arthritis, moreover, noninflammatory conditions like traumatic arthritis may have some inflammatory signs. Therefore, rheumatologists have identified some sets of clinical features that can differentiate between inflammatory and noninflammatory arthritis with good sensitivity and specificity (**Table 7**). *Morning stiffness* is defined as the time to maximal improvement after prolonged period of inactivity. Inflammatory arthritis is characterized by the presence of prolonged early morning stiffness (after waking up in the morning) and is present at least for 30 minutes, sometimes may be for hours. Activity (gentle use of the joints) improves the symptoms but inactivity increases the stiffness. **Flowcharts 1** and **2** summarize the approach to a patient with musculoskeletal pain.

DIAGNOSIS

Acute polyarthritis is a diagnostic challenge as this category of arthritis has much differential diagnosis and many a times it is not possible to diagnose the exact cause at the onset of disease. Acute inflammatory polyarthritis could either be a self-limiting viral arthritis or it could be life-threatening and can cause high mortality. It could be the onset of a chronic illness such as RA. The causes may be RA, lupus, vasculitis, hematological malignancies, septic arthritis, reactive arthritis, crystal arthropathies, etc.

For diagnosing patients with chronic oligoarthritis or polyarthritis, we need to identify the pattern of evolution of joint involvement. There are three patterns of joint involvement. They are additive, migratory, and recurrent (intermittent). In additive pattern, the affected joints are added progressively,

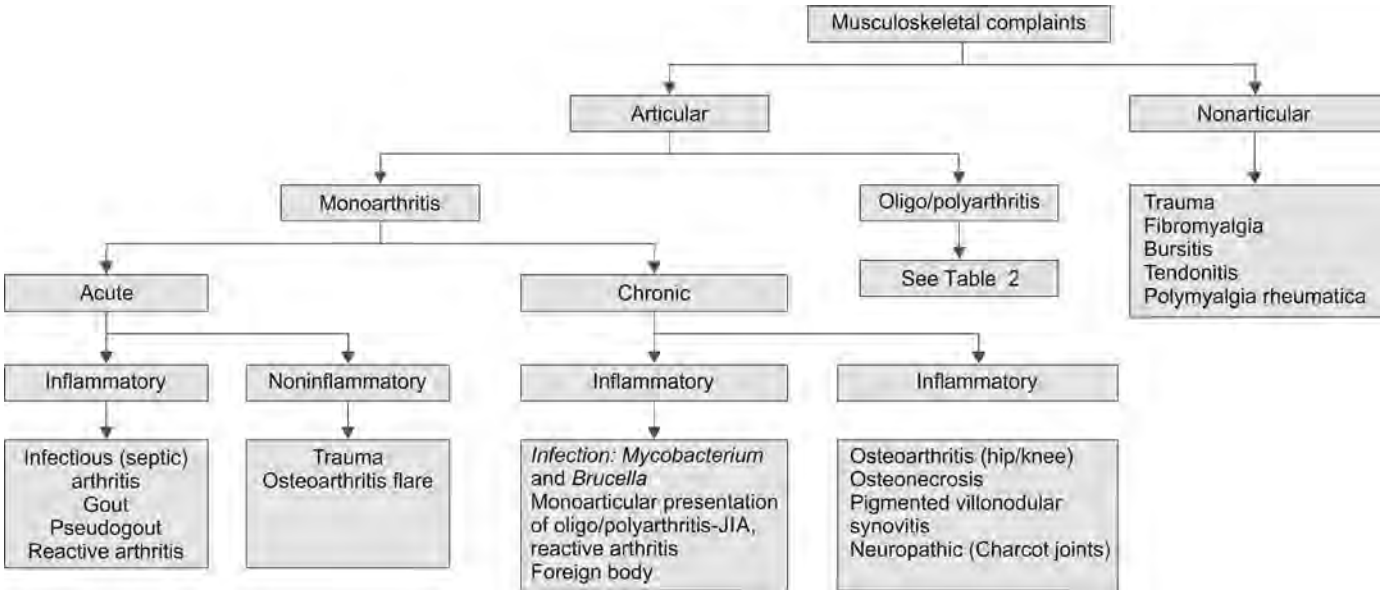
TABLE 7: Clinical features distinguishing inflammatory and noninflammatory arthritis.

	Inflammatory	*Noninflammatory arthritis*
Early morning stiffness (EMS)	>30 minutes, may last for hours	Brief
Inactivity stiffness	Prolonged, precipitated with prolonged inactivity	Brief, precipitated with brief periods of rests (gel phenomenon)
Pain increase	Prolonged inactivity	On repeated use of joints
Pain decrease	With exercise and gentle use of joints	On taking rest
Constitutional symptoms—fatigue, low grade fever, and weight loss	+	–
Effusion	+++	+/–
Erythema	+/–	–
Crepitus	–	+++
Malalignment/deformity	–	+
Instability	–	+/–

i.e., many joints are getting involved over time, e.g., RA. In migratory pattern, the inflammatory process flits from one joint to another as seen in rheumatic fever and gonococcal arthritis. In intermittent or recurrent pattern there are episodes or crises of arthritis separated by symptom-free "intercritical" intervals, e.g., palindromic rheumatism and acute gout.

Apart from pattern, distribution of joint involvement (topography) also helps in further narrowing down the diagnostic possibilities. Before describing the topography, one should be aware of the following anatomical regions and pattern of joints involvement. Peripheral joints are the joints of extremities, axial joints mean the spine and sacroiliac joints, root joints mean which connects axial with peripheral joints, i.e., shoulder and hip joints. Proximal arthritis mainly affects the large joints, i.e., proximal to wrist or ankle and spine, e.g., spondyloarthropathy (SpA), Behçet's, and juvenile idiopathic arthritis (JIA). Distal arthritis mainly affects small joints of hands and feet with or without involvement of ankle and wrist, e.g., SLE and RA. Arthritis can be predominantly proximal or predominantly distal or it can be a mixture of both involving small and large joints. For peripheral arthritis, it is important to note the symmetry or asymmetry of joint involvement. Symmetrical involvement means arthritis affects the same joint groups on each side of the body and asymmetrical involvement means that there is no correlation between the joints affected on either side. Topography of joints and their differential diagnosis are shown in **Flowchart 3**.

Although most rheumatic disease diagnosis is made through detailed history and physical examination but investigations are also helpful in some cases, if used judiciously. Investigations are important guides not only for screening and confirming diagnosis but they also help in following disease



(JIA: juvenile idiopathic arthritis)

activity and response to treatment. Investigations may also determine the prognosis of the disease.

As the understanding of rheumatic disease progresses, new biomarkers are developed and the utility of existing ones is refined. Laboratory tests can be valuable guides for screening, confirming diagnosis, establishing disease stage, and prognosis, as well as for following disease activity and response to treatment.

The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) frequently correlate well with disease activity in inflammatory disorders. Rheumatoid factor (RF) and anti-cyclic citrullinated peptide (anti-CCP) antibodies are helpful in diagnosing RA. The specificity of RF for RA is poor. Antinuclear antibodies (ANAs) are found in many patients with rheumatic diseases and in essentially all patients with SLE and systemic sclerosis (SSc). Under the proper clinical conditions, the finding of a positive ANA assay is an indication for additional investigations directed at identifying the precise autoantibody leading to the ANA pattern. Autoantibodies directed against individual antigens have increased specificity for particular diseases. These autoantibodies are associated with a range of different rheumatic diseases (**Table 8**). Some investigators believe anti-CCP antibodies have a role in the pathogenesis of RA. Despite the development of increasingly sophisticated serologic tests and imaging techniques, SF analysis remains one of the most important diagnostic tools in rheumatology. Imaging modalities that are important in rheumatology include conventional radiography, computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, radionuclide imaging, arthrography, bone densitometry, and angiography.

TREATMENT

For successful treatment, identifying each condition and its variations is essential. Various types of medication are prescribed to treat rheumatic diseases (**Table 9**). Some drugs only treat symptoms such as pain and inflammation, while others can alter the course of the disease. Disease-modifying antirheumatic drugs (DMARDs) are a class of drugs indicated for the treatment of inflammatory arthritides including RA, psoriatic arthritis (PsA), and ankylosing spondylitis (AS). They can also be used in the treatment of other disorders including connective tissue disease such as SSc, SLE, and Sjögren's syndrome (SS), as well as in treatment of inflammatory myositis, vasculitis, uveitis, inflammatory bowel disease, and some types of cancers. DMARDs are classified as either conventional DMARDs or biologic DMARDs. Biologic DMARDs are highly specific and target a specific pathway of the immune system in rheumatic disease (**Table 10**).

TABLE 8: Rheumatic diseases and autoantibodies.

Pattern	*Nuclear antigen*	*Clinical associations*
Anti-dsDNA	Antibodies to dsDNA	• High specificity for SLE • Often correlates with more active, more severe disease • ELISA test is very sensitive and can be positive in other diseases, normal people
Anti-histone	Five major types exist	• SLE, drug-induced SLE, and other autoimmune disease • SLE patients will likely be positive for other autoantibodies as well
Anti-ENA	• Sm (Smith) • RNP (ribonucleoprotein) • RNA–protein complexes	• High specificity for SLE • Mixed connective tissue disease • Higher prevalence in African American and Asian patients
Anti-SSA (Ro)	Ribonucleoproteins	SLE (especially subacute cutaneous lupus), neonatal lupus, and Sjögren's syndrome
Anti-SSB (La)	Ribonucleoproteins	Sjögren's syndrome, SLE, and neonatal SLE
Anti-centromere	Antibody to centromere/kinetochore region of chromosome	• Limited scleroderma • High rate of pulmonary hypertension • Primary biliary sclerosis
Anti-Scl-70	Antibodies to DNA topoisomerase 1	• Diffuse scleroderma • Risk of pulmonary fibrosis
Anti-Jo-1	Antibody to histidyl-tRNA synthetase	• Poly/dermatomyositis • Patients tend to have interstitial lung disease, Raynaud's phenomenon, mechanic's hands, and arthritis • Typically resistant to treatment
Anti-SRP	Antibody to signal recognition protein	• Cardiomyopathy • Poor prognosis
Anti-PM-Scl	Antibody to nucleolar granular component	Polymyositis/scleroderma overlap syndrome
Anti-Mi-2	Antibodies to a nucleolar antigen of unknown function	• Dermatomyositis • Favorable prognosis

(dsDNA: double stranded deoxyribonucleic acid; ELISA: enzyme-linked immunosorbent assay; SLE: systemic lupus erythematosus)

SUMMARY

Rheumatic disorders are among the most prevalent chronic diseases of the musculoskeletal system and connective tissue, and they can affect a wide range of age groups. Their etiology is still not completely clear, and they cannot be effectively prevented. Identifying each condition and its variations is essential for effective treatment.

152 CHAPTER

Evaluation of Mental Health and Common Psychiatric Emergencies

Mohammad Anzal Rehman, Mansoor Masarrat Husain

INTRODUCTION

Mental and behavioral health disorders constitute a significant portion of all emergency department (ED) visits. A systematic review in 2016 concluded 4% of ED visits to be attributable to psychiatric causes. However, prevalence has been shown to have a significant degree of variability between institutions. Commonly encountered acute presentations involve self-harm, substance abuse, suicidality, agitation, and/or exacerbations of underlying mood, anxiety, and thought disorders. The prevalence of psychiatric disease presentation to the ED has seen a significant rise over the years. Despite the relative frequency of presentation, Emergency physicians still face considerable challenges when encountering these patients. This is owed in no small part to the fact that psychiatric emergencies are vastly underrepresented in most emergency medicine academic curriculums. Reduced exposure to psychiatric disease during clinical training, along with the inherently confounding nature of acute mental illness often contribute to emergency physician hesitance when faced with these patients in the ED. Nevertheless, the ED continues to grow increasingly responsible for providing care to patients presenting with mental and behavioral health issues, making it crucial for emergency physicians to practice and develop skills in acute psychiatric care. This chapter will attempt to highlight techniques in recognition, assessment, management, and disposition of commonly encountered psychiatric emergencies.

EVALUATION OF MENTAL HEALTH

Assessment at Triage

The psychiatric patient may present to the ED in a variety of ways. These patients are often either referred by existing psychiatric and primary care providers, or they are brought in by police or emergency medical services due to acutely agitated, self-harming, disruptive, or intoxicated states. Occasionally, patients with psychiatric complaints will refer themselves to the ED, and there are even instances where psychiatric disease is newly uncovered by the emergency physician while evaluating the patient for a separate medical condition. Recognition of psychiatric disease therefore forms an integral component of appropriate care for these individuals. Most emergency triage systems are ill-equipped to adequately recognize patients with mental or behavioral health issues, as they are generally tailored toward assessment for medical complaints. However, specialized triage assessment systems, termed as *Mental Health Triage Scales (MHTS)* (**Table 1**), may provide more reliable means of gauging severity in psychiatric illness for patients presenting to the ED. Understandably, severity is usually estimated by assessment of risk of harm to self and/or others.

Evaluation

The initial ED assessment for a psychiatric patient frequently aims to identify the presence of a medical condition that may be causing or worsening the patient's mental health before addressing the psychiatric issue. The American College of Emergency Physicians (ACEP) recommends a focused medical assessment in the ED whereby any organic causes of disease can be identified through relevant diagnostic evaluation as needed based on the patient's presenting signs and symptoms.

Routine laboratory testing and diagnostics are not recommended to exclude medical causes for the patient's condition. Investigations may be useful, however, in those patients over 45 years of age with new onset of psychiatric symptoms, those with cognitive impairment, delirium, substance abuse or withdrawal, decreased levels of consciousness, abnormal vital signs, or advanced age (≥65 years).

History

Patients with mental and behavioral disorders present a unique challenge to the interviewing physician. An altered mental status may predispose to inaccurate, unreliable, and incomplete histories when taken from the patient themselves. Where patients can adequately articulate their problems, fear of repercussions or ulterior patient motives may confound the reported history. When conducted amidst the commotion of the ED, history taking can turn into quite an unsettling experience for the patient.

TABLE 1: Example of a commonly used Australian Mental Health Triage Scale (MHTS).

Triage code	*Description*	*Treatment acuity*	*Typical presentation*
1	Definite danger to life (to self and others)	Immediate	• Violent behavior • Possession of weapons • Self-destructive behavior in emergency department (ED)
2	Probable risk of danger to self and others (severe behavioral disturbance)	Emergency (within 10 minutes)	• Extreme agitation/restlessness • Physically/verbally aggressive • Require restrain • Attempt to self-harm and others also
3	Possible risk of danger to self and others (moderate behavioral disturbance and severe distress)	Urgent (within 30 minutes)	• Agitation/restlessness • Intrusive/bizarre/disorganized behaviors • Confusion withdrawn and uncommunicative • Suicidal ideation, hallucination, delusion paranoid ideas, severe symptoms of depression, and anxiety. Elated and irritable mood
4	Moderate distress	Semiurgent (within 60 minutes)	• No agitation restlessness • Irritability without aggression • Cooperative • Gives coherent history • Symptoms of anxiety depression without suicidal ideation
5	No harm to self and others (no acute distress and no behavioral disturbance)	Nonurgent (within 120 minutes)	• Cooperative • Communicative • Known patient of psychotic symptoms • Financial/social/relationship problem • Minor adverse effect of medication

Source: Broadbent M, Moxham L, Dwyer T. The development and use of mental health triage scales in Australia. Int J Ment Health Nurs. 2007;16(6):413-21.

Good interview technique involves the use of calm, open-ended questions, with emphasis and further elaboration on concerning signs of illness. Besides discussion of recent symptoms and the current condition, it is vital to also obtain information about past medical, surgical, and family history, known medication or substance use, lifestyle, allergies, and previous hospital visits or admissions. When possible, utilize accompanying or known friends, family, caretakers or even law enforcement, and emergency medical services personnel as sources of information. History taking questions should attempt to explore and identify changes in mood, affect, thought, speech, judgment, altered perceptions, and substance abuse, with particular emphasis on suicidal or homicidal ideation.

Physical Examination

Unfortunately, due to the complexity and unconventional presentations of psychiatric disease in the ED, physicians often overlook performing a complete physical examination and thorough review of systems. Since medical disease can cause or even worsen psychiatric complaints, the importance of an initial medical assessment for the patient cannot be understated.

When examining the patient who displays signs of altered mental status, considered exclude nonpsychiatric causes, an organized approach is useful to ascertain the specific type of alteration and its degree. Begin by evaluating the patient's level of consciousness, which will vary based on their alertness, awareness, and attention. A commonly used tool to assess for this is the Glasgow Coma Scale (GCS), which looks at motor, verbal, and eye-opening responses to estimate the patient's consciousness level. Any alteration in consciousness will undoubtedly also impact cognition and behavior.

Cognitive assessment should start by assessing the patient's orientation, which indicates awareness of their situation and surroundings. Orientation assessment involves asking the patient to identify themselves, usually with a request to verbalize their full name, and then mention where they are and what time (or time of day) it is to establish orientation to person, place, and time. You may proceed further with a focused *Mini-mental State Examination (MMSE)* to review the patient's attention, memory, and executive function (**Table 2**). The ease of incorporation and relatively short amount of time needed to complete assessment makes the MMSE one of the more relevant tools to integrate into ED examinations for altered mental status.

An impaired cognitive ability may signify dysfunction secondary to dementia or delirium. The unpredictable and changeable pattern of delirium may be better identified using the *Confusion Assessment Method (CAM)*. The CAM diagnostic algorithm looks at four features:

1. Acute onset and fluctuating course
2. Inattention
3. Disorganized thinking
4. Altered level of consciousness

The diagnosis of delirium is then made when both features 1 and 2 are present along with either one of 3 or 4.

TABLE 2: Example of a standard Mini-mental State Examination form.

Mini-mental State Examination (MMSE)	Patient name: _____ Date: _____ Medical Record Number: _____	
One point for each correct answer	Patient score	Maximum score
Orientation		
What is the (year) (season) (date) (day) (month)?	__	5
Where are we: (state) (county) (town or city) (hospital) (floor)?	__	5
Registration		
Name three common objects (e.g., apple, table, and penny)	__	3
Note: Take 1 second to say each. Then ask the patient to repeat all three after you have said them. Give 1 point for each correct answer. Then repeat them until he/she learns all three. Count trials and record. Trials:		
Attention and calculation		
Spell "world" backwards. The score is the number of letters in correct order. (D___L___R___O___W___).	__	5
Recall		
Ask for the three objects repeated above. Give 1 point for each correct answer.	__	3
Note: Recall cannot be tested if all three objects were not remembered during registration		
Language		
Name a "pencil" and "watch"	__	2
Repeat the following: "No ifs, ands, or buts"	__	1
Follow a three-stage command: "Take a paper in your right hand, fold it in half and put it on the floor"	__	3
Read and obey the written statement: "close your eyes"	__	1
Write a sentence (with subject and verb)	__	1
Copying		
Copy the following: 	__	1
Total Score	___	30
Key: **24–30: No cognitive impairment** **18–23: Mild cognitive impairment** **0–17: Severe cognitive impairment**

INVESTIGATIONS

As mentioned earlier, laboratory testing is guided by focused medical assessment for each patient and routine investigations may not be necessary for the evaluation of patients without high risk of disease, despite the common practice of being requested from the emergency physician by psychiatric facilities and colleagues. When incorporated, the most essential test to include is blood glucose at triage or initial presentation, along with a full set of vital signs, oxygenation, and electrocardiogram (ECG) where feasible.

Other valuable laboratory investigations that may be useful include a complete blood count (CBC), electrolytes, comprehensive metabolic panel, urinalysis, pregnancy testing, and blood levels of known psychiatric medication (e.g., lithium, valproate, etc.) as appropriate for the patient. Suspicion of drug or alcohol intoxication should be established by clinical assessment of level of consciousness, cognition, coordination, gait, and/or nystagmus. Current ACEP guidelines advise against routine urine toxicological screens in awake, alert, and cooperative ED patients as these will not affect acute care management. Blood alcohol concentrations also correlate

poorly with level of intoxication, which should be a clinical diagnosis rather than a laboratory one. These are usually only utilized where altered mental status has no other known or explained etiology.

Computed tomography (CT) or magnetic resonance imaging (MRI) scans of the brain are often debated for their use in exclusion of organic causes in the psychiatric patient. However, there are very few instances where neuroimaging will result in actionable findings in acute psychiatric complaints, leading to recommendations against using them routinely for these patients. In the ED, a noncontrast CT may be of some benefit in those patients with acute psychiatric presentations that have focal neurologic deficit, head trauma, new-onset seizures, new-onset psychosis in older patients (psychotic disorders unlikely to manifest for the first time in those older than 40 years), immunosuppression, excessive cognitive decline, or altered level of consciousness not otherwise explained by other etiologies.

HIGH-RISK PSYCHIATRIC PRESENTATIONS IN THE EMERGENCY DEPARTMENT

Agitation

A US study in 2018 revealed that, though the prevalence of agitation among patients presenting to the ED is approximately 2.6%, an overwhelming majority of agitated patients require restraint, with many patients experiencing subsequent clinical events. Despite the fact that agitated patients present unique challenges that include violence toward healthcare professionals, most physicians tend not to receive formalized training in managing these high-risk individuals.

Causes of agitation may be metabolic, ranging from electrolyte abnormalities, abnormal glucose levels, and hypoxia to disorders of thyroid hormones and nutritional deficiencies (e.g., Wernicke's encephalopathy). Infectious causes, shock, thermal dysregulation, intracranial injury or abnormality, and toxins can all manifest as agitation. Psychiatric causes of agitation can include psychosis, schizophrenia, delusions, and personality disorders. It is therefore essential to keep broad a differential diagnosis in mind when dealing with agitated patients, as most of the conditions above will likely require rapid identification and timely management for reversal of symptoms.

Initial assessment of the agitated patient should prioritize safety, with adequate screening of the patient for weapons, interview conducted in a room that allows privacy without compromising security, easily accessible entry and exit points for the provider and readily available personnel and protocols for appropriate restraint and intervention, as necessary. The ED physician should consider the use of verbal deescalation tactics first when the situation allows, and the patient appears to be receptive and cooperative. These include communicating with the patient in a calm, concise, and respectful manner while avoiding provocative statements, threats, and condescension.

If verbal techniques fail to manage the patient's agitation, the use of restraint should be considered. Typically, chemical restraint is preferable to physical restraint, but these may be used in combination as appropriate for the severely combative patient. Pharmacologic options traditionally incorporate antipsychotic agents and benzodiazepines. Classically, first-generation (typical) antipsychotics such as haloperidol [2.5–5 mg intramuscular/intravenous (IM/IV)] were used. However, second-generation (atypical) antipsychotics, such as olanzapine (10 mg IM or 5–10 mg PO) have been shown in recent studies to perform better with lower rates of adverse events compared to first-generation antipsychotics. Commonly used benzodiazepines include lorazepam (2–4 mg IM/IV) and midazolam (2.5–5 mg IM/IV). All medication used to control agitation should aim to calm, not sedate the patient, and can be titrated up to achieve the desired effect.

Several recent studies have explored the use of IM ketamine at 5 mg/kg (1–2 mg/kg IV) in controlling agitation, revealing that it may be superior in efficacy, safer, with a faster onset when compared to conventionally used medication, such as haloperidol and midazolam. However, the drug may be associated with more complications, loses its effect faster and can even cause acute agitation in patients with schizophrenia.

Physical restraint, when applied, should be done so in a systematic, team-based approach with coverage of five points (four limbs and head) and avoidance of prone positioning. In any form of restraint, postrestraint monitoring and evaluation should be implemented to assess for any adverse effects from the intervention to the patient and progression of patient condition.

Delirium

Delirium has been described as an acute disturbance in attention and awareness that fluctuates in severity and is not otherwise explainable by an existing underlying disease process. It can present as hypoactive, hyperactive, or mixed type, with the sign being highly predictive of worse outcomes, especially in older patients.

Unfortunately, healthcare providers often fail to recognize delirium in the ED, leaving patients vulnerable to clinical deterioration and showcasing a need for a more systematic approach to better identify delirium. Though several tools exist to facilitate recognition of delirium in healthcare settings, the CAM may be preferred for use in the ED, largely due to its superior performance in reliably identifying delirium as well as its feasibility as a bedside assessment method. According to the CAM, criteria for delirium are met if the patient has an acute onset with fluctuating course and inattention with either disorganized thinking or an altered level of consciousness.

Several variables can serve as triggers for delirium. These include drugs (e.g., anticholinergics, alcohol, medication interactions or changes, sedative, or anesthetic medication), electrolyte disturbances, infection, cerebral abnormalities (e.g., stroke, encephalopathy, and space-occupying lesions), uremia, shock, hypoxia, and cardiac injury (e.g., heart failure, arrhythmia, or arrest). Management of delirium therefore revolves primarily around identification and treatment of the underlying cause. Ongoing delirium with no identifiable cause or no significant improvement with intervention may be managed pharmacologically with antipsychotic medication, such as haloperidol.

Catatonia

Catatonia is a neuropsychiatric phenomenon that can be observed in various neurologic, medical, and psychiatric disorders. While it was initially perceived to be associated with

schizophrenia, over the past few decades it has been shown not to be uniquely linked to any one disease and is slowly being recognized as its own distinct entity.

Catatonia can present as a wide variety of symptoms, such as stupor, negativism, posturing, echolalia, echopraxia, rigidity, waxy flexibility, agitation, mutism, and catalepsy. Immobility and mutism have been shown to be the most common signs of catatonia, but three or more of the signs above are considered diagnostic. Catatonia is generally classified into two subtypes: excited (e.g., agitation, impulsivity, and excitement) and retarded-stuporous (e.g., rigidity, immobility, stupor, mutism, and echophenomena) and catatonia. Malignant catatonia is a rare, severe form that presents with hyperthermia, tachypnea, hypotension, tachycardia, labile blood pressure, and excitement alternating with stupor.

It is important to note that catatonia may be associated with an underlying medical cause and management should focus on investigation for and reversal of these where appropriate. Catatonia also lends itself to various medical complications, such as pulmonary embolism, rhabdomyolysis, urinary tract infection, dehydration, aspiration, and electrolyte abnormalities.

Patients are primarily treated with benzodiazepines, such as lorazepam and diazepam, which have shown to be particularly effective in retarded-stuporous types of catatonia. Typical antipsychotics, antidopaminergics, and neuroleptics are generally avoided as they may worsen disease symptoms. Symptoms refractory to benzodiazepines may be candidates for electroconvulsive therapy (ECT).

Self-harm

Self-harm is described as an intentional injury or poisoning of oneself, which may or may not include suicidal ideation or attempt. It is usually a manifestation of a maladjusted emotional response to distressing stimuli or triggers. Patients of self-harm are often particularly vulnerable and distraught, with the extreme nature of the phenomenon making them more likely to present to EDs. Therefore, it is vital for healthcare providers assigned to these patients to understand the fragile nature of presentation and their roles in providing compassionate care without the influence of commonly encountered negative attitudes surrounding the concepts of self-harm.

Current standards of assessment for self-harm in the ED are highly variable and risk assessment tools for suicide are underdeveloped and often not properly utilized, increasing the likelihood that many patients with substantial risks are missed or undetected. Improved awareness about self-harm with regular, formalized training, and the potential integration of psychiatric liaison team (PLT) in the ED can all assist in improving care for these patients.

Protect the patient first by placing them in a private room without any dangerous objects, de-escalate any acute agitation as needed and perform a focused medical assessment to search for any underlying organic condition. Patients should undergo risk assessment for suicide and safety for discharge. Consideration of risk should combine clinical judgement as well as factors for family and community, with a low threshold for consultation with the psychiatry team. Specific risk factors to identify would include prior attempts, history of psychiatric illness, presence of triggering events (e.g., abuse), signs of impulsiveness, anhedonia, or psychosis as well as access to firearms.

Communication plays a vital role in exploring the frequency and intensity of suicidal ideation, and the physician should attempt to ascertain the presence of a prepared plan, history of previous attempts, and patient's beliefs on self-harm to thoroughly comprehend the risk of suicide. Presence of social, religious, or personal coping mechanisms may be protective for some patients. Most patients with considerable risk of suicide will typically be admitted to the hospital. However, any patients discharged after being deemed to be low risk should cautiously and comprehensively document their decision-making, risk assessment, findings, rationale, and any consultations as appropriate.

OVERVIEW OF PSYCHIATRIC ILLNESS

Mood Disorders

Mood can be defined as a state of mind or an emotion that one is feeling. A mood disorder occurs when this state of mind lasts for a significant length of time and significantly impairs function. The Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) broadly separates mood disorders into two groups—depressive disorders and bipolar disorders.

The etiology of mood disorders is not fully understood as there are many complex factors at play including neuroanatomy, neurochemistry, drug and alcohol use, and complex environmental, social, and cultural factors that can vary significantly in different patient populations.

Depressive Disorders

The most common feature of depressive disorders is a feeling of anhedonia, which is defined by a loss of interest or feeling of pleasure in activities and situations that would bring joy to most people.

Up to one in five Americans will meet the DSM-5 criteria for a depressive disorder at some point in their life. Mood disorders are very common in patients who present to the ED. One study showed that 76% of patients with depressed mood visited an ED one or more times in the last 6 months. Another study showed that on screening patients who visited an ED using the Beck Depression Inventory-II (a widely used test for measuring the severity of depression), 15% had mild depression, 20% had moderate depression, and 8% had severe depression.

Life events such as being the subject of abuse (physical, sexual, emotional, financial, domestic, and neglect), bereavement, chronic illness, and catastrophe can all trigger or worsen symptoms of a depressive disorder. These psychosocial factors are often complex and not easily defined.

There is a link between low levels of norepinephrine, serotonin, glutamate, and γ-aminobutyric acid in the brain and the likelihood of suffering a depressive episode. Antidepressant medications target these neurochemicals (and others) and aim to increase their levels. Other physiological factors that have been implicated in depressive disorders include cortisol levels and neuroanatomical variations. Additionally, there is some evidence towards familial concordance in severe mood disorders pointing towards a genetic link.

The *DSM-5* criteria for diagnosing depression are as follows:

- Depressed mood (also irritable mood in children and adolescents)
- Loss of pleasure or diminished interest in almost all activities (anhedonia)

- Significant weight change or appetite disturbance (failure to achieve expected weight gain in children)
- Sleep disturbance (too little or too much sleep)
- Psychomotor retardation or agitation
- Fatigue or loss of energy
- Feelings of worthlessness
- Decreased ability to think or concentrate or indecisiveness
- Recurrent thoughts of death, recurrent suicidal ideation (with or without a plan), and a plan for committing suicide or a suicide attempt.

At least one of the first two symptoms and five of above list in total must be present together over a 2-week period. These feelings must cause significant impairment socially to the patient. They must not be the direct result of a medical condition or due to substance misuse. There must also not be another mental health diagnosis that better explains the symptoms and the patient must not have a diagnosis of a bipolar disorder.

There are many useful *mnemonics for depression*. One easy way to remember the diagnostic criteria is to use the word "depression" as your guide (**Table 3**).

There are certain special considerations in depressive disorders. Patients can present with somatic symptoms including sleep disturbance, appetite, and weight loss and amenorrhea. Careful screening of patients may reveal a depressive disorder as a cause for their symptoms. Also, one should be mindful of postnatal depression in postpartum women as up to 10% of women can be diagnosed with a major depressive episode. This is especially important when considering the health of the family unit and potential for abuse of the newborn.

Bipolar Disorder

Bipolar disorders are characterized by episodes of extreme mood changes from severe depression to abnormally elevated mood that last from days to weeks. If there are features of psychosis, then that period can be described as "mania" but if the symptoms are less severe, then it is described as "hypomania". While bipolar disorders are rare in the ED, there is a higher rate of hospitalization and potential for harm and thus must be approached with careful consideration.

During a manic episode there must be significant impairment to the patient's life, need for hospitalization, or psychotic symptoms. Common features of mania include over-cheerfulness, over-talkativeness, and over-activity. These can also frequently be associated with episodes of irritability and distractibility. There can be thought disorders including flight of ideas and delusions of grandeur or a feeling of grandiosity. These are often associated with impairment in judgement and irresponsible behavior and impetuousness in activities such as gambling and sexual relations.

The *DSM-5* criteria for diagnosing a manic episode are as follows:

- Distinct period of abnormally, persistently elevated mood or irritability, and persistent goal-directed activity or energy lasting at least 1 week (or if hospitalization is needed)
- During the period of mood disturbance, three or more (four if the mood is irritability) of the following:
  - Inflated self-esteem or grandiose thoughts
  - Decreased need for sleep
  - Increased talkativeness
  - Racing thoughts or flight of ideas
  - Distractibility
  - Increase in goal directed activity or psychomotor agitation
  - Excessive involvement in pleasurable activities that have potential for harm (sexual/financial/behavioral)
- The mood disturbance is sufficiently severe enough to impact patient's occupation/social functioning; requires hospitalization to prevent harm to patient or those around them; and features of psychosis are present.
- The symptoms are not caused by the effects of a medical condition or drugs/alcohol.

Differential Diagnosis of Mood Disorders

Many medical conditions including hypothyroidism, Parkinson's disease, dementia, and long-term, serious medical conditions including cancer and ischemic heart disease (IHD) can cause the patient to have major depressive symptoms. These symptoms may be treated similarly to a formal depressive disorder but are often linked to the underlying condition and either the physiological or psychosocial impact on the patient's life.

Substance abuse including drugs and alcohol can often cause symptoms like a mood disorder and have significant negative impact on the life and functioning of the patient. Help must be sought to engage the patient in lifestyle modification and rehabilitation and referral to the appropriate services in your area should be explored.

Many prescription medications can also have mood-related side effects—antipsychotic and antiepileptic medications are linked to depressive features and steroids have been known to cause manic symptoms.

Grief and bereavement and experiencing significant stressors are linked to mood disorders but it should be noted that feelings of guilt, loss of self-esteem, or significant impact on a patient's occupation or social activity may indicate an underlying depressive disorder. Normal grief and adjustment reactions vary among individuals and in different cultures, but rarely last longer than a few months.

Treatment of Mood Disorders

Patients are often in crisis and steps should be taken to place them in a quiet, private environment, engage with the patient, and try and reduce their agitation. If verbal and environmental

O	Only me to blame (guilt)
N	No concentration

Source: Davies AC, Birley H, Chiganze A. Chlamydia is being managed in primary care. BMJ. 2006;332(7540):551.

strategies to calm the patient fail, then one can consider giving medications to reduce anxiety and calm the patient.

Oral medications such as lorazepam (1–2 mg), haloperidol (2–10 mg), or promethazine (25–50 mg) are preferred. IM medications can be considered if the patient is not compliant with oral medications. If it is deemed by the attending physician that the patient is at significant risk of immediate harm to themselves or to others then physical restraint and IV sedation using benzodiazepines or haloperidol can be used.

Whenever chemical or physical restraint is used, it must be justifiable, reasonable, proportional to the situation, and used for the minimal length of time needed. As ever, one must be ready to deal with any adverse outcomes.

Specialist drugs including antidepressants and antipsychotic medications must be prescribed by those experienced in their use and as such, most patients who at high risk of harm from their depressive disorder, suffering major depression, or experiencing bipolar symptoms should be referred to psychiatric services for further care.

All patients with depressive symptoms require an assessment of suicide risk. If there is risk of self-harm/suicide or risk of the patient harming others, then inpatient care must be arranged. Otherwise, it is possible to discharge patients home with close outpatient follow-up with psychiatric services or a suitable family medicine doctor.

Anxiety Disorders

Anxiety is a normal emotion that healthy people feel at times. If a person feels a disproportionate amount of anxiety or for prolonged periods of time, then there may be an underlying anxiety disorder. Anxiety disorders can affect to 20% of adults at some point in their lives and can vary from specific phobias (7–9%), social anxiety (7%), panic disorder (3%), and generalized anxiety disorder (3%).

Panic Disorders

A panic attack is an abrupt period of fear and discomfort associated with physical and cognitive symptoms.

The *DSM-5* criteria for diagnosing panic disorder are as follows—four or more of the following symptoms:

- Palpitations, pounding heart, or accelerated heart rate
- Sweating
- Trembling/shaking
- Shortness of breath/feeling of smothering
- Feelings of choking
- Chest pain or discomfort
- Nausea/abdominal distress
- Feeling dizzy, unsteady, lightheaded, or faint
- Chills/heat sensations
- Paresthesia (numbness or tingling sensations)
- Derealization (feeling of unreality) or depersonalization (being detached from oneself)
- Fear of losing control/going crazy
- Fear of dying

A patient who experiences multiple panic attacks may have an underlying panic disorder or another mental health disorder and often this requires specialist consultation before a diagnosis can be made. Panic disorder is often accompanied with specific behavioral changes in the patient leading them to avoid situations and locations and can lead to significant changes in the patient's personality leading them to become withdrawn, passive, or dependent on others.

Generalized Anxiety Disorder

In some people, the excessive worry and anxiety about different events, topics, and activities can be very difficult to control. In generalized anxiety disorder, the symptoms occur on most days for at least 6 months. This excessive anxiety is associated with three of the following six symptoms:

1. Restlessness or feeling "on edge"
2. Irritability
3. Feeling easily fatigued
4. Difficulty in concentrating or going blank
5. Muscle tension
6. Sleep Disturbance

Post-traumatic Stress Disorder

Post-traumatic stress disorder is caused by witnessing or experiencing a highly traumatic event and manifesting symptoms of re-experiencing the events months or years later. The symptoms can range from mild anxiety symptoms to more severe symptoms that lead the patient to avoid triggers and can lead to changes in personality like those in anxiety disorders.

General Approach to Panic Disorders

Take a thorough history about the precipitants and situation leading to the symptoms. Pay special consideration to alcohol and drug use (both prescribed and illicit). Take a full social and past social history to help determine if there are any elements in the patient's life that may have led to their current state of mind.

It is also important to pay attention to stimulant use including caffeine and nicotine (tea, coffee, and tobacco usage) as excessive use of these can exacerbate anxiety states.

There are many significant medical conditions that can present with anxiety symptoms and one must try and exclude these as the cause of symptoms (**Table 4**).

TABLE 4: Common medical conditions that can present with anxiety or present as an anxiety disorder.

Cardiac	• Acute coronary syndromes (MI and angina) • Cardiac dysrhythmias • Congestive cardiac failure
Respiratory	• Pulmonary embolus • Asthma and COPD exacerbations • Hypoxia/hypercapnia
Endocrine	• Hyperthyroidism • Hypoglycemia • Pheochromocytoma • Hypoparathyroidism
Neurological	• TIAs and stroke • Seizure disorders/postictal state • Head injury/intracranial bleeding
Environmental	• Alcohol intoxication and withdrawal • Drug abuse/intoxication and acute withdrawal carbon monoxide poisoning

(COPD: chronic obstructive pulmonary disease; MI: myocardial infarction; TIAs: transient ischemic attacks)

Treatment for Anxiety Disorders

Significant anxiety can sometimes manifest as acute agitation. In these patients, proceed with cautious verbal and environmental de-escalation strategies as described earlier, with use of medical or physical restraint as appropriate to the circumstance.

Specialist treatment with selective serotonin reuptake inhibitors (SSRIs) and serotonin and norepinephrine reuptake inhibitors SNRIs should be initiated by doctors experienced in their use and hence the patients should be referred to psychiatric services. Benzodiazepines must be prescribed with caution due to risks of addiction and dependence. It may be appropriate to use them in short, minimal dosed prescriptions from the ED to allow patients to bridge the gap till they can be seen and assessed by psychiatric services.

Other treatment modalities including counselling, psychotherapy, and cognitive behavioral therapy (CBT) have been shown to improve symptoms. Often a combination of medication, counselling and CBT, is needed for long-term treatment success.

Most patients with anxiety disorder can be discharged from the ED with arrangements for outpatient follow-up. However, patients with suicidal or homicidal ideation, severe depressive symptoms, or psychosis require inpatient care.

THOUGHT DISORDERS, PSYCHOSIS, AND SCHIZOPHRENIA

Thought Disorders

Formal thought disorders (FTDs) are disorders of organized thinking that manifest as disorganized language (speech and writing). There are >25 forms of thought disorder that have been described and these are often features of schizophrenia. FTDs can also be present in neurological and neurodegenerative conditions, manic disorders, and mood disorders.

Common types of thought disorders include (but are not limited to):

- Alogia (poverty of speech) where there is lack of speech or content
- Thought blocking where there is an abrupt break in a train of thought
- Derailment (knight's move thinking) where speech or writing moves from one idea to another that is either unrelated or very loosely related to the last idea
- Flight of ideas where thoughts move rapidly from one topic to another
- Neologisms where the person makes up new words that may be used to describe an item or idea
- Illogicality where the person reaches a conclusion which does not follow a logical chain of ideas
- Echolalia where a question or statement is repeated multiple times

Formal thought disorder can be present in >90% of psychosis.

Psychosis

Psychosis is a condition where the mind has difficulty in determining what is real and what is not. It is a combination of delusions (beliefs that contradict rational argument) and hallucinations (experiences where one hears, sees, or feels something that are not real) and can be caused by drugs, alcohol, sleep deprivation, postpartum illness, and also schizophrenia and mood disorders (**Table 5**).

Workup of psychotic symptoms should be focused on excluding medical causes before a diagnosis of a mental health condition can be made. A thorough history and examination including collateral history (if possible) should be taken. CBC, kidney function test, Electrolytes, Liver function test, and a venous blood gas should all be performed as well as syphilis serology, if indicated. An electroencephalogram (EEG) should be considered if epilepsy is a possibility. Neuroimaging in the form of CT and/or MRI should also be performed.

TABLE 5: Causes of psychosis.

Primary psychiatric conditions	• Schizophrenia • Mood disorders • Schizoaffective disorder • Delusional disorder • Personality disorders • PTSD
Neurodegenerative	• Alzheimer's • Parkinson's • Lewy body dementia
Neurological	• Space-occupying lesions/tumors • Stroke • MS • Epilepsy
Infection	• Encephalitis • HIV/AIDS • Malaria • Syphilis
Autoimmune	• SLE • Sarcoidosis
Endocrine	• Hypothyroidism and hyperthyroidism • Hypoglycemia • Hypoparathyroidism and hyperparathyroidism • Cushing's
Metabolic	• Electrolyte derangement • Liver failure • Renal failure • B12 deficiency
Environmental and social	• Alcohol excess and withdrawal syndrome • Toxins including heavy metals • Poisoning • Recreational drugs • Medications (sympathomimetics, dopamine agonists, steroids, and stimulants)

(AIDS: acquired immunodeficiency syndrome; HIV: human immunodeficiency virus; MS: multiple sclerosis; PTSD: post-traumatic stress disorder; SLE: systemic lupus erythematosus)

Schizophrenia

Schizophrenia is a mental health disorder that is characterized by multiple or continuous episodes of psychosis and thought disorder in the absence of an obvious organic cause (although there are known genetic and environmental factors including heavy cannabis use). Males are more commonly affected than females and lifetime incidence is around 1 in 200. There is significant impact on patient's lives as around half of people with schizophrenia suffer lifelong symptoms and life expectancy may be reduced by 20 years due to an increase in suicides and physical health conditions.

The *DSM-5* criteria for schizophrenia are as follows:

- The presence of two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated), with at least 1 of them being (1), (2), or (3): (1) delusions, (2) hallucinations, (3) disorganized speech, (4) grossly disorganized or catatonic behavior, and (5) negative symptoms.
- For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas (e.g., work, interpersonal relations, or self-care) is markedly below the level achieved before onset; when the onset is in childhood or adolescence, the expected level of interpersonal, academic, or occupational functioning is not achieved.
- Continuous signs of the disturbance persist for a period of at least 6 months, which must include at least 1 month of symptoms (or less if successfully treated); prodromal symptoms often precede the active phase, and residual symptoms may follow it, characterized by mild or subthreshold forms of hallucinations or delusions.

Negative symptoms are a lack of normal emotional responses or thought processes and include blunted affect (flat expression or little emotion); alogia (poverty of speech); anhedonia (inability to feel pleasure); lack of desire/ability to form relationships; and apathy.

A note should be made of schizoaffective disorder which is considered a separate mental health illness to schizophrenia and includes features of both schizophrenia and a mood disorder (manic and depressive types).

Treatment of schizophrenia and schizoaffective disorder should be instigated by experienced mental health physicians. In the ED, patients who are at risk to themselves or others may require sedation (using haloperidol or benzodiazepines) and/or restraint (using the least invasive and risky method possible). Treatment may include antipsychotic medications, psychotherapy, and counselling. These therapies may be performed as inpatient care or in the community, but the ultimate decision should be left to the psychiatric team and early referral from the ED is advised.

SUMMARY

Significant portion of all ED patient constitute mental and behavioral health disorders. Commonly psychiatric acute presentations involve self-harm, substance abuse, suicidality, agitation, and/or exacerbations of underlying mood, anxiety, and thought disorders. Over the years prevalence of psychiatric disease presentation to the ED has seen a significant rise. Emergency physicians still face considerable challenges when encountering these patients despite the relative frequency of presentation, psychiatric emergencies are vastly underrepresented in most emergency medicine academic curriculums. Emergency physician hesitant to face the psychiatric emergency due to reduced exposure to psychiatric disease during clinical training, along with the inherently confounding nature of acute mental illness often contribute to with these patients in the ED. Nevertheless, the ED continues to grow increasingly responsible for providing care to patients presenting with mental and behavioral health issues, making it crucial for emergency physicians to practice and develop skills in acute psychiatric care. Emergency physician should be aware of techniques in recognition, assessment, management, and disposition of commonly encountered psychiatric emergencies.

153
CHAPTER

Acute Pelvic Pain

Dolly C Yadav

INTRODUCTION

Acute pelvic pain is commonly defined as acute onset lower abdominal pain of <3 months duration. Globally, about a tenth of the emergency department (ED) visits are attributed to abdominal pain. However, data is unavailable for the prevalence of acute pelvic pain since it is not distinguished from abdominal pain in studies. It is estimated that over a third of women, in the reproductive age group, experience pelvic pain unrelated to menstruation. Moreover, acute pelvic pain possesses a diagnostic challenge as the multisystem etiologies frequently have overlapping and nonspecific pain, symptoms, and physical examination findings. As with any other clinical presentation, causes of acute pelvic pain can be life-threatening and have lasting sequels. Hence, it is imperative that an emergency physician studies management of acute pelvic pain which is illustrated in this chapter.

ANATOMY, PATHOPHYSIOLOGY, AND ETIOLOGY

The female pelvis comprises organs of the reproductive system—vagina, uterus, fallopian tubes, and ovaries; urinary system—ureters and urinary bladder; gastrointestinal system—sigmoid colon and rectum; as well as components of the musculoskeletal system. Acute pelvic pain can originate from the reproductive organs or from any structures that lie next to or pass through the pelvis. The pelvic organ nerve innervation is from T9–L1 and S2–S4 spinal nerves. Pain may be initiated by inflammation, distention, or ischemia of an organ, or by spillage of blood, pus, or other material into the pelvis. The dull aching or the visceral pain is a result of the overlap of afferent innervation supplying the pelvic organs and the appendix, ureters, and colon, making their precise localization difficult. On the other hand, sharp stabbing like results pain when the afferent nerves in the parietal peritoneum adjacent to an affected organ are stimulated. Further characteristics of pelvic pain along with features and differential diagnoses are illustrated in **Table 1**.

EMERGENCY DEPARTMENT EVALUATION

The history and physical examination help in arriving at the definitive diagnosis. However, due to overlap of clinical presentations and frequent atypical presentations, diagnosis is often reached after investigations, especially pregnancy test and radiological imaging.

History

The characteristics of pain must be included in history as these throw light on the possible disease processes, as shown in **Table 1**. Furthermore, detailed social history should include the patient's sexual history, history of sexually transmitted infection (STI), sex partner's symptoms and details on intrauterine device (IUD), induction of ovulation during infertility treatment; besides questions pertaining to gynecologic, obstetric, urologic, gastroenteric histories must also be elicited. It is fairly common to utilize the mnemonic SAMPLE for comprehensive history taking—Signs and symptoms, Allergies, Medical history, Past medical history particularly about abdominopelvic surgery, Last meal timing, and Events leading to this presentation. Although one study concluded that sexual history and self-assessment can be used as a highly effective predictor of a patient not being pregnant, another study found that 7% of women who denied being pregnant and stated normal last menstrual cycle, tested positive for pregnancy test. Nevertheless, it is a safe practice to test every female with abdominopelvic pain, in reproductive age group and intact reproductive organs, for pregnancy.

Physical Examination

In accordance to the initial assessment in the ED, a rapid primary assessment must be undertaken to recognize and manage life-threatening conditions prior to undertaking detailed systemic examination. In addition to the abdominal and pelvic examination, it is advised to assess other systems as the pain in the pelvic region may be referred due to pathology in other organ system. While performing abdominal

TABLE 1: Characteristics of acute pelvic pain with corresponding features and differential diagnoses.

Pain characteristics	*Features*	*Differential diagnoses*
Site of pain	Right lower quadrant of the abdomen	Acute appendicitis, pyelonephritis, ectopic pregnancy, ovarian cyst or torsion, ureteric colic, inguinal hernia, mittelschmerz, and musculoskeletal pain
	Left lower quadrant of the abdomen	Diverticulitis, ectopic pregnancy, ovarian cyst or torsion, pyelonephritis, ureteric colic, perirectal abscess, inguinal hernia, mittelschmerz, and musculoskeletal pain
	Lower abdomen	Cystitis, bowel obstruction, inflammatory bowel disease, dysmenorrhea, ectopic pregnancy, uterine perforation or myomas, abortion, pelvic inflammatory disease (PID), endometritis, ovarian hyperstimulation syndrome, placental abruption, ovarian vein thrombosis, incarcerated/strangulated hernia, displaced intrauterine device, somatization disorder, and musculoskeletal pain
Onset of pain	Acute	Vascular, obstructive, and viscus perforation causes
	Subacute	Inflammatory causes
	Chronic	Malignancy and inflammatory causes
Character of pain	Tearing like	Dissection of aorta or its branches
	Stabbing like	Irritation of parietal peritoneum
	Colicky	Obstruction of tubular organ and smooth muscle spasms, e.g., ureteric colic
	Dull	Visceral pain
Radiation of pain	Loin to groin	Nephrolithiasis
	Migration of pain from umbilicus to right lower abdomen	Acute appendicitis
	Radiation to back	Aortic dissection, PID, and cystitis
Associating factors of pain	Hypotension or signs of shock	Ruptured ectopic pregnancy, leaking aortic aneurysm, and aortic dissection
	Fever	Acute appendicitis, PID, and pyelonephritis
	Diarrhea, nausea, vomiting, and anorexia	Gastrointestinal pathology
	Vaginal bleeding or discharge, dyspareunia, and cervical motion tenderness	Sexually transmitted infection (STI), PID, and tubo-ovarian abscess (TOA)
	Vaginal bleeding	Placental abruption, miscarriage, and mittelschmerz
	Urinary frequency or hesitancy, hematuria	Nephrolithiasis and urinary tract infection (UTI)
	Pressure-like feeling in perineum	Uterine prolapse
Time course or pattern of the pain	Mid-cycle vaginal bleeding	Mittelschmerz
	During and postcoital pain	PID and gynecological malignancy
	Infertility treatment	Ovarian hyperstimulation syndrome (OHSS) and ovarian torsion
	Urogenital procedure or surgery	Wound infection or sepsis, venous thrombosis, venous thrombophlebitis, and thermal injury
	Trauma	Sexual assault, intimate partner violence, and female genital mutilation
Aggravating factors	Change in posture	Musculoskeletal pain
	Menstruation	Endometriosis and adenomyosis
	Dyspareunia	PID and TOA
	Bouncy movements like jumping or travelling over bumpy road	Peritonitis

Continued

Continued

Pain characteristics	*Features*	*Differential diagnoses*
Relieving factors	Laying still	Peritonitis and musculoskeletal pain
	Passage of urine	Acute urinary retention
Severity	Mild discomfort	PID, UTI, mesenteric ischemia, and hernia
	Moderate pain	Peritonitis, aortic aneurysmal leak or dissection, appendicitis, ovarian or adnexal cyst, miscarriage, placental abruption, strangulated or incarcerated hernia, and musculoskeletal pain
	Uncontrollable	Ovarian or adnexal torsion, ureteric colic, and labor pain

examination, note for surgical scars, assess for tenderness, palpating mass, signs of peritonitis, costovertebral angle tenderness, and digital rectal examination for occult blood. Traditionally, pelvic examination in the ED consists of bimanual and speculum examination. For diagnosing pelvic inflammatory disease (PID), cervical motion or uterine or adnexal tenderness is elicited by bimanual examination. Upon speculum examination, anatomy, source of vaginal bleeding or discharge, masses, and status of cervical os, can be evaluated and endocervical swabs collected. However, these days STI are often tested on self-swabbed vaginal samples or by urine antigen tests. There is a lack of accuracy and reproducibility of pelvic examination, even when undertaken by experienced examiners; positive examination findings do not necessarily rule in serious pathology; and a normal examination does not rule out significant disease; rendering pelvic examination undesirable in the ED. On the contrary, in an unstable patient of trauma, hemodynamic instability, suspected organ prolapse causing acute urinary retention, a pelvic examination is advised in order to identify a source and quantify blood loss, manual aspiration of uterine contents (i.e., retained products of conception) and identify the prolapsed organ, which may be easily reduced. To avoid legal consequence, it is highly recommended to take help of a chaperone during physical examination in case the emergency physician is male or if the patient is uncomfortable. Adolescents, pregnant, and postpartum women deserve special attention. Confidentiality, local laws pertaining to consent, and high-risk behavior makes adolescent population uniquely challenging to evaluate. Besides, for completing medical assessment in adolescents, consent from the patient, understanding of the laws pertaining to consent, and building rapport are vital.

Investigation

Although acute pelvic pain may be caused by pathologies from different organ systems, an important determinant of diagnostic approach in a woman with intact reproductive organs, in reproductive age, is the pregnancy test. More than often, this is undertaken as a point of care testing either using urine or blood sample for beta-subunit of human chorionic gonadotropin (beta hCG). These tests are sensitive to 25 IU/L and become positive 3–4 days after implantation. By 7 days after implantation, or the time of the expected menstrual period, 98% of the pregnancy tests will be positive. A pregnancy test is required in almost all the women of reproductive age with intact reproductive organs. A positive test may indicate intra- or extrauterine pregnancy, or molar pregnancy, or cancer. Hence, it is advised that patients with a positive pregnancy test should undergo ultrasound assessment, bedside or formal, to evaluate for ectopic pregnancy.

In the evaluation of STI or PID or tubo-ovarian abscess (TOA), the nucleic acid amplification tests (NAATs) to detect chlamydia and gonorrhea are often used in the ED. These tests amplify and detect deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) sequences and are much more sensitive than previous chlamydia and gonorrhea tests. Urine NAATs have sensitivities and specificities similar to those of cervical samples. Still, cervical wet mount can be useful in detecting bacterial vaginosis and trichomoniasis, especially to identify antibiotic-resistant organisms when lately antibiotic course for gonorrhea or chlamydia has been finished. Additionally, urine analysis may show pyuria suggesting urinary tract infection (UTI) or hematuria suggesting ureteral stone. It is advised to perform urinalysis in all pregnant patients irrespective of absence of UTI symptoms. Although the white cell count is one of the most common tests ordered in the ED, it is not adequate by itself to diagnose or dispose patient with acute pelvic pain.

It is estimated that up to 65% of patients presenting with nontraumatic abdominopelvic pain will receive a radiological imaging study in the ED. However, selecting an initial imaging modality is challenging as the differential diagnosis for abdominopelvic pain in women is so wide-ranging. The goal of imaging is to make the most accurate diagnosis using the least amount of radiation; therefore, transvaginal ultrasonography is the imaging modality of choice. The American College of Radiology Appropriateness Criteria state pelvic sonography as the preferred first-line imaging modality in the evaluation of acute pelvic pain in pregnant and nonpregnant women of reproductive age when an obstetric or gynecologic condition is suspected, and in the initial assessment of a suspected nongynecologic condition in a pregnant patient. This can be attributed to its ready availability, cost-effectiveness, noninvasive nature, and lack of ionizing radiation.

Furthermore, a patient with a positive pregnancy test results in whom a definite intrauterine pregnancy cannot be seen is presumed to have an ectopic pregnancy until proved otherwise. In 5–10% of ectopic pregnancies though, a pseudosac, which mimics intrauterine pregnancy, may be seen on transvaginal ultrasonography. A pseudosac is characterized by only a single echogenic ring in contrast to an intrauterine pregnancy recognized by double echogenic rings (double decidual sac sign). Also, presence of free intra-abdominal fluid on ultrasound images is consistent with hemorrhage from either an ectopic pregnancy or a ruptured ovarian cyst and must be addressed expediently. Although sonography can be useful, CT is typically the preferred first-line imaging modality in the evaluation of nongynecological causes of pelvic pain in a

nonpregnant woman. If a CT is entirely negative, there is little to no utility in obtaining an immediate follow-up ultrasound.

Diagnosis

Upon completion of evaluation, the emergency physician must be able to reach at a diagnosis. **Table 2** summarizes the differential diagnosis in acute pelvic pain with corresponding ED investigations and **Flowchart 1** shows the algorithmic approach to acute pelvic pain in the ED.

TREATMENT

The goal of the emergency management is to rule out acute causes of abdominal pain associated with high morbidity and mortality, such as acute ovarian/adnexal torsion or ectopic pregnancy, TOA, appendicitis, dissection, abdominal aortic aneurysmal rupture, mesenteric ischemia, strangulated or incarcerated hernia; to assess for the possibility of neoplasm or malignancy; and either to refer the patient to the appropriate consultant or to discharge them with a clear plan for follow-up with an obstetrician/gynecologist. Simultaneously, the pain must be managed adequately as a good medical practice. Although nonsteroidal anti-inflammatory drugs (NSAIDs) are preferred medications for pain, narcotic medications can be utilized if the pain score is high. Ondansetron, metoclopramide, or promethazine are commonly used antiemetics, when indicated. Whenever intra-abdominopelvic infection is suspected, antibiotics must be initiated. It is advised to include metronidazole with an aminoglycoside for anaerobic and gram-negative coverage. Alternative to metronidazole, clindamycin may be used. It is also advised to follow national and institutional antibiotic regimen policies. Although for cervicitis, a single dose of intramuscular ceftriaxone and a single dose of oral azithromycin suffice, PID requires prolonged therapy with broad-spectrum antibiotics.

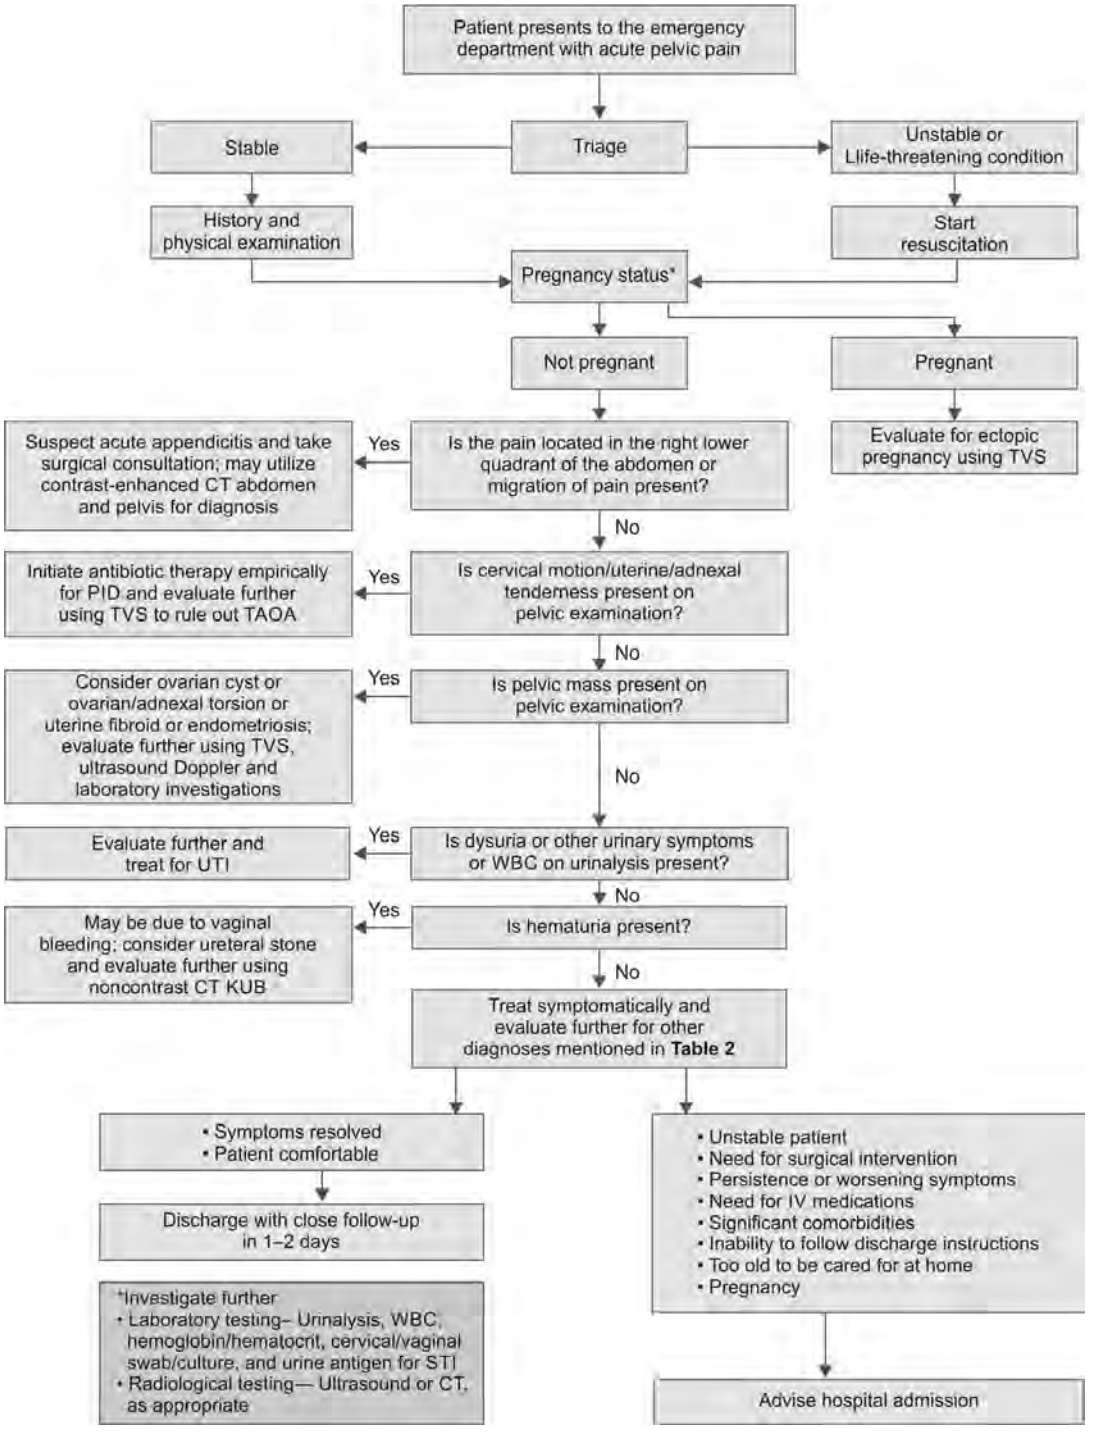
Antibiotic therapy for STI and PID is targeted at the causing organisms. Outpatient therapy with ceftriaxone, azithromycin, or doxycycline is commonly used and is as effective as parenteral treatment in mild-to-moderate disease. Inpatient therapy with cefotetan or cefoxitin intravenously and oral doxycycline is recommended for those with severe infections, including TOA. An alternative regimen is intravenous clindamycin and gentamicin. Delay in diagnosis and treatment of PID probably contributes to inflammatory sequelae in the upper reproductive tract; hence, therapy must be initiated empirically. Additionally, arrangements should be made to link the partners of women who have PID to care.

DISPOSITION AND FOLLOW-UP

First and foremost, patient with a critical etiology of acute pelvic pain must be appropriately resuscitated. Subsequently, the need for admission is decided upon clinical condition of the patient, persistence or worsening of signs and symptoms, need for intravenous medications, significant comorbidities, and vulnerability of the patient which prevents the patient to follow discharge instructions or cared for at home. The rest of the

TABLE 2: Differential diagnosis of acute pelvic pain with corresponding emergency department (ED) investigations.

Women of reproductive age	*Gynecologic diagnoses:* • Endometriosis, adenomyosis, dysmenorrhea, degenerating uterine fibroid, mittelschmerz, ovarian torsion, pelvic inflammatory disease (PID), ruptured ovarian cyst, tubo-ovarian abscess (TOA), ovarian hyperstimulation syndrome, complication of surgery or procedure, and malignancy	• Pregnancy test • White cell count • Hemoglobin and hematocrit • Urinalysis • Transvaginal and/or transabdominal ultrasound
	Gastrointestinal diagnoses: • Appendicitis, bowel obstruction, diverticulitis, hernia, irritable bowel syndrome, mesenteric venous thrombosis, perirectal abscess, volvulus, and bowel obstruction	• Pregnancy test • White cell count • Hemoglobin and hematocrit • Urinalysis • Abdominopelvic CT
	Urologic diagnoses: • Urinary tract infection, stone in bladder or ureter, and acute retention of urine	
	Others: • Dissecting aortic aneurysm, pelvic trauma, sexual assault, lead poisoning, malingering, narcotic seeking, porphyria, sickle cell crisis, and somatization disorder	
Pregnant women	Ectopic pregnancy, corpus luteum hematoma, ovarian vein thrombosis, placental abruption, uterine impaction, postpartum endometritis, and ovarian torsion	• Pregnancy test • White cell count • Hemoglobin and hematocrit • Blood group and Rh factor • Urinalysis • Transvaginal and/or transabdominal ultrasound
Adolescents	Similar to women of reproductive age, with the addition of imperforate hymen and transverse vaginal septum	
Postmenopausal women	Similar to women of reproductive age minus ectopic pregnancy and ovarian torsion	



Patient presents to the emergency department with acute pelvic pain
Triage
Stable
Unstable or Llife-threatening condition
History and physical examination
Start resuscitation
Pregnancy status*
Not pregnant
Pregnant
Is the pain located in the right lower quadrant of the abdomen or migration of pain present?
Yes
Suspect acute appendicitis and take surgical consultation; may utilize contrast-enhanced CT abdomen and pelvis for diagnosis
No
Evaluate for ectopic pregnancy using TVS
Is cervical motion/uterine/adnexal tenderness present on pelvic examination?
Yes
Initiate antibiotic therapy empirically for PID and evaluate further using TVS to rule out TAOA
No
Is pelvic mass present on pelvic examination?
Yes
Consider ovarian cyst or ovarian/adnexal torsion or uterine fibroid or endometriosis; evaluate further using TVS, ultrasound Doppler and laboratory investigations
No
Is dysuria or other urinary symptoms or WBC on urinalysis present?
Yes
Evaluate further and treat for UTI
No
Is hematuria present?
Yes
May be due to vaginal bleeding; consider ureteral stone and evaluate further using noncontrast CT KUB
No
Treat symptomatically and evaluate further for other diagnoses mentioned in Table 2
• Symptoms resolved
• Patient comfortable
Discharge with close follow-up in 1–2 days
*Investigate further
• Laboratory testing– Urinalysis, WBC, hemoglobin/hematocrit, cervical/vaginal swab/culture, and urine antigen for STI
• Radiological testing— Ultrasound or CT, as appropriate
• Unstable patient
• Need for surgical intervention
• Persistence or worsening symptoms
• Need for IV medications
• Significant comorbidities
• Inability to follow discharge instructions
• Too old to be cared for at home
• Pregnancy
Advise hospital admission

(IV: intravenous; KUB: kidney, ureter, and bladder; PID: pelvic inflammatory disease; STI: sexually transmitted infection; TOA: tubo-ovarian Abscess; TVS: transvaginal sonography; UTI: urinary tract infection; WBC: white blood cell)

FLOWCHART 1: Approach to acute pelvic pain in the emergency department.

patients are discharged from the ED after initiating treatment with thorough discharge instructions. The ED discharge instructions must include details of treatment, follow-up plan, and return to the ED instructions; along with information of the potential risks of infertility, disability, and malignancy caused by treatment delays or noncompliance. It is advisable that the discharged patients are reviewed in a day or two in the ED or gynecology clinic. In a STI or PID patient, it is also advised to link, treat, and follow-up patient's sexual partner.

SPECIFIC CONDITIONS IN NONPREGNANT FEMALES

Ovarian Cysts

An ovarian cyst is a sac filled with liquid or semiliquid material that arises in an ovary. The vast majority of these lesions are benign. Most ovarian cysts begin as physiologic follicular or corpus luteal cysts; they become symptomatic by several

mechanisms: rupture of contents with subsequent chemical peritonitis, torsion of enlarged ovaries, and mechanical pressure on adjacent structures due to large size. Functional cysts, formed as part of the normal menstrual cycle, are fluid-filled sacs in the ovary, and are considered cysts once >2 cm in dimension. Most patients with ovarian cysts are asymptomatic, however, some present with sudden-onset, unilateral, dull, or colicky pain, which may begin after sexual intercourse. Besides, pain due to cyst rupture or torsion arises suddenly where as a slowly growing cyst results in pressure effect and chronic dull pain. The risk factors for ovarian cyst formation include infertility treatment, pregnancy, hypothyroidism, tamoxifen, cigarette smoking, and tubal ligation. Risk of cyst rupture increases with ovulation; there is an increased risk with ovulation induction treatments and a decreased risk with use of oral contraceptive pills. **Table 3** describes the characteristic features of different ovarian cysts. In polycystic ovarian syndrome, the ovary often contains multiple cystic follicles (2–5 mm in diameter) as viewed on ultrasound.

Most of the ovarian cysts are discovered incidentally during ultrasonography or routine pelvic examination. As per American College of Obstetrics and Gynecology (ACOG) guidelines, transvaginal ultrasound is the preferred imaging modality for assessment of a suspected pelvic mass. The definitive diagnosis of all ovarian cysts is made based on histologic analysis. Pregnancy test, white cell count, hemoglobin and hematocrit, urinalysis, endocervical swabs, serum biomarkers such as cancer antigen 125 (CA125), hCG, L-lactated dehydrogenase, alpha-fetoprotein, and inhibin may aid in the differential diagnosis of cysts and in the management of cyst-related complications. In most cases, the ovarian cyst is benign and asymptomatic, requires no further management, and will resolve on its own. In other cases, ovarian cyst-related complications, such as rupture and hemorrhage or torsion, occur. In a postmenopausal patient, a persistent cyst <10 cm in dimension in the presence of a normal CA125 value may be monitored with serial ultrasonographic examinations. On the contrary, persistent ovarian cysts >10 cm (especially if symptomatic) and complex ovarian cysts should be considered for surgical removal. Thus, management depends largely on the degree of pain and hemorrhage, and sometimes on the type of cyst. Patients with cysts without concern for torsion and without large hemorrhage can be managed conservatively as outpatients with symptom control and follow-up with a gynecologist for a repeat ultrasound in 4–6 weeks. Rarely, a dermoid cyst or an endometrioma can rupture spilling cysts contents respectively, sebaceous or chocolatey, into the abdominal cavity; leading to chemical peritonitis and shock; almost always requiring an emergent surgical intervention.

Ovarian Torsion or Adnexal Torsion

Ovarian or adnexal torsion is an uncommon but noteworthy cause of acute pelvic pain because it is a surgical emergency, and prompt diagnosis is critical for preserving ovarian function and future fertility. Ovarian torsion can occur at any age, but most frequently occurs in women of reproductive age. Torsion occurs when the adnexa, ovary, or seldomly fallopian tube alone, completes at least one full turn around the long axis of the infundibulopelvic ligament and the tubo-ovarian ligament; initially decreasing the lymphatic draining and venous return from the ovary, followed by hemorrhagic infarction and necrosis of the adnexal structures distal to the point of torsion. It is important to note that, the ovaries have dual blood supply from the ovarian and uterine arteries, and thus, torsion can occur without complete loss of vascularity. Classically, patients present with sudden-onset, severe, and unilateral pelvic pain that may develop after episodes of exertion, frequently associated with nausea and vomiting. Unfortunately, atypical presentations are common and include mild, intermittent, and bilateral pain. History of previous torsion, adnexal masses or cysts, use of assisted reproductive technologies leading to ovarian hyperstimulation, polycystic ovarian syndrome, pregnancy, and previous tubal ligation are the risk factors for torsion of ovary or adnexa. It is thought that mass effect of the sigmoid colon prevents left adnexal twisting. Similarly, endometriosis, PID, and lesions which have a role in affixing the ovary to the pelvic wall may have a role in reducing the likelihood of torsion. Upon pelvic examination, a tender adnexal mass may be palpated. Leukocytosis has been shown to have a modest positive predictive value for adnexal torsion.

TABLE 3: Characteristics of different types of ovarian cysts.

Types of ovarian cyst	*Characteristic features*
Follicular cyst	Follicular cysts occur when the nondominant follicle does not reabsorb and instead grows in size; are thin-walled, avascular, and usually unilocular; and more prevalent
Corpus luteal cysts	Corpus luteal cysts occur when they persist beyond menstruation; are thicker, with irregular and hypervascular walls; more likely to be symptomatic; and more likely to rupture or hemorrhage
Pathologic cysts	• Examples are endometriomas, dermoid cysts, or cystic components of benign or malignant neoplasms; cause pain from growth, rupture, or hemorrhage • *Dermoid cysts* are growths filled with various types of tissue such as fatty material, hair, teeth, bits of bone, and cartilage • *Endometriomas* are collections of endometrium-like material on the outside of the ovary; are filled with a thick chocolate-type material and hence known as "chocolate cysts" • *Cystadenomas* are cysts that develop from cells on the outer surface of the ovary; benign; grow very large; and cause pain • *Neoplastic cysts* arise via the inappropriate overgrowth of cells within the ovary and may be malignant or benign. The most frequent malignant neoplasms arise from the surface epithelium (mesothelium); others may contain granulosa cell tumors from sex cord-stromal cells and germ cell tumors from primordial germ cells. The benign counterparts of these cancers are serous and mucinous cystadenomas

Transvaginal ultrasonography with color Doppler analysis is the method of choice for the evaluation of ovarian/adnexal torsion because it can show morphologic and physiologic changes in the ovary and can help in determining whether blood flow is impaired. Furthermore, in 50–81% of cases of ovarian torsion, an underlying lesion is seen in the ipsilateral ovary. In a premenopausal woman, the ovary is considered enlarged if the greatest ovarian dimension is >4 cm or the volume is >20 cm^3. The presence of the *"whirlpool sign"*, a clockwise or counter-clockwise wrapping of hypoechoic vessels around a central axis, correlates closely with surgically proven torsion. Multiple small, uniform, and peripherally located cysts displaced to the cortex of the engorged ovary are seen in as many as 74% of cases. This finding is sometimes referred to as the "string-of-pearls" sign. The presence of an enlarged ovary with lack of intraovarian arterial or venous flow is highly indicative of torsion, particularly if the typical appearance of an enlarged ovary with small peripheral cysts is depicted. However, the presence of adnexal flow should not be interpreted as ruling out the diagnosis. The most diagnostically accurate sonographic signs are abnormal ovarian blood flow and the presence of free fluid. Since, the diagnostic accuracy of ultrasound is found to be 74.6%, ovarian torsion should not be ruled out when typical findings are absent, especially when clinical history is suggestive of the condition. Abdominopelvic CT may be useful to diagnose other possible causes of lower abdominal pain. The CT findings in ovarian torsion includes enlarged adnexal structure (>5 cm), thick and straight blood vessels draped around the lesion, complete absence of enhancement, hemorrhage or gas in the torsed lesion, misplacement of the torsed structure (to the midline or contralateral side), deviation of the uterus to the ipsilateral side, infiltration of the periadnexal fat, tubal thickening, thickened vascular pedicle with engorged vessels, and ascites.

Regardless of whether laboratory and radiologic studies yield normal results, a patient with a history and physical examination findings suggestive of ovarian or adnexal torsion should be admitted and either operated on or observed by a gynecologist. If no gynecologist is immediately available, transfer to a tertiary center for higher level of care is warranted. Besides, laparoscopy can be used for both confirmation of the diagnosis and treatment. There is an approximately 80% chance of normal follicular development on follow-up ultrasound upon detorsion of adnexa. During the surgery, cyst drainage or cystectomy, along with fixing the adnexa to reduce the chances of retorsion; salpingo-oophorectomy, if the adnexa remain necrotic after detorsion; may be required. Detorsion of the adnexa during pregnancy has not been found to compromise fetal well-being. However, if the corpus luteum cyst is removed during salpingo-oophorectomy, supplemental progesterone is indicated. An adnexal mass concerning for malignancy, in postmenopausal patients, may need extensive resections with biopsies and so surgical intervention may be delayed.

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) is an infrequent, iatrogenic complication of ovarian stimulation for infertility treatments. Since the frequency of infertility treatment is increasing and because OHSS can cause multi-organ dysfunction and death, it is vital that the emergency physicians become familiar with OHSS. This syndrome is characterized by ovarian enlargement due to multiple ovarian cysts and an acute fluid shift into the extravascular space. OHSS is classified into mild, moderate, and severe. Mild cases of OHSS present with abdominal distension and discomfort, nausea, and vomiting, and have an ovarian enlargement of 5–12 cm. In addition to features of mild category, once ultrasonographic evidence of ascites is present, patients are classified as moderate OHSS. Consequently, patients are categorized as severe OHSS when in addition to all of the above features, clinical evidence of ascites and/or hydrothorax and breathing difficulties, change in the blood volume, increased blood viscosity due to hemoconcentration, coagulation abnormalities, and diminished renal perfusion and function are present. It is desirable to maintain a high degree of clinical suspicion and a low threshold for admission. The emergency physician must note that aggressive palpation of the abdomen can precipitate follicular rupture and early surgery may cause extensive bleeding from ovarian cysts. Fortunately, OHSS is a self-limiting disease. Therefore, treatment is largely conservative and supportive and includes early surgical intervention in cases of ovarian torsion or hemorrhage; paracentesis to address ascites as this reduces the pressure on the inferior vena cava and diaphragm; placement of a transthoracic tube to manage pleural effusions. Nonetheless, laparotomy during torsion and intraperitoneal hemorrhage is lifesaving and recommended. Significant morbidity and fatalities do occur in cases of severe OHSS. However, the prognosis is excellent in mild or moderate cases of OHSS, and in severe OHSS, if appropriate treatment is given.

Pelvic Inflammatory Disease

Pelvic inflammatory disease encompasses a spectrum of inflammatory disorders of the upper female genital tract, including any combination of endometritis, salpingitis, TOA, and pelvic peritonitis. The common organisms causing PID are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, microorganisms that comprise the vaginal flora such as anaerobes, *Gardnerella vaginalis*, *Haemophilus influenzae*, enteric gram-negative rods, *Streptococcus agalactiae, cytomegalovirus (CMV)*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Mycoplasma genitalium*. Furthermore, women <25 years, multiple sexual partners, not using condom, recent treatment for STI, or human immunodeficiency virus (HIV)-positive status are the risk factors for PID. Many episodes of PID go unrecognized. While some cases are asymptomatic, others get misdiagnosed due to mild or nonspecific symptoms or signs such as abnormal bleeding, dyspareunia, and vaginal discharge. The treatment should be initiated as soon as the presumptive diagnosis of PID is made to prevent long-term sequelae such as increased risk for ectopic pregnancy, infertility, recurrent infection, and chronic pelvic pain. Likewise, the Centers for Disease Control and Prevention (CDC) recommends that a sexually active women with unexplained pelvic pain and one or more of the following—cervical motion or uterine or adnexal tenderness has a high suspicion for PID and empiric treatment must be initiated in these patients. These criteria have a sensitivity of >95%. **Table 4** explains CDC's diagnostic criteria for PID. The evaluation of PID includes pregnancy test; bimanual examination to elicit cervical motion or uterine or adnexal tenderness; speculum examination for cervical friability; cervical or vaginal swab or culture or first void urine NAAT for *N. gonorrhoeae* and *C. trachomatis;* cervical wet mount test for *Trichomonas*

TABLE 4: The Centers for Disease Control and Prevention's sexually transmitted diseases treatment guidelines, 2015 recommended diagnostic criteria for pelvic inflammatory disease (PID).

A diagnosis of PID is made when patient presents with abdominopelvic pain plus one or more mandatory criteria on examination (to initiate empiric therapy, only one mandatory criterion must be fulfilled)

Mandatory criteria (one or more with pelvic pain):	Additional criteria:
1. Cervical motion tenderness 2. Uterine tenderness 3. Adnexal tenderness	1. Oral temperature >101°F (38.3°C) 2. Abnormal cervical discharge or cervical friability 3. Presence of white blood cells on microscopy of vaginal fluid 4. Elevated erythrocyte sedimentation rate 5. Elevated C-reactive protein 6. Laboratory documentation of cervical infection with *Neisseria gonorrhoeae or Chlamydia trachomatis*

The diagnostic approach for PID includes:

- Endometrial biopsy with histopathologic evidence of endometritis
- Transvaginal ultrasonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia)
- Laparoscopic abnormalities consistent with PID

vaginalis and bacterial vaginosis; white cell count; transvaginal sonography (TVS); and/or transabdominal ultrasonography. TVS may be normal or show thickened fallopian tubes (>5 mm), and/or cogwheel sign in PID. Pelvic or TOAs may be seen as complex adnexal masses with multiple internal echoes. Pelvic ultrasound is also useful in evaluating the possibility of ectopic pregnancy, ovarian torsion, hemorrhagic ovarian cyst, appendicitis, or endometriosis. Abdominopelvic CT and MRI may also be employed in the diagnosis of PID. Also, endometrial biopsy can be used for the histopathologic diagnosis of endometritis; however, the procedure requires operating room setting. Furthermore, laparoscopy is used to obtain a more accurate diagnosis of salpingitis and a more complete bacteriologic diagnosis, and is gold standard for diagnosing PID.

Pregnant women suspected to have PID are at high risk for maternal morbidity and preterm delivery. These women should be hospitalized and treated with intravenous antibiotics. Women with HIV infection and PID when compared with HIV-negative women with PID were found to have similar symptoms, microbiologic findings and response to treatment; except higher rates of concomitant *M. hominis* and streptococcal infections and TOA. The treatment and disposition of PID is tabulated in **Table 5**. Since intravenous infusion of doxycycline is painful, it should be administered orally when possible. Noteworthy, bioavailability of oral and intravenous doxycycline is similar. Additionally, men who have had sexual contact with a woman with PID during the 60 days preceding her onset of symptoms should be evaluated, tested, and presumptively treated for chlamydia and gonorrhea, regardless of the etiology of PID or pathogens isolated from the woman. If a woman's last sexual intercourse was >60 days before onset of symptoms or diagnosis, the most recent sex partner should be treated. Patient should be instructed to abstain from sexual intercourse until they and their sex partners have been adequately treated (i.e., until therapy is completed and symptoms have resolved, if originally present). An uncommon complication of PID is Fitz-Hugh–Curtis syndrome or perihepatitis. Patients present with PID and right upper quadrant pain which responds to antibiotic treatment as mentioned above. Improving patient education; abstinence and reducing the number of sexual partners, consistent use of barrier contraceptives; extensive testing for STIs and pre-exposure vaccination in at risk population; empiric treatment and postexposure prophylaxis for HIV and STI; and treating the sexual partner, can reduce the incidence of PID.

Tubo-ovarian abscess may be suspected in a toxic looking PID patient with a significantly tender adnexal mass on pelvic examination and ultrasound. These patients must be admitted for intravenous antibiotics with anaerobic coverage and close monitoring. In case of no improvement in 2–3 days of initiating treatment, laparoscopic or surgical intervention or alternative diagnosis must be considered. Most TOA resolve; however, some may necessitate drainage. Laparotomy in TOA is reserved for ruptured abscesses or when other treatment modalities fail and may include unilateral salpingo-oophorectomy or hysterectomy and bilateral salpingo-oophorectomy depending on patient's choice of preserving fertility.

Dysmenorrhea

One of the most common causes of lower abdominal pain in women of reproductive age is dysmenorrhea or painful menstruation. Dysmenorrhea associated with absence of pelvic pathology is primary dysmenorrhea, commonly seen in adolescents; whereas in secondary dysmenorrhea a pathological cause of pelvic pain is identifiable, such as endometriosis. Most dysmenorrhic patients can be discharged from the ED after treatment with NSAIDs analgesics. Some may require hormonal contraceptive and these patients will require close follow-up.

Leiomyomas or Uterine Fibroids

Leiomyomas are estrogen-dependent, smooth muscle benign tumors, arising from the uterus or myometrium. Depending on their location in the uterus, these are categorized as submucosal (project into the cavity of the uterus), intramural (contained within the myometrium), or subserosal (project outside the uterus). Furthermore, these can have peduncle and may twist on it obstructing its own blood supply. Most women

TABLE 5: Management of pelvic inflammatory disease (PID)—diagnosis, treatment, and disposition.

PID	*Diagnosis*	*Treatment*	*Disposition*
Mild-to-moderate PID	PID without any mass or tubo-ovarian abscess (TOA)	• Ceftriaxone 250 mg intramuscularly once PLUS • Doxycycline 100 mg twice a day orally for 14 days • WITH or WITHOUT • Metronidazole 500 mg twice a day for 14 days	Outpatient follow-up with instructions to abstain from sexual intercourse until treatment is complete and until their partner or partners have been treated
Severe PID	PID with mass or TOA	• Cefotetan 2 g intravenously twice a day OR • Cefoxitin 2 g intravenously four times a day PLUS • Doxycycline 100 mg twice a day orally or intravenously *For TOA to the above therapy, add the following*: • Clindamycin 900 mg intravenously thrice a day PLUS • Gentamicin loading dose (2 mg/kg), followed by a maintenance dose (1.5 mg/kg) intravenously thrice a day or substituted with a single daily dosing (3–5 mg/kg) OR • Ampicillin/sulbactam 3 g intravenously four times a day PLUS • Doxycycline 100 mg orally or intravenously twice a day	Inpatient treatment to ensure clinical stability and improvement in cases of hemodynamic instability, peritonitis, severe systemic symptoms, concern for treatment failure of oral antibiotics (no clinical improvement after 72 h of initiation of oral therapy), pregnancy, and inability to tolerate oral antibiotics

with leiomyomas are asymptotic while the rest present with heavy menstrual bleeding or menorrhagia. It is noteworthy that acute pelvic pain results only when the fibroid has degenerated or torsed (gynecological emergency) or is associated with adenomyosis or endometriosis. Uterine fibroids are usually diagnosed on ultrasound unless they increase in size and are palpable on pelvic examination. When they enlarge, they lay pressure on adjacent pelvic organs and structures. Management in the ED includes analgesia and outpatient follow-up with gynecology unless torsion or heavy vaginal bleeding or transfusion necessitate inpatient admission.

Malposition Intrauterine Device

Intrauterine devices are one of the most effective contraceptive methods. In patients who have pelvic pain with an IUD, it is of utmost importance to completely evaluate them and exclude other causes of pain, such as PID, with and without abscess formation, and ectopic gestation. One of the most significant factors necessitating IUD removal is pelvic pain, which includes insertional pain, intermenstrual cramps often associated with spotting and bleeding, and increased dysmenorrhea. The larger stiff IUD produces localized endometrial ulceration and inflammation as they do not conform to endometrial cavity shape and cause pain. Additionally, endometrial prostaglandin release secondary to the presence of an intrauterine foreign body may also play an important role. The risk for PID associated with IUD use is primarily confined to the first 3 weeks after insertion. If an IUD user receives a diagnosis of PID, the IUD does not need to be removed. However, the woman should receive antibiotic treatment according to the recommendations and should be closely followed up. If no clinical improvement occurs within 48–72 hours of initiating treatment, IUD removal should be considered. A systematic review of evidence found that treatment outcomes did not generally differ between women with PID who retained the IUD and those who had the IUD removed. Although rare, acute pelvic pain may be caused by IUD malposition due to uterine perforation. Lactation and recent delivery are found to be independent cofactors for increased risk of uterine perforation following IUD insertion. Management in such cases begins with analgesia and a pelvic examination to check for the string of the IUD at cervical os. If present, perform an ultrasound to confirm appropriately located IUD and search for alternative diagnosis of pain. However, if the IUD string is not present at the os or is too short or not visualized in the uterus on ultrasound, it either has been expelled out or has perforated the uterus. Subsequently, an X-ray kidney, ureter, and bladder (KUB) should be ordered to visualize the IUD in the abdomen. If the IUD is seen in the abdominal area, immediate expert consultation should be taken to retrieve it surgically. If the KUB X-ray does not locate the IUD, chances are that it has been expelled out.

Endometriosis/Adenomyosis

Endometriosis is presence of endometrial-like tissue outside the uterus whereas when the endometrial-like tissue is present within the uterine muscle, the condition is known as adenomyosis. Both of these ailments result in recurrent inflammation and are seen in women of reproductive age who present with dysmenorrhea, pelvic pain, and subfertility. Dysuria and hematuria can be presenting features in cases where there is bladder involvement; painful defecation and blood in stools sometimes occur in cases where there is bowel involvement. Pelvic examination is notoriously inaccurate in estimating the volume of endometriosis, and X-rays or ultrasound or magnetic resonance imaging techniques do not improve the diagnostic accuracy. Laparoscopy remains the cornerstone of accurate diagnosis of endometriosis. ED management includes pain control using NSAIDs and gynecology outpatient follow-up.

SUMMARY

- Acute pelvic pain possesses a diagnostic challenge due to overlapping multisystem etiologies and nonspecific evaluation findings.
- Determining the pregnancy status is the critical first step in the management algorithm.
- The pelvic examination, due to lack of accuracy and reproducibility, is no longer desirable in the emergency department.
- The goal of ED management is to differentiate life or fertility-threatening emergencies from conservatively treatable pathologies.
- Pelvic ultrasonography is the first choice of imaging investigation for the gynecological causes of acute pelvic pain in all patients and for the nongynecological causes in a pregnant patient.
- A contrast-enhanced CT plays a central role in the nongynecological causes of acute pelvic pain or if the symptoms cannot be clearly localized or the ultrasound findings are unclear.
- Ovarian torsion can occur without complete loss of vascularity due to dual blood supply.
- It is desirable to maintain a high degree of clinical suspicion and a low threshold for admission for OHSS characterized by ovarian enlargement and an acute fluid shift into the extravascular space.
- Upon suspicion of pelvic inflammatory disease, empiric antibiotic therapy must be initiated for the patient and sexual partner.

154
CHAPTER

Abnormal Uterine Bleeding

Sanjukta Dutta, Mainak Majumdar

INTRODUCTION

Abnormal uterine bleeding (AUB) can be broadly defined as bleeding from uterine corpus which is abnormal in volume, duration, regularity, or frequency. It can be acute or chronic and occurs in absence of pregnancy. It may lead to loss of fertility and may end up in poor quality of life even leading to destructive surgeries such as hysterectomy in extreme cases.

Normal average blood loss is 30–35 mL per menstrual cycle. More than 80 mL blood loss per cycle is considered abnormal. Acute AUB is an episode of heavy bleeding which warrants immediate intervention to prevent exsanguination. Chronic AUB refers to bleeding that is persisting for >6 months. Various type of vaginal bleeding has been defined by *International Federation of Gynaecology and Obstetrics (FIGO)* (**Table 1**).

Globally around 9–14% women experience AUB during the childbearing years of life. In India, the prevalence is around 18%.

TABLE 1: Definition of various types of vaginal bleeding: FIGO classification of bleeding.

Type	*Definition*
Abnormal uterine bleeding	• Bleeding which is abnormal with respect to regularity, volume, frequency, or duration • May be acute or chronic (>6 months)
Heavy menstrual bleeding	Excessive menstrual bleeding which hampers physical, social, and emotional quality of life
Amenorrhea	Bleeding absent >6 months
Prolonged menstrual bleeding	Menstrual bleeding continuing for >8 days in each cycle
Intermenstrual bleeding	Episodes of bleeding interspaced between otherwise normally timed cycle
Irregular menstrual bleeding	Unpredictable onset of menstrual period, with cycle >20 days for more than a year
Postmenopausal bleeding	Bleeding occurring >12 months after menstruation has seized

(FIGO: International Federation of Gynaecology and Obstetrics)

BASIC PHYSIOLOGY

Normal menstrual cycle depends upon complex feedback mechanisms involving the hypothalamus, pituitary gland, and the ovaries. During the first half of the menstrual cycle, i.e., the follicular (proliferative) phase, estrogen level rises causing thickening of endometrium while follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secreted from the anterior pituitary stimulates the ovaries to release the oocyte.

During the second half of the cycle, i.e., the luteal (secretary) phase, the corpus luteum (formed from the residual follicular capsule after ovulation) secretes progesterone and estrogen to maintain the structural integrity of the endometrium to facilitate implantation. Involution of corpus luteum occurs in absence of human chorionic gonadotropin (hCG) (if implantation does not take place) with fall in serum concentration of progesterone and estrogen which in turn leads to vasoconstriction of spiral arterioles of endometrium resulting in sloughing of endometrial lining thus causing menstrual bleeding.

ETIOLOGY

Female of different age group with vaginal bleeding present to emergency department and emergency physician should aware of causes related to their age (**Box 1**). A large number of females who present with bleeding in emergency are in the reproductive age group. Pregnancy must always be ruled out for these women. Menopausal women who have per vaginum (PV) bleeding may be have genital tract malignancies, the most common being cancer endometrium. Cancer endometrium is also prevalent in women above age 35 years with history of heavy menstrual bleeding. Endometrial biopsy with or without hysteroscopy must be performed in all these women before initiating therapy. Other differential diagnoses to be kept in mind for menopausal causes of bleeding are atrophic endometritis, urinary infection, or bleeding per rectum.

Points to Remember

- In first 2–3 weeks of life, infants may present with vaginal bleeding. This is mostly nonpathological caused by sloughing and shedding of endometrium due to waning

BOX 1: Age-related etiology—vaginal bleeding.

Adolescent
- Anovulatory cycle (hypothalamic-pituitary-ovarian axis immaturity), pregnancy, and exogenous hormones/oral contraceptive pill (OCP)
- Coagulopathy and pelvic infections

Reproductive
- Pregnancy, anovulatory cycle [polycystic ovary syndrome (PCOS)], exogenous hormones/OCP, leiomyoma, and cervical/endometrial polyps

Perimenopausal
- Anovulatory cycle
- Leiomyoma
- Cervical/endometrial polyps
- Thyroid dysfunction

Postmenopausal
- Atrophic vaginitis
- Exogenous hormones
- Endometrial cancer
- Other neoplasms: Vulvar, vaginal, and cervical

Life-threatening causes
- Acute heavy menstrual bleeding, genitourinary trauma, and uterine arteriovenous malformation (AVM)
- Acronym for abnormal uterine bleeding: PALM-COEIN
- Polyp, adenomyosis, leiomyoma, malignancy, and hyperplasia (structural causes)
- Coagulopathy, ovulatory dysfunction, endometrial causes, iatrogenic causes not yet classified (nonstructural)

of maternal hormonal levels. The condition is self-limiting and does not require treatment.
- In women >45 years of age or in women with risk factors, malignancy and endometrial hyperplasia must be ruled out as amount of bleeding may not always correlate with the disease.

EVALUATION OF ABNORMAL UTERINE BLEEDING

Before the detailed assessment is carried out, one must check for the five crucial parameters:
1. Age
2. Pregnancy (established/unknown)
3. Volume of blood loss
4. Hemodynamic stability
5. Associated acute abdomen

Based on the above information, various differentials are kept in mind while taking history, performing examination, and ordering investigations.

Age

A large number of females who present with bleeding in emergency are in the reproductive age group. Pregnancy must always be ruled out for these women. Menopausal women who have PV bleeding may be have genital tract malignancies, the most common being cancer endometrium. Cancer endometrium is also prevalent in women above age 35 years with history of heavy menstrual bleeding. Endometrial biopsy with or without hysteroscopy must be performed in all these women before initiating therapy. Other differential diagnoses to be kept in mind for menopausal causes of bleeding are atrophic endometritis, urinary infection, or bleeding per rectum. Prepubertal girls presenting with bleeding PV are less common. Causes in this age group include trauma, endocrine tumors, and rare genital tract tumors.

Pregnancy

Pregnancy could be intrauterine or ectopic. Ectopic pregnancy is associated with small volume of bleeding with or without preceding amenorrhea. Pain abdomen is invariably present and of mild-to-severe intensity. In initial phase of rupture, patient's vital parameters may be well compensated, thus this differential must always be borne in mind even in stable patients who do not give history of amenorrhea. The ectopic pregnancy could be ruptured (requiring immediate surgery) or unruptured (qualifying for expectant/medical/surgical management). Threatened or inevitable abortion presents with small volume bleeding with or without pain. Patients are invariably stable. Ultrasound confirms the diagnosis. Incomplete or complete abortions are associated with heavy bleeding and pain. Sometimes patients may be in stage of early compensated hypovolemic shock due to blood loss. Second and third trimester pregnancy bleeding could be due to placenta previa or abruptio placentae. Bleeding is painless in the former while abruption is associated with painful, slight, brownish or dark, or fresh bleeding. Ultrasound confirms placenta previa but may not be useful to diagnose placental abruption.

Volume of Blood Loss

Common gynecological causes of heavy bleeding are fibroids, adenomyosis, dysfunctional uterine bleeding, polyps, trauma, bleeding disorders, uterine inversion, cancers, and polycystic ovaries. *Common obstetric causes of heavy bleeding are* incomplete or complete abortions, placenta previa-vasa previa, placental abruption, and postpartum hemorrhage. *Common gynecological causes of light or irregular bleeding are* polyps, polycystic ovaries, thyroid dysfunction, cancers, pelvic inflammatory disease, and ruptured ovarian hemorrhagic cyst. *Common obstetric causes of light bleeding are* ectopic pregnancy, threatened abortion, placental abruption, and placenta previa.

Hemodynamic Stability

Patients who present to emergency room with bleeding PV could be in various stages of shock. As in all emergency room protocols, the doctors and nurses must first initiate resuscitation of hemorrhagic shock. Minimum of two wide bore intravenous (IV) access lines must be secured. Blood samples must be drawn for crossmatching packed cells, hematocrit values and prothrombin time (PT), international normalized ratio (INR), and activated partial thromboplastin time (APTT). Urine for pregnancy or serum beta-hCG may be ordered if clinically indicated. Bedside ultrasound is the imaging of choice for these patients. While packed red blood cells are being issued by the blood bank, hypovolemia must be corrected with colloids and crystalloids. Foleys catheter may be inserted for intake output monitoring. In case surgical

intervention is anticipated, anesthetists, and operating room staff are informed in advance.

Once detailed history, examination, and necessary investigations confirm the diagnosis, immediate treatment action to eliminate cause of bleeding must be initiated. In case medical therapy is planned, patient could be transferred to either intensive care unit or wards based on the patient's clinical condition and results of investigations in triage.

Associated Acute Abdomen

Questions must be directed to elicit onset, duration, intensity of pain along with aggravating, and relieving factors. When slight vaginal bleeding is associated with severe pain abdomen, most common causes include ectopic pregnancy, torsion, and ruptured hemorrhagic ovarian cyst. Bleeding is invariably an incidental finding and reason for emergency presentation is the pain. Pregnancy related causes are placental abruption. Nongynecological cause can be ureteric colic with hematuria. Heavy bleeding with pain abdomen maybe encountered in adenomyosis, fibroids, and abortions. Pain may be present in cases of acute pelvic inflammatory disease with incidental PV bleeding.

History

Best medical practice always teaches the doctor to always take a complete history of the patient even in emergency setting. Questions must be asked while keeping various causes of the presentation in mind. Vital information to be elicited includes a detailed menstrual history, age, and marital status, history suggestive of bleeding disorders, associated amenorrhea, fever, gastrointestinal symptoms, giddiness, and pain.

Menstrual history must include a complete assessment of duration and volume of blood loss, including number of days of heavy and light bleeding. Volume of loss is assessed by the number of sanitary napkins or tampons used. Bleeding lasting >7 days and more than three to four sanitary napkins a day is abnormal. Passage of large clots indicates heavy bleeding. Clots >1 cm indicate blood loss of >80 mL in a cycle. Past menstrual cycle pattern including duration and length of cycles must be asked for. In cases of suspected pregnancy related cause, scanty flow in last menstrual period must be inquired. The gestation maybe greater than amenorrhea in cases with implantation bleeding.

When the woman gives prolonged history of menorrhagia, questions must be directed to rule out fibroids (heavy flow on day 2 of cycle), adenomyosis (dysmenorrhea), polycystic ovaries (irregular cycles, hirsute features, acne, and weight gain), thyroid disorders (weight changes, cold or heat intolerance, and constipation), and bleeding disorders (easy bruisability).

In cases with history of fever, hemorrhagic cystitis or acute pelvic inflammatory disease may by the etiological factor. Past medical history must be asked along with details of all medications taken including any hormonal intake or history of being on blood thinners.

Suspicion of coagulopathies should be considered if, history of heavy bleeding from menarche, postpartum hemorrhage, surgical bleeding, dental procedural bleeding (any one point), one episode of bruising per month, one episode of epistaxis per month, gum bleeding, and positive family history (any two points). Patients who screen positive for coagulopathy should be evaluated further viz, investigations for von Willebrand factor, ristocetin cofactor, and opinion of hematologist is warranted.

Physical Examination

General Examination

Upon presentation to triage, patient's vital parameters are obtained with a cardiac monitor. Signs of hemodynamic instability include tachycardia, hypotension, cold clammy extremities, pallor, and sweating. Mucosal hemorrhage, purpura, or petechial rashes maybe present in patients with bleeding disorders. Hirsutism, acne, and oily skin are present in poly cystic ovarian syndrome. Virilization may indicate an androgen secreting tumor.

Systemic Examination

Respiratory and cardiovascular systems must be checked. Per abdomen examination must be stepwise including inspection, palpation, and auscultation. On inspection, shape and contour of abdomen gives information about pelvic masses or intra-abdominal bleeding which lead to distension. Large fibroids and uterine size in pregnancy can be detected on palpation of the uterus. Presence and location of tenderness on palpation also helps narrow down the differential diagnosis to suspected causes of painful bleeding. Suprapubic tenderness is present in urinary tract infections and uterine pathology whereas in tubo-ovarian pathology the pain is in the iliac fossa. Hepatosplenomegaly may also be present in cases of chronic anemia and malignancies.

Per Speculum Examination

Per speculum examination must be carried out with all aseptic precautions with a good light source and positioning of the patient. Examination must be gentle. Clots present must be removed gently to assess for cervical lesions like polyps or masses. Care must be taken before dislodging large clots in hemodynamically unstable patients. There can be torrential bleeding once a clot is dislodged, especially in cases of genital trauma and pregnancy. In cases of big vaginal lacerations with heavy bleeding, it is prudent to shift patient to the operating room with adequate blood arranged prior to complete assessment of the laceration. Examination under anesthesia and suturing can be performed simultaneously. In such cases, vaginal packing must be done in triage to reduce blood loss in the duration required to shift the patient to the operating theater.

In cases of incomplete abortions, products of conception are also noticed mixed with the blood clots. Grape-like vesicles are present in cases of complete molar pregnancies. A previous antenatal ultrasound and evaluation in triage can clinch the diagnosis and the patient is immediately taken for suction curettage without further delay. Molar evacuations are associated with increased complications such as bleeding and embolism; hence such cases must be referred to higher centers with cardiopulmonary backup for curettage.

Bimanual Examination

As with speculum examination, bimanual examination must be very gentle. A careless bimanual examination can result intra-abdominal bleeding due to dislodgment of clot and worsening of shock in cases of ruptured or impending rupture ectopic. Uterine size, shape, and contour are felt for and adnexal masses are ruled out. Fullness in pouch of Douglas indicates

presence of fluid. Cervical motion tenderness is present in cases of ectopic pregnancy. Bimanual examination must never be performed in cases of suspected placenta previa.

Points to Remember

In elderly or postmenopausal women, genital examination especially speculum examination can be painful due to dry mucosa or vaginal atrophy. Proper explanation of the examination process with reassurance and gentle maneuver along with generous use of anesthetic jelly is warranted. In suspected sexual assault victim, follow proper administrative and medicolegal protocol. Carefully examine patients to pick up early signs of hemorrhagic shock.

INVESTIGATIONS

Blood Investigations

After securing good IV access, samples are drawn for blood grouping and Rh typing, crossmatching of blood products, complete blood count (CBC) with hematocrit, PT, INR, APTT, serum beta-hCG in indicated cases, thyroid profile in indicated cases, kidney function test (KFT) and liver function test (LFT) in indicated cases, and viral markers if the patient requires surgery.

Imaging Studies

Ultrasound (transvaginal where possible) is the diagnostic modality of choice in emergency setting. Not only is it quick, but also relatively easy and also possible to perform at the bedside, if needed. In pregnant women, transvaginal sonography (TVS) can localize a pregnancy at a minimum beta-hCG value of 1,500 IU/mL. Color Doppler studies are useful in cases of ectopic and torsion. Sometimes, MRI may be required if ultrasound is unable to clinch the diagnosis. Hysteroscopy is required for diagnosis, visualization, and characterization of intrauterine abnormalities.

MANAGEMENT

Initial Treatment

Assessment of airway, breathing and circulation should be carried out first with appropriate interventions. Volume status assessment and its correction should be priority. In case of hemorrhagic shock, urgent blood and blood product transfusion is required.

Immediate resuscitation with IV fluids, IV tranexamic acid and IV pain medication is given. Antacids and antiemetics must be given if patient requires anesthesia. Invariably the patient is not in nil per oral status as required for surgery. Tamponade to the uterus can be given with roller gauze pack, balloon devices as done in postpartum hemorrhage, if needed.

Tranexamic acid (competitive plasminogen activation inhibitor):
Dose: 1–1.3 g IV (10 mg/kg) or 1.3 g oral every 8 hours. Contraindications in thrombotic/thromboembolic disease, thrombophilia, and vascular disease.

Nonsteroidal anti-inflammatory drugs (NSAIDs): Reduces pain and bleeding in AUB secondary to ovarian dysfunction by facilitating vasoconstriction via prostaglandin $F_2\alpha$ and thromboxane A. NSAIDs are contraindicated in bleeding disorder, gastrointestinal bleeding/ulcers, platelet function abnormalities, and renal dysfunction.

Naproxen dose: 500 mg 12 hourly until bleeding diminishes or pain in controlled.

Ibuprofen dose: 400 mg 6 hourly until bleeding diminishes or pain in controlled.

Mefenamic acid dose: 500 mg 8 hourly for 4–5 days or until bleeding ceases.

Treatment of Bleeding Per Vaginum in Hemodynamically Unstable Patients

Immediate Invasive Technique

Intrauterine tamponade with Foley catheter, 26F with 30 mL saline in bulb.

Uterine Curettage

It is the treatment of choice for profuse bleeding in hemodynamically unstable women. Curettage is the best modality of therapy in cases of inevitable abortions and incomplete abortions. Curettage removes all products of conception quickly. Completeness of procedure can be confirmed on ultrasound. In centers where ultrasonography (USG) is not available, the surgeon must look for four signs: (1) grating sensation of all walls, (2) reduction is size of the uterus, (3) bubbles seen at the os, and (4) closing of the os. Misoprostol may be used in conjunction with curettage. Prior usage of misoprostol helps contract the upper cavity and open cervical os. Postprocedure, misoprostol helps to keep the uterus well contracted and also expel any small piece of conception.

Emergency curettage can be used as treatment modality in nonpregnant women with heavy bleeding and hemodynamic instability who do not respond to initial measures like injectable tranexamic acid. Emergency curettage should be performed if radioimaging shows increased endometrial thickness despite prolonged and profuse bleeding. This immediately relieves the symptoms and also provides histopathological correlation so as to chalk out the further treatment plan to prevent future menorrhagia. Disadvantage of curettage is that if further treatment is not initiated, it cannot prevent future episodes of heavy bleeding.

Various studies compare results of uterine curettage to hormone therapy show that time required for bleeding to subside is more with medical management. Anesthesia is avoided in medical therapy. Medical therapy maybe preferred if it yields results without need of more blood transfusion. It can also be given after curettage to stop bleeding after the procedure.

High-dose Intravenous Estrogen

Mechanism of action of estrogen therapy is promotion of regrowth of endometrium over the bleeding denuded epithelial surface. Estrogen stabilizes lysosomal membranes and stimulates promotion of endometrial ground substance. A randomized control trail of 34 cases was carried out where women with heavy bleeding were treated with IV conjugated equine estrogen (CEE), 25 mg Premarin in 5 mL saline was instilled over 2 minutes. The dose was repeated every 3–5 hours, if bleeding persisted. In the placebo arm, 200 mg of lactulose was given. The difference in the two arms was not statistically significant in the first 3 hours. However, after 72 hours, 72% of patients in the CEE arm showed improvement versus 38% in the placebo arm. Bleeding persisted at 8 hours in two women

in the CEE group. There was no correlation between histology on endometrial biopsy and success of therapy. 39% women had nausea and vomiting requiring treatment in the CEE arm versus 13% in the placebo group.

If bleeding persists beyond 8 hours, estrogen therapy must be stopped and other treatment modalities started. Maintenance therapy is started once bleeding decreases with IV Premarin. 2.5 mg Premarin four times a day can be continued for 21 days. A progestin must be given in the next 10 days. Maintenance therapy can also be started with oral contraceptive (OC) pills containing 35 μg estrogen. Initially two tablets are given for 5 days, followed by once a day for 20 days. Potential serious side effects of high-dose estrogen include thrombosis and embolism. Thus, minimum dose to produce desired result must be used. In high-risk category, like women at high risk for thrombosis, estrogen therapy is contraindicated.

Uterine Artery Embolization

Uterine artery embolization (UAE) is the first line of management of bleeding due to uterine arteriovenous (AV) malformations. It should not be used as first choice of therapy over emergency hysterectomy due to technical challenges and length of the procedure. However, in higher institutes with good clinical experience of performing the procedure, it can be performed in women who desire future fertility. Current evidence however does not establish safety in future pregnancies. Adverse outcomes in pregnancy have been reported after embolization procedure.

Surgical Management of Ectopic Pregnancy

Laparoscopic surgery is invariably feasible in higher centers with good emergency, anesthesia, and blood bank facilities. Only in hemodynamically unstable patients where head low position is not possible, laparotomy is considered. Goals of surgery must include correct time management to prevent complications due to the delay. A team approach and good communication with anesthetist is imperative to detect any anticipated complications on time.

Hysterectomy

In obstetric cases, when initial measures such as bimanual compression, oxytocin, uterine tamponade, and repair of lacerations fail, patient is taken up for emergency laparotomy. A gynecologist must be well versed with anatomy of the iliac, uterine artery, and ureter. A broad ligament hematoma can be treated with uterine artery ligation at its origin. Internal iliac ligation is recommended to control atonic or traumatic postpartum hemorrhage when previous measures fail. When internal iliac ligation fails, obstetric hysterectomy is performed to save the life of the woman. In gynecological cases of heavy uncontrolled bleeding with hemodynamic instability, when all measures fail, in rare circumstances, emergency hysterectomy maybe performed to treat uncontrolled bleeding.

Treatment of Bleeding Per Vaginum in Hemodynamically Stable Patients

Estrogen Therapy

High-dose oral estrogen therapy is most effective in controlling menorrhagia. It carries risk of thrombosis and embolism and should not be used in high-risk patients. Estrogen therapy alone is more effective than combined estrogen-progesterone therapy because progestins inhibit synthesis of estrogen receptors and increase estradiol dehydrogenase, thereby impeding the rapid proliferation of endometrium induced by estrogen.

Estrogen-progesterone Therapy

This is also used to control heavy and prolonged bleeding. Initial dose is two tablets a day for 5 days, followed by once a day for 20 days. Withdrawal bleeding maybe slightly heavy but usually stops in 7 days.

Progestin Therapy

Medroxyprogesterone 10 mg, two tablets twice a day are started to treat menorrhagia of anovulatory etiology. Progestins inhibit further endometrial growth in women with thickened endometrium. After 5–7 days, the dose is reduced to once or twice a day for a total duration of 25 days. Progesterone causes thinning of endometrium, thus controlling the bleeding. Only progesterone therapy is less effective than estrogen, especially in cases where bleeding is due to denudation of the endometrium.

Endometrial Ablation

This is the procedure of choice after endometrial biopsy confirms benign nature disease. Relatively simple and noninvasive, ablation can help treat the symptom of heavy bleeding without much long-term or short-term complications.

DISPOSITION

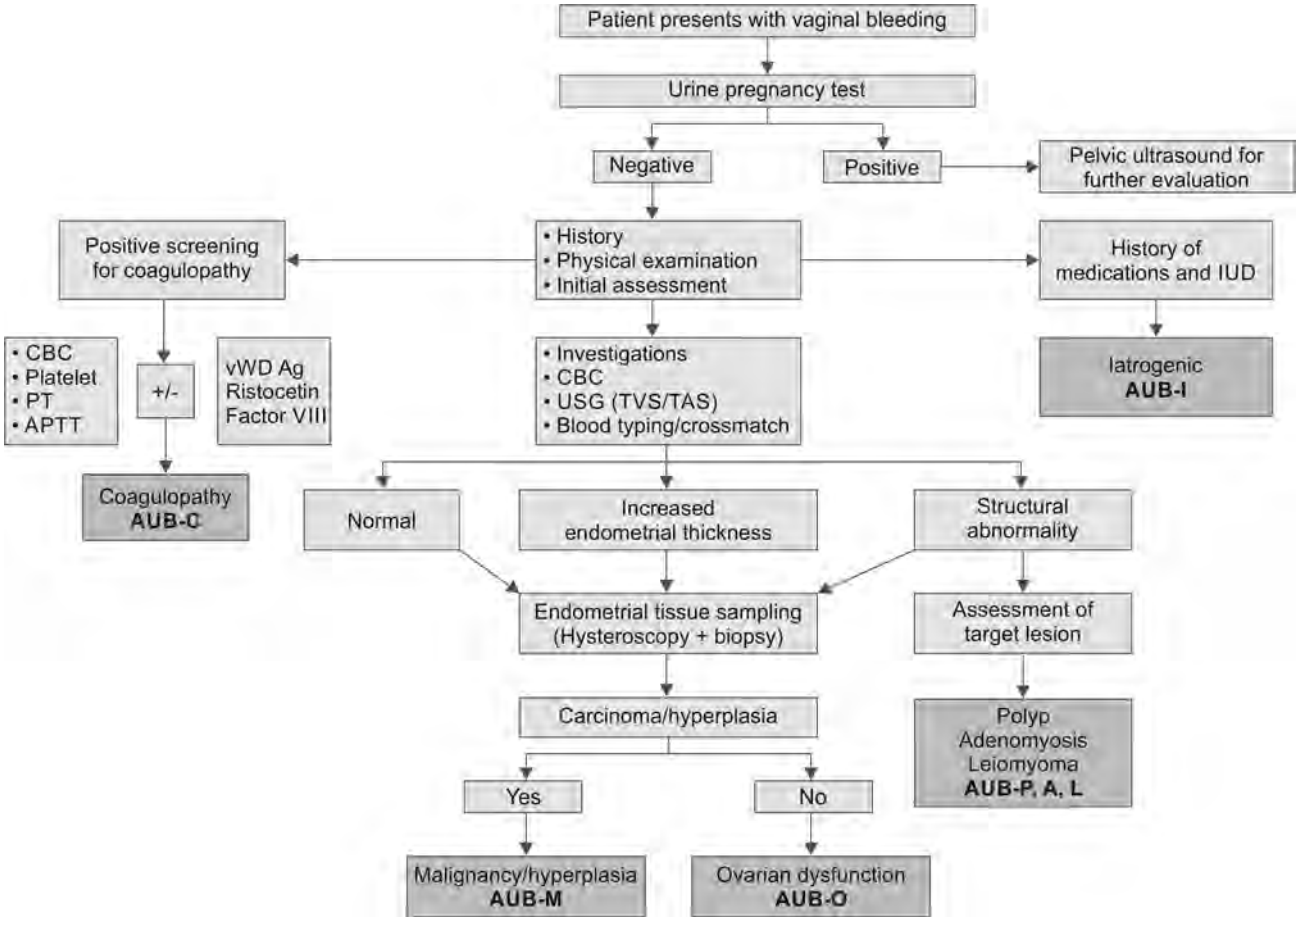
- Hemodynamically stable patients with mild bleeding can be discharged after emergency management with advice to follow-up with gynecologist.
- Unstable patients and patients with significant active bleeding should be admitted for immediate intervention, further evaluation and management.
- Need for surgical intervention depends upon several factors as discussed above.
- Referral for endometrial biopsy or tissue sampling in patients with risk factors and age >40 years.

SUMMARY

Keys to successful outcome in management of emergency vaginal bleeding are thorough knowledge of etiological factors, good time management, and emergency team approach to arrive at the correct diagnosis while resuscitating the patient at the same time, followed by administering the appropriate therapy. Speed, close vigilance, and time-to-time reassessment ensure success of therapy. All patients with AUB will present in emergency as vaginal bleeding. Thus, it is imperative to differentiate the source and the cause.

Thumb Rule 1: All patients in reproductive age group who present with vaginal bleeding to be screened for pregnancy.

Thumb Rule 2: In nongravid patients, careful pelvic examination should be done to rule out sources and causes of bleeding other than the uterus. Approach to vaginal bleeding is summarized in **Flowchart 1**.



(APTT: activated partial thromboplastin time; AUB-A: abnormal uterine bleeding due to adenomyosis; AUC-C: AUB due to coagulopathy; AUB-L: AUB due to leiomyoma; AUB-M: AUB due to malignancy and hyperplasia; AUB-O: AUB due to ovulatory dysfunction; AUB-P: AUB due to polyp; CBC: complete blood count; IUD: intrauterine device; PT: prothrombin time; TAS: transabdominal sonography; TVG: transvaginal sonography; vWD Ag: von Willebrand disease antigen)

FLOWCHART 1: Approach to abnormal uterine bleeding.

155
CHAPTER

Ectopic Pregnancy

Sonal Parihar

INTRODUCTION

Ectopic pregnancy (EP) is one of the most dreaded and nightmarish obstetric emergencies. It can lead to massive hemorrhage, infertility, or death. As the name indicates, ectopic means outside. When the conceptus instead of implanting in the uterus, implants outside in the tube (97.7%)/ovary (0.2%)/abdomen (1.4%), or even the cervix (1:1,000 to 1:16,000) its known as EP. In our country, it is one of the most common emergencies in which doctor finds it hard to explain the urgency to the patient, the latter remains unconvinced most of the time unless they present in a state of shock. If left undiagnosed, misdiagnosed or late diagnosed—it can be fatal. Rate of EP is highest among older women and incidence is obviously highest in reproductive age group—25–34 years women. Ruptured EP is the major cause of death in first trimester. Its incidence is 2% of all pregnancies and mortality rate is 4–10%. The incidence of EP has drastically increased over the years because of assisted reproductive technology (ART), delayed conceptions, and better diagnostic tools.

CAUSES

Theoretically anything that hampers or delays the migration of blastocyst to the uterine cavity can be a cause for ectopic. There are various risk factors which can cause an EP (**Table 1**), still many ectopic would occur without any identifiable risk factor.

TABLE 1: Major causes for ectopic pregnancy.

Pelvic causes	*Epidemiological causes*
• Tubal surgery (including sterilization) • Pelvic inflammatory disease (including STDs) • Anatomic abnormality of tubes • Contraceptive failure (both OCPs and IUCD, especially progesterone IUCD) • ARTs (unknown cause), IVF (especially multiple embryo transfer) • History of previous ectopic (22% increase in risk) • Prior spontaneous abortion • History of infertility • Abnormal endometrium factors (e.g., IUCD)	• Maternal age above 35 (age-related tubal changes) • Cigarette smoking—alters tubal motility • History of multiple sexual partners

(ARTs: assisted reproductive technologies; IUCD: intrauterine contraceptive device; IVF: in vitro fertilization; OCPs: oral contraceptive pills; STDs: sexually transmitted diseases)

TYPES OF ECTOPIC PREGNANCY

We all know that fertilization takes place in the ampulla of fallopian tube following which the zygote implants after 7–8 days in the uterus. Only the uterine cavity is designed to expand and accommodate the growing fetus. So, whenever the implantation happens outside uterus it results in ectopic. Various types of EP are shown in **Figure 1**.

Tubal Ectopic

It is the most common site with 80% in ampullary region, 12% in isthmus, 5% in fimbria, 2.3% in interstitium, and 2% in cornua. Generally, it happens because of damage to (1) tubal mucosa which prevents transport of fertilized egg to the uterus, and (2) defects in ovum resulting in premature implantation or elevated estradiol or progesterone levels inhibiting tubal migration.

In 50% cases, it is due to infection in the tube, there is a threefold increase in the risk of ectopic in cases of pelvic inflammatory disease (PID). 25% cases happen due to some kind of tubal surgery. Implantation causes penetration of zygote in muscular wall of tube which surrounds itself with maternal blood vessels as in uterine implantation. There is pain because of intermittent distension of the thin tube and leakage of blood through the fimbrial end. There are three ways it can end: (1) Spontaneous involution, (2) Once the stretching capacity of tube is met, it either bursts (ruptured ectopic), or (3) The abortus is partially or completely extruded out of the fimbrial end into peritoneal cavity or into the vagina (tubal abortion). Most dangerous is cornual pregnancy because firstly

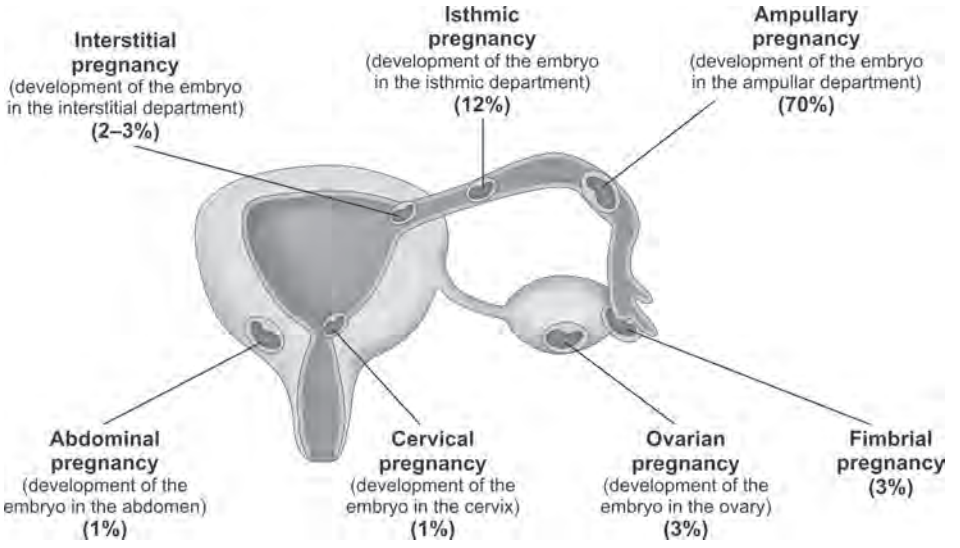

FIG. 1: Types of ectopic pregnancy.

it is close to myometrium and hence can benefit from its blood supply and secondly it has more space to grow and hence can grow larger (10–14 weeks) before rupture.

Cervical ectopic occurs in <1%, generally due to: (1) cervical tissue damage due to dilation and curettage (D&C) endometrial damage, (2) adhesions/fibrosis/previous cesarean/D&C, and (3) in vitro fertilization. It is one of the most dreaded and dangerous sites for EP which can cause profuse vaginal bleeding or uterine rupture and would generally end up in hysterectomy.

Abdominal Ectopic (<1%)

Mostly this develops from early rupture or tubal abortion, when the conceptus reimplants in the peritoneal cavity.

Cesarean Scar Ectopic

With increasing rates of cesarean section, the incidence of scar ectopic is increasing. It is rare, difficult to diagnose, and can cause massive bleeding.

Heterotopic Pregnancy

Simultaneous intrauterine (IU) and extrauterine gestations have been very rare historically (1 in 10,000), but due to ART this rate has increased to 1 in 4,000 now—so not so rare now.

In all cases of ectopic, the implantation is abnormal so the growth of conceptus is abnormal and hence the rise of beta-human chorionic gonadotropin (β-hCG), a hormone produced by the trophoblast is also very slow. There is no doubling after 48 hours as in normal pregnancies. No single value is of any use whether high or low.

CLINICAL PRESENTATION

Most classic presentation would be:

- *Amenorrhea* (of 1.5–2 months), although the presentations are varied and we cannot expect every case to be symptomatic—15–20% cases do not have a history of missed periods.
- *Abdominal pain:* Usually severe, syncopal, peritoneal in nature, and constant. It can be crampy, intermittent, or even absent. Shoulder pain implies free fluid (FF) (significant hemorrhage) in peritoneal cavity causing diaphragmatic irritation and referred shoulder pain.
- *Vaginal bleeding* with or without symptoms of hypotension. Scant bleeding or spotting or even heavy bleeding cannot exclude ectopic. Hypotension without significant vaginal hemorrhage is highly suggestive of EP.

TABLE 2: Differential diagnosis of ectopic pregnancy (EP).

Patients presenting as nonpregnant	*Pregnant patients*
Appendicitis	Normal (intrauterine pregnancy)
Inflammatory bowel disease	Threatened abortion (most common)
Ovarian pathology	Inevitable abortion
Ovarian cyst	Molar pregnancy
Ovarian torsion	Heterotopic pregnancy
Pelvic inflammatory disease	Implantation bleeding
Endometriosis	Corpus luteum cyst (if ruptures)
Sexual assault/trauma	Lateral implanted pregnancy (arcuate uterus) misdiagnosed as interstitial EP
Urinary tract infection	
Ureteral colic	

Features of Concern "Red Flags"

Hypotension because of hemorrhagic shock can be dangerous and is the major cause of death. Undiagnosed ruptured ectopic is main cause. Medical or surgical abortion without confirming intrauterine pregnancy (IUP) can lead to rupture of an EP. Differential diagnosis of ectopic is a big list. Patients not presenting with a classic history can end up getting a wrong diagnosis and wrong line of treatment. **Table 2** shows the differential diagnosis related to and not related to pregnancy. It includes almost all first trimester complications. Beware of heterotrophic pregnancy; it can be dangerous if left undiagnosed.

EVALUATION

History

The classic presentation as mentioned before is highly diagnostic. Any pain in first trimester should be treated as ectopic (pain is seen in 90% ectopic) unless proved otherwise. The idea is to check for all the risk factors with detailed history. Take detailed obstetric history. History of ectopic increases the risk of repeat ectopic to 22%. This rate also depends upon location of implantation and type of management (type of surgery—salpingectomy/salpingostomy; medical management). Discuss about previous medical/surgical history and substance abuse/smoking. Also discuss sexual activity and use of contraception, current medications/over the counter (drugs) (OTCs), etc. If a lady is pregnant postligation (laparoscopic salpingectomy/electrocautery), it should be assumed as ectopic until proved otherwise especially within 15 years.

Examination

Take vital signs. You may or may not find tachycardia, hypotension (shock)/bradycardia (vagal stimulation). Signs and symptoms of shock due to excessive bleeding are sometimes not clear due to compensatory mechanisms in healthy young women. Tenderness and guarding may be there because of adnexal mass (10–20%). Cervical motion tenderness (if blood present in vault). Cervix may show bluish discoloration. Uterus soft and bulky (may be normal size). Bimanual examination is not reliable in case of guarding.

Interpretation of Findings

Any patient with early pregnancy, mild bleeding, uterine/adnexal tenderness, and mild pain abdomen should raise high suspicion for EP. In such presentations, even if the patient does not give a history of amenorrhea, get a urine pregnancy test. If bleeding is heavy with clots and tissue, it generally points towards threatened or incomplete miscarriage, but ectopic cannot be ruled out as endometrial sloughing in failing ectopic may be seen as heavy bleeding.

INVESTIGATIONS

The goal is to make an early diagnosis to reduce morbidity and prevent mortality. Complete blood count (CBC) Blood grouping and typing, coagulation profile and blood sugars are essential investigations in emergency department.

Ultrasonography

Transvaginal scan (sensitivity 90%) is preferred. Demonstration of an echogenic adnexal mass which moves separately from ovary (blob sign) with FF is highly suggestive (almost 100%) of ectopic, large amount of FF alone has 86% risk and if live embryo is demonstrated in adnexa with empty uterus [seen more easily in transvaginal sonography (TVS)], its 100% diagnostic (**Table 3**). TVS can visualize gestational sac (GS), yolk sac (YS), and fetal pole at 4.5, 5.5, and 6.0 weeks, respectively. If an embryo without cardiac activity is visualized within uterus, fetal demise is diagnosed if crown rump length (CRL) ≥5 mm. Otherwise follow-up is required. This is where role of β-hCG starts. See below (discriminatory zone).

TABLE 3: Ancillary ultrasound sonography (USG) findings suggestive of ectopic pregnancy in high-risk patients.

Ancillary findings	*% Risk of ectopic pregnancy*
Any free pelvic fluid (either rupture or leakage from tubal opening)	52%
Complex pelvic mass	72%
Moderate/large amount of free pelvic fluid	86%
Tubal ring	>95%
Mass and free fluid	97%
Hepatorenal free fluid	Almost 100%

TABLE 4: Estimated beta-human chorionic gonadotropin (β-hCG)levels after conception.

Postconception weeks	*B-hCG Level (mIU/mL)*
<1 week	5–50
1–2 weeks	50–500
2–3 weeks	100–5,000
3–4 weeks	500–10,000
4–5 weeks	1,000–50,000
5–6 weeks	10,000–100,000
6–8 weeks	15,000–200,000
8–12 weeks	10,000–100,000

Intermediate ultrasonographic findings: Empty uterus, nonspecific fluid collections, echogenic material, abnormal sac, and single GS.

Diagnostic ultrasonographic features of scar ectopic: Empty uterine and cervical canal, GS seen in the anterior portion of lower uterine segment (LUS), absence of a healthy myometrium between bladder and the GS, and high vascularity at the scar level.

Diagnostic ultrasonographic features of cervical ectopic: Normal size uterus with empty endometrial cavity, embryo in cervical canal, tightly closed internal os, high vascularity in cervical canal, a thin (1–3 mm) or absent myometrial layer between GS and bladder, and presence of prominent subvascular pattern in area of cervix.

Beta-Human Chorionic Gonadotropin

A positive urine test with no IUP on USG is highly suspicious. If the patient is stable, we can opt for serial serum β-hCG measurements. As is clear from the **Table 4**, β-hCG shows a rising trend until 9–10 weeks, then plateaus. No single β-hCG value can be diagnostic. A failed IUP and resolving EP will show a lower than normal hCG value and falling trends. A developing ectopic will show rising titers but it will not double in 48 hours as is commonly seen in normal IUP. Ruptured ectopic will

show very low or absent levels of β-hCG, hence sonography is a must even at very low β-hCG. Serum β-hCG is detected at concentration of ≥10 mIU/mL and urine test at concentration of ≥20 mIU/mL.

Discriminatory Zone

It was developed to establish a relation between β-hCG and USG findings. It is the level of β-hCG at which sonography should detect an IUP. Hence a value below the discriminatory zone (DZ) with empty uterus on USG is intermediate. Levels higher than DZ with empty uterus are highly suggestive of EP. With TVS, the DZ is 1,500 mIU/mL and 6,000 mIU/mL with TAS.

Variations

- Normal pregnancy may show only 53% rise in 48 hours
- Rise of >53% β-hCG does not rule out ectopic
- Ectopic can also show doubling (21% cases)
- hCG is expected to decrease by 21–35% in 2 days in spontaneous miscarriage.

Hence, serial measurements are done to increase or decrease the suspicion rather than diagnosing.

Serum Progesterone

No value is diagnostic. It is the major hormone for pregnancy support. Initial 8–10 weeks, it is produced by ovaries, thereafter placenta takes over and levels keep on rising and then plateaus with levels of >20 ng/mL. In general, 100% pregnancies with value ≤5 ng/mL will be pathologic. There is no use of serial measurements. P levels >25 ng/mL have 97% sensitivity for viable IUP. It is not a recommended standard tool but is of use when USG is negative, β-hCG is very low, and the doctor is contemplating D&C or laparotomy.

Dilation and Curettage

Identification of chorionic villi in endometrial samples diagnoses 70% of normal IUPs, except in patients undergoing ART.

Culdocentesis

Not done these days because of advent of β-hCG. Moreover, it is neither very sensitive, nor very specific.

Laparoscopy

It can be both diagnostic as well as therapeutic.

Magnetic Resonance Imaging

It is useful in diagnosis of scar ectopic.

TREATMENT

Rapid Fluid Resuscitation

Ectopic pregnancy is a time specific gynecolgic emergency. Immidiate assessment of airway breathing circulation should be done and further volume status should be supported by intravenous fluid and blood and blood products. Further management decision should be taken with the help of USG and β-hCG.

Surgical Treatment

Generally laparoscopy/sometimes laparotomy—this decision will depend upon patient's condition, doctor's expertise, availability of team, sonography findings, etc. Sometimes intraoperative bleeding or frozen pelvis during laparoscopy leads to laparotomy.

- *Salpingectomy*: If family is complete or opposite tube is normal, tube is in good condition.
- *Salpingostomy*: If patient is stable, future fertility is required, endometriosis or pelvic adhesions, opposite tube absent/not in good condition, and if technically feasible. But it increases the risk of repeat ectopic because of damaged mucosa of tube. Repeat β-hCG after 7 days, if >1,000 mIU/mL or >15% of original level, persistent EP is diagnosed. This can happen in 10% cases and will need methotrexate (MTX) or reoperation.

Medical Management with Methotrexate

If minimal symptoms, patient is stable, normal baseline liver function test (LFT) and renal function test (RFT), tubal mass <3.5 cm in diameter, no fetal heart, no evidence of rupture, and future fertility is desirable.

Methotrexate act as an antimitotic, folate antagonist, inhibits dihydrofolate reductase (DHFR) enzyme, interferes with fetal deoxyribonucleic acid (DNA) synthesis, destroys rapidly dividing cells, and causes involution of pregnancy. Monitoring of doses is done according to serial hCG levels. *Success rate* is 85–98%, not much difference between single/multiple dose regimen but depends upon pretreatment hCG levels. Prognostic factors which can lead to higher failure rate are: (1) larger tubal diameter, (2) fetal cardiac activity present, (3) higher pretreatment β-hCG, and (4) severe abdominal pain. *Failure rate* is 14.3% (if pretreatment hCG > 5,000 IU) in such cases multiple doses are recommended, 3.7% (if pretreatment hCG < 5,000 IU). Contraindications to MTX administration are presented in **Table 5**.

TABLE 5: Contraindications to MTX administration.

Absolute contraindications	***Relative contraindications***
Intrauterine pregnancy	Embryonic cardiac activity detected by TVS
Evidence of immunodeficiency	hCG > 5,000 mIU/mL
Moderate-to-severe anemia, leucopenia, and thrombocytopenia	Ectopic pregnancy >4 cm in size (TVS)
Insensitivity to MTX	Refusal to accept blood transfusion
Acute pulmonary disease	Inability for patient to return for follow-up
Active peptic ulcer disease	
Hepatic/renal dysfunction	
Breastfeeding	
Hemodynamic instability	

(hCG: human chorionic gonadotropin; MTX: methotrexate; TVS: transvaginal sonography)

Side Effects

Abdominal pain (75%), flatulence, stomatitis, vaginal bleeding, weakness, dizziness, syncope, and hair loss are the common side effects. *"Separation pain"* happens 3–7 days after MTX treatment due to tubal abortion/distension due to hematoma formation. It is a lower abdominal pain, self-limited and responds to nonsteroidal anti-inflammatory drugs (NSAIDs). It is suggested to perform CBC and USG to differentiate such pain from ruptured tube pain. Unwanted outcomes are long resolution period and increased waiting time for future fertility.

Dose

About 50 mg/m^2 single intramuscular (IM) dose. Patient need rescue surgery in 5% cases of MTX failure, if unstable vital signs, decreasing hemoglobin, intolerable pain, and evidence of rupture on USG.

Follow-up is done with β-hCG on (day 4 and 7) initial rise in β-hCG till day 4, then between day 4 and 7, 15% decrease from pretherapy level—if not, repeat MTX dose. After day 7, weekly β-hCG till it comes to zero, this might take 2–3 months. If weekly reports do not show a fall of 15% or more, repeat dose of MTX can be given (maximum three doses). Pelvic examinations should be avoided to minimize the risk of rupture. Patients should avoid sexual intercourse for 14–21 days after treatment or until β-hCG becomes undetectable, avoid pregnancy in next 3 months, take folic acid supplements.

Do not forget to administer anti-D (50 μg), if Rh negative (alloimmunization can occur with even 0.1 mL fetal blood admixing). If β-hCG to start with was very low (<1,000) and shows a falling trend, then just serial assays without any active treatment can be done—till the levels drop to zero. Treatment plan is summarized in **Flowchart 1**.

Special Cases

Cervical Ectopic

Foley catheter is used to give tamponade, placed beyond the internal os and filled with 30 mL saline—mostly after curettage. To reduce blood supply—ligation of uterine artery/internal iliac artery/or angiographic embolization of these arteries is done before curettage along with chemotherapy. Curettage or hysterectomy—former can cause excessive hemorrhage. Latter is lifesaving treatment and is treatment of choice in women diagnosed with cervical ectopic pregnancy (CEP) in second trimester and those who do not desire further pregnancy. Rarely conservative approach by USG-guided instillation of KCl/MTX can be used. Systemic CTH is also an option.

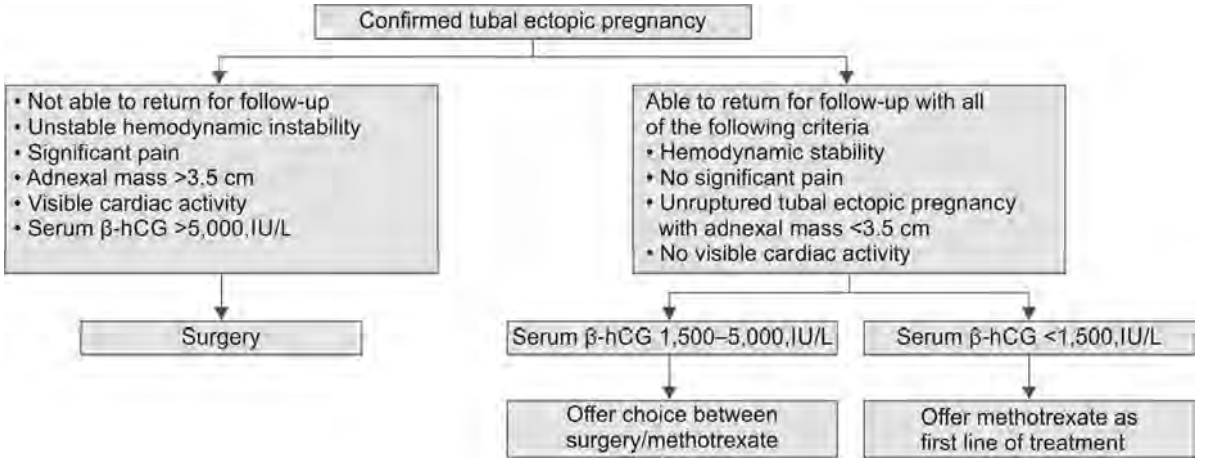
Scar Ectopic

Generally, excision of the scar along with products of conception will be required. Sometimes the pregnancy may expel spontaneously like an abortion (some cases reported).

SUMMARY

Classic presentation of ectopic pregnancy includes mild pain abdomen, positive urine pregnancy test, and mild bleeding with or without signs and symptoms of hemorrhagic shock (only 20%). Most patients would have positive urine pregnancy test, empty uterus on sonography with/without nonspecific fluid collection with ≤5 ng/mL.

With advanced technology and excellent diagnostic modalities, we are at a much better position to diagnose and treat this emergency and avoid laparotomy as well as hysterectomy. Whatever treatment modality is used, it does not affect the fertility (except salpingectomy which will obviously reduce the fertility). Further fertility mainly depends upon patient's age, past history, and state of her pelvis.



Confirmed tubal ectopic pregnancy
• Not able to return for follow-up
• Unstable hemodynamic instability
• Significant pain
• Adnexal mass >3.5 cm
• Visible cardiac activity
• Serum β-hCG >5,000 IU/L
Able to return for follow-up with all of the following criteria
• Hemodynamic stability
• No significant pain
• Unruptured tubal ectopic pregnancy with adnexal mass <3.5 cm
• No visible cardiac activity
Surgery
Serum β-hCG 1,500–5,000 IU/L
Serum β-hCG <1,500 IU/L
Offer choice between surgery/methotrexate
Offer methotrexate as first line of treatment

FLOWCHART 1: Treatment plan for ectopic pregnancy.

CHAPTER

Emergencies during Pregnancy

Devyani Misra, Mariyum Faruqi

INTRODUCTION

A healthy mother and healthy baby are the desired outcome of all pregnancies. However, and unfortunately, this normal state of altered body physiology may not always take a favorable course. Maternal morbidity and mortality can result from a complication arising during pregnancy or worsening of a preexisting condition in the woman. Worldwide, an estimated 211 women die from pregnancy and related complications for every 100,000 live births and according to the World Health Organization (WHO), around 295,000 women died during and following pregnancy in 2017. In India, according to the Sample Registration System, a demographic sample survey by the government, the mortality rate for the period 2016–2018 is estimated to be 113/100,000 live births which turns out to be a huge number when considering the actual births. The deadly triad of hemorrhage, preeclampsia, and infection contribute majorly toward mortality accounting for over a third of the causes and the importance of prompt diagnosis and management of these cases cannot be overemphasized. Another significant contributor to maternal mortality is unsafe abortion and complications of abortion which can only be controlled by avoiding unwanted pregnancies.

Obstetric emergencies can arise at any point in time and it is important to diagnose the condition and institute prompt treatment as needed. The early half of pregnancy can have complications related to miscarriages or infection arising as a result of unsafe abortions. Nearly 10 lakh abortions are carried out in India annually and almost 10 women die per day due to related complications. Diagnosis of abortion and treatment of related complications is thus of utmost importance. Since the patient is first attended by the emergency physician, it is imperative that early pregnancy complications be addressed. Pregnancy is often missed or overlooked so it is advisable to ask regarding the last menstrual period in a woman of reproductive age group and carry out a urine pregnancy test whenever in doubt. Liaising with the on-call gynecologist can be helpful. Another important complication in early pregnancy is excessive nausea and vomiting or hyperemesis gravidarum (HG). Though nausea and vomiting complicate most of the pregnancies and can be managed as outpatient, hyperemesis though rare (3%), necessitates prompt inpatient management with intravenous fluid to prevent catastrophic complications.

In the second half of pregnancy, antepartum hemorrhage complicates 3–5% of pregnancies. Of these there are two types, placenta previa where the placenta is implanted partially or completely in the lower uterine segment and abruptio placentae, where there is separation of a normally located placenta. It is one of the most common causes of maternal collapse and the emergency room (ER) physician must institute prompt resuscitation as patient may have collapsed before reaching the hospital due to exsanguination. Another frequently encountered pregnancy complication is hypertensive disorders which have an incidence of 5–10% and are a cause of significant morbidity and mortality. The ER physician has to be acquainted with the antihypertensives that can be used to control high blood pressure in pregnant women and also treatment of eclamptic seizures if the woman has convulsed as a result of hypertensive disorders. As a dictum, all seizures in pregnant women, especially in the second half, should be considered eclampsia unless proved otherwise. Use of the miraculous magnesium sulfate to control seizures should be highlighted and administration should be taught to all ER staff.

Preterm labor with an incidence of 10–15% and prelabor membrane rupture contribute toward neonatal morbidity and mortality and are a common complication in pregnancy. Also, infection as a result of membrane rupture can cause chorio-amnionitis and morbidity in the mother and needs treatment. Correct diagnosis and management are thus important.

In cases pertaining to the obstetric specialty, the primary duty of the ER physician is to diagnose the pregnancy complication and commence initial treatment. Resuscitation may often be required and one must not forget the pressure effects of the gravid uterus which hampers the venous return. Should there arise a need for intubation, it should be carried out by a specialist keeping in mind the difficulties that may be encountered in pregnant women. Promptness of management will decide the outcome in many situations like hemorrhage and thus the effect on morbidity and mortality. Having a sound knowledge of possible obstetric emergencies and anticipating possible complications, the ER physician can contribute significantly toward lowering maternal morbidity and mortality. In the following text, we will discuss a few of the obstetric emergencies mentioned here, how to make a diagnosis, and go about the treatment (**Table 1**).

TABLE 1: Emergencies during pregnancy.	
First 20 weeks of pregnancy	• Nausea, vomiting, hyperemesis, and gravidarum • Spontaneous abortion • Septic abortion
After 20 weeks of pregnancy	• Chronic and gestational hypertension: ○ Preeclampsia ○ HELLP ○ Eclampsia • Placenta previa • Vasa previa • Premature rupture of membrane • Preterm labor

(HELLP: hemolysis, elevated liver enzyme levels, and low platelet count)

NAUSEA AND VOMITING OF PREGNANCY AND HYPEREMESIS GRAVIDARUM

Nausea and vomiting in pregnancy (NVP) is a rather frequent symptom occurring in 70–80% women. NVP is one of the most common reasons for hospitalization in pregnancy and negatively affect the quality of life. In most pregnant women the condition is self-limiting, yet, in a few, symptoms may persist throughout the duration of pregnancy.

Hyperemesis gravidarum is a rare but severe form of NVP reported in 0.3–3.6% pregnancies and an obstetric emergency. Other causes of severe nausea and vomiting should be excluded before coming to the diagnosis of HG.

Etiology/Causes

Exact etiology contributing to symptoms of NVP/HG remains largely eluded. A familial predisposition to NVP exists implicating a genetic cause. Women who have NVP/HG in one pregnancy tend to suffer from the condition in subsequent pregnancies. Various theories have been proposed which include biochemical, immunological, and psychosocial causes. Human chorionic gonadotropin (hCG) hormone released from the placenta during pregnancy is primarily associated with NVP and conditions with higher hCG levels as multiple pregnancy and trophoblastic disease have increased severity. Other common associations are high estradiol and leptin levels, low body mass index (BMI) and female fetus.

Pathophysiology

Excessive vomiting results from emetogenic effects of hCG the pathogenesis of which is largely unknown. There are no marked changes in the organ systems other than features of dehydration and malnutrition in severe cases. Some cases of HG may develop Wernicke's encephalopathy due to vitamin B1 deficiency.

Clinical Presentation and Red Flags

Nausea and vomiting in pregnancy and HG are two ends of a spectrum with NVP presenting as mild form of the disease whereas severe forms present as HG.

In mild cases, nausea and vomiting typically appears by fourth to seventh weeks of pregnancy and resolves completely in 90% women by 20–22 weeks. Around 10% pregnant women may continue to have NVP throughout pregnancy. NVP which has onset after 11 weeks of pregnancy should raise suspicion of some underlying pathology and warrants evaluation. NVP may be associated with retching, hypersalivation, and feeling sick or nauseated.

Hyperemesis gravidarum, the severe form of NVP, is marked by a triad of severe protracted nausea and vomiting associated with weight loss >5% prepregnancy weight, dehydration, and electrolyte imbalances. Severe untreated forms may present with malnutrition, dehydration, neuropathies, Wernicke's encephalopathy, coma, and death. Serious maternal complications may also occur due to Mallory–Weiss tears and esophageal rupture, splenic avulsion, and pneumothorax associated with excessive vomiting.

A Pregnancy Unique Quantification of Emesis (PUQE) score (**Table 2**) has been used to classify the severity of NVP and assessment of improvement of symptoms with treatment. Using PUQE score it is possible to objectively quantify the disease severity and ensure uniformity in treatment to be given. Women with mild NVP can be managed with oral medication. Ambulatory daycare management can be done in cases where vomiting persists despite medication and PUQE score is <13. Those women whose symptoms are not relieved or persist despite treatment with PUQE score >13 need to be admitted (**Box 1**).

Evaluation

History

History of NVP/HG in prior pregnancy must be elicited. Quantification of symptom severity by PUQE score with effects on quality of life should be assessed. Rule out other possible causes of vomiting, history of drug intake, coexisting urinary infection, abdominal pain, and history of chronic *Helicobacter pylori* infection or any other infection. Also, assess family support to elicit psychological/neurological causes for the symptoms.

Physical Examination

This includes assessment of well-being of the woman. Measure the temperature, pulse, blood pressure, respiratory rate, oxygen saturation, and weight. Assess the alertness while looking for signs of dehydration and muscle wasting. An abdominal examination must be done which may indicate alternate causes for the symptoms. Other systems to be examined if history is indicative.

Interpretation of Findings

Altered consciousness, presence of significant weight loss, dehydration, and muscle wasting are indicative of disease severity and warrant immediate treatment.

Investigations

Investigations are done to assess severity and progress of treatment. Some special investigations may be needed to rule out other causes **Table 3**.

TABLE 2: Pregnancy Unique Quantification of Emesis (PUQE) index.					
PUQE-24 scoring system	***1***	***2***	***3***	***4***	***5***
In the last 24 hours, for how long have you felt nauseated or sick to your stomach?	Not at all	1 h or less	2–3 h	4–6 h	>6 h
In the last 24 hours have you vomited or thrown up?	Did not throw up	1–2 times	3–4 times	5–6 times	≥7 times
In the last 24 hours, how many times have you had retching or dry heaves without bringing anything up?	No time	1–2 times	3–4 times	5–6 times	≥7 times
PUQE-24 score: Mild ≤6; Moderate 7–12; Severe ≥13					

BOX 1: Indications for inpatient management in NVP/HG (red flags).

- Continued nausea and vomiting and inability to keep down oral antiemetics
- Continued nausea and vomiting associated with ketonuria and/or weight loss >5% of body weight and/or dehydration and electrolyte imbalance
- Coexisting condition requiring treatment

(HG: hyperemesis gravidarum; NVP: nausea and vomiting in pregnancy)

TABLE 3: Investigations to assess severity of NVP/HG.	
Investigation	***Abnormalities***
Urine dipstick	Ketonuria
Urine culture	Urinary tract infection
Complete blood count	Infections, anemia, and hemoconcentration
Blood glucose	Diabetes
Renal function test	Kidney diseases, dehydration, and acute kidney injury
Serum electrolytes/ABG	Hypokalemia/hyperkalemia, hyponatremia, metabolic hyperchloremic alkalosis, and hypocalcemia
Liver function test	Hepatitis and raised transaminases/ bilirubin
Serum amylase	Pancreatitis
Thyroid function test	Hypothyroidism/hyperthyroidism
Ultrasound scan	Multiple pregnancy, molar pregnancy, gallstones, and ovarian/cyst torsion

(ABG: arterial blood gas; HG: hyperemesis gravidarum; NVP: nausea and vomiting in pregnancy)

Treatment

Many oral antiemetics are safe for use in NVP (**Table 4**). Women not responding to single medication may be given combination of different drugs. Parenteral route may be preferable for those with persistent NVP/HG.

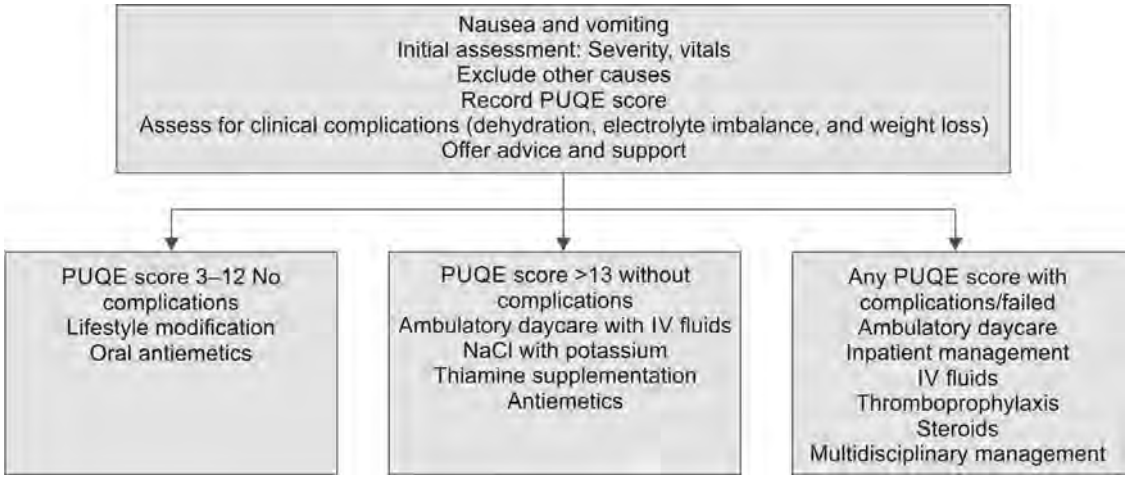
Metoclopramide should be used with caution due to possibility of extrapyramidal symptoms. Ondansetron has limited data on safety but is highly effective and used as second-line management. Corticosteroids are used only in resistant cases.

TABLE 4: Antiemetics recommended for use in pregnancy.	
First line	• Cyclizine 50 mg PO, IM or IV 8 hourly • Prochlorperazine 5–10 mg 6–8 hourly PO; 12.5 mg 8 hourly IM/IV; 25 mg PR daily Promethazine 12.5–25 mg 4–8 hourly PO, IM, IV or PR • Chlorpromazine 10–25 mg 4–6 hourly PO, IV or IM; or 50–100 mg 6–8 hourly PR
Second line	• Metoclopramide 5–10 mg 8 hourly PO, IV or IM (maximum 5 days duration) • Domperidone 10 mg 8 hourly PO; 30–60 mg 8 hourly PR • Ondansetron 4–8 mg 6–8 hourly PO; 8 mg over 15 minutes 12 hourly IV
Third line	Corticosteroids: Hydrocortisone 100 mg twice daily IV; once clinical improvement occurs, convert to prednisolone 40–50 mg daily PO, dose gradually tapered until the lowest maintenance dose that controls the symptoms is reached

(IM: intramuscular; IV: intravenous; PO: by mouth; PR: by rectum)

For the cases needing inpatient management, initial assessment should include airway, breathing, circulation, disability, and exposure (ABCDE) and fluid resuscitation should be guided by degree of shock. Initial resuscitation should be done with crystalloids containing sodium and chloride with supplementation of potassium. Dextrose infusion to be avoided unless sodium has been replenished and thiamine as it can precipitate Wernicke's encephalopathy. Maintenance fluid therapy should be guided by vital monitoring, use of fluid balance charts, daily weight measurement, daily blood counts, urea, creatinine, and electrolytes. Proton pump inhibitors or H_2 antagonists may be added to relieve gastritis or esophagitis. Intravenous antiemetics can be gradually replaced with oral medication once fluid therapy is weaned off. Thromboprophylaxis with low-molecular weight heparin is indicated in admitted patients unless contraindicated. Multidisciplinary team management with nutritionist, endocrinologist, and gastroenterologist should be used when enteral or parenteral treatment is required.

As a last resort, in patients not responding to any treatment modality and with remitting severe symptoms, termination of pregnancy may be considered. Women on discharge from the hospital should have individualized treatment plans. Women who continue to have NVP in second and third trimesters of pregnancy need to be monitored for adequate fetal growth. Iron preparations need to be used cautiously as these can exacerbate symptoms. **Flowchart 1** summarizes the approach to NVP.



(IV: intravenous; PUQE: Pregnancy Unique Quantification of Emesis)

FLOWCHART 1: Approach to nausea and vomiting in pregnancy.

SPONTANEOUS ABORTION

The National Center for Health Statistics, the Centers for Disease Control and Prevention (CDC), and the WHO all define abortion as any termination of pregnancy, spontaneous (which occurs without any means) or induced (termination of pregnancy using medication or surgical procedures), prior to 20 weeks of gestation or with a fetus born weighing <500 g. Nearly 10–20% of all clinical pregnancies end in miscarriages. More than 80% of losses occur before 13 weeks of pregnancy called as early pregnancy loss.

Pathophysiology

In early pregnancy loss, death of the embryo or fetus occurs first along with hemorrhage into the fetal membranes leading to tissue necrosis and subsequent expulsion of the conceptus. Since chromosomal abnormalities are the most common cause, the products of conception may not have any identifiable embryonic elements and termed anembryonic pregnancy, accounting for nearly half of early pregnancy losses. Embryonic pregnancy, on the other hand, may have an abnormality of the embryo or fetus or placenta due to chromosomal anomalies or even be normal. In later losses, the fetus may be expelled live and may die only after birth.

Classification

An abortion is said to be "early" when it occurs prior to 12 weeks and "late" after 12 weeks. Spontaneous abortion may be classified as (1) threatened, (2) inevitable, (3) incomplete, (4) complete, (5) missed, and (6) septic depending on the clinical presentation. These may occur as isolated event or recurrent losses.

Risk Factors

Many risk factors have been identified which can lead to abortions; however, in most cases there may be no definite cause or even a combination of factors (**Table 5**).

Evaluation

Clinical Features

Clinical features differ depending upon the type of abortion. Period of amenorrhea followed by pain abdomen, vaginal bleeding, or passage of product of conceptus are the most common signs and symptoms seen in early pregnancy loss. The various types of abortions may be differentiated on the basis of clinical presentation, examination findings complemented by ultrasonographic findings.

Threatened Abortion

When the process of miscarriage has started but continuation of pregnancy is still possible. Bleeding occurs through a closed cervical os during the first 20 weeks of pregnancy and may persist for days to weeks. There may be accompanying lower abdominal discomfort, cramps, pain, pressure, or lower backache. If the bleeding tends to be heavy, it may eventually progress to pregnancy loss. For those whose bleeding resolves and pregnancy continues, there is persists an increased tendency for development of obstetric complications such as placenta previa, placental abruption, fetal growth restriction, preterm birth, preterm rupture of membranes, and increased operative deliveries.

Inevitable Abortion

It is a clinical type of miscarriage where the abortion process has progressed to a state where from continuation of pregnancy is impossible. In some cases, there is bleeding under the chorion (subchorionic hematoma) with separation of membranes stimulating uterine contractions. In early second trimester, pregnancies are complicated by rupture of membranes prior to achieving the period of viability and tend to progress to expulsion due to onset of uterine contractions. When this process has reached a stage where pregnancy cannot be salvaged, abortion is said to be inevitable. Sometimes products of conception may be seen to come out through the external os. Resuscitation of the patient is to be done and evacuation of the

TABLE 5: Causes of spontaneous abortion.	
Fetal factors	
Genetic causes	• 95% maternal and 5% paternal gametogenesis errors • Aneuploidy—trisomy (trisomy 13, 16, 18, 21, and 22) 64%, monosomy (XO or autosomal monosomy) 7% • Polyploidy (9%)—triploidy, tetraploidy, structural rearrangements (6%)
Maternal factors	
Age	Risk increases with advancing maternal age
Race	More common in Hispanics and Blacks
Habits	Smoking, alcohol consumption, and excessive caffeine uses
Infections	*Chlamydia*, bacterial vaginosis, and genital tuberculosis
Endocrine causes	Uncontrolled thyroid dysfunction (hypo/hyperthyroidism), uncontrolled diabetes mellitus, luteal phase defect, polycystic ovarian syndrome, systemic lupus erythematosus, and obesity
Anatomical causes	• Uterine anomalies: Septum, synechiae, leiomyoma/fibroids • Cervical incompetence
Thrombophilia	Inherited or acquired
Radiation exposure	Therapeutic as in malignancy
Toxins	Antineoplastic drugs, misoprostol, quinine, occupational exposure to sterilizing agents, and nitrous oxide
Idiopathic	

uterus with surgical or medical (oxytocin infusion) methods may be needed for management.

Incomplete Abortion

During abortion, the fetus and placenta may be expelled together in early pregnancy but tend to deliver separately in advanced gestations. The fetus may deliver first and the placental tissue may be retained in the uterus or only partially expelled leading to incomplete abortion. This may present as continued bleeding after passage of products or development of infection. On internal examination the cervical os remains open. It may be diagnosed clinically and ultrasound confirms the diagnosis with retained products in the uterine cavity.

Complete Abortion

There is history of bleeding per vagina, cramps, and passage of tissue followed by closure of the cervical os. This is accompanied by relief of symptoms of pain and bleeding. The entire conceptus may be expelled completely. On ultrasonography, the uterine cavity is empty.

Missed Abortion

The fetus is dead and retained in the uterine cavity and the cervical os is closed in cases of missed abortion. The diagnosis is confirmed by ultrasound or histopathology of products of conception. Those occurring at <10 weeks are termed "embryonic demise" and between 10 and 12 weeks as "early fetal demise". There may be no symptoms at all or slight bleeding/blood stained or brownish discharge per vaginally. When retained for a prolonged period, the size of uterus may be smaller than the period of gestation. Symptoms of pregnancy experienced by the pregnant woman usually subside. The diagnosis is confirmed on ultrasonography.

Septic Abortion

Septic abortion is the entity when any of the abortions, whether spontaneous or induced, are complicated by infection.

Red Flags

Presence of any of the following may warrant further evaluation for an alternate diagnosis like ectopic pregnancy or intensive management for development of sepsis and its complications.

- Giddiness with syncopal attacks
- Severe abdominal pain
- Fever with chills
- Persistent/intermittent heavy bleeding
- Purulent/foul-smelling vaginal discharge

Investigations

Blood investigations for complete blood counts, ABO, and Rh grouping should be done. All routine antenatal investigations should be done. Should ultrasonography be needed, transvaginal scan is preferred (**Box 2**). Serial serum β-hCG should be done where there is a doubt of pregnancy viability or the uterine cavity is empty even with a positive urine pregnancy test, giving rise to pregnancy of unknown location and ruling out ectopic pregnancy.

Treatment

General Measures

A detailed history and physical examination are important to make a diagnosis. Vitals should be monitored and blood loss estimated. Resuscitaion is started with intravenous fluid

BOX 2: Ultrasound features of pregnancy loss.

- Mean sac diameter (MSD) ≥25 mm and no embryo visible
- Crown rump length (CRL) ≥7 mm and no heartbeat visible
- No embryo with heartbeat visible ≥2 weeks after initial scan with gestational sac without a yolk sac
- No embryo with heartbeat visible ≥11 days after initial scan with gestational sac with a yolk sac

as required. Blood transfusion may be needed if the bleeding has been profuse or lead to exsanguination of the woman with fall in blood pressure and tachycardia. For anticipated procedure intravenous antibiotics may be given to reduce the postoperative infections. Informed consent should be taken. Depending upon the state of abortion and type of abortion, various treatment options can be implemented.

Expectant Management

Many women expel the conceptus spontaneously and no further treatment may be required.

Threatened abortion is managed expectantly along with bed rest, progesterone/hCG support, and correction of anemia along with watchful expectancy.

Inevitable abortion may be managed expectantly till some complication like heavy bleeding arises necessitating prompt uterine evacuation.

Some cases of incomplete abortion can also be managed expectantly, however, along with higher failure rates there is also an increased chance of development of sepsis.

In complete abortion, when there is definite history of passage of products of conception, an ultrasound finding of thin endometrial lining with empty uterine cavity confirms the diagnosis when there was a viable pregnancy earlier. The symptoms of pain and bleeding tend to subside.

Missed abortion can be managed expectantly but failure rates may be as high as 50% necessiating uterine evacuation.

Medical Management

Misoprostol (prostaglandin E1) is the drug used commonly to induce expulsion of products of conception.

Some cases of incomplete abortion may be managed with oral misoprostol dose of 600 μg. Alternatively, an 800 μg vaginal or a 400 μg oral or sublingual misoprostol dose may be used.

Missed abortion may be managed medically with a single 800 μg dose vaginally and few may need repeat doses to accomplish the process.

Medical therapy with misoprostol has failure rates of 15–40%.

Surgical Management

It is done in women opting for surgical management or those with failed conservative/medical management. In incomplete abortion, dilatation and curettage may be required to control the bleeding and evacuate the uterine cavity. In case of missed abortion, suction curettage is required. For any procedure, informed consent is must including the possibility of complications. Surgical management results in a quick resolution of symptoms with 95–100% success rate.

Complications of Surgical Management

- *Infection*: If products of conception are retained and the woman presents with symptoms of uterine infection, repeat uterine evacuation may be needed with broad-spectrum antibiotics.
- *Hemorrhage*: Severe bleeding may result from the abortion itself or trauma during the procedure and may require transfusion.
- *Uterine perforation:* Around 1–4 in1,000 cases may be complicated by uterine perforation. Once a perforation is suspected, as a give way feel during procedure, it is wise to abandon the procedure and keep the patient under monitoring. Rarely, laparotomy may be needed to manage hemorrhage in patients with deteriorating condition.
- *Cervical trauma*: Forceful dilatation of the cervix causes damage to the external os in 1 in 100 women leading to cervical incompetence in future pregnancies.
- Menstrual disturbances
- Chronic pelvic inflammation
- *Uterine synechiae* leading to secondary amenorrhea

Women must be informed that any of these complications can occur during surgery. Further treatment in the form of blood transfusion, laparoscopy or laparotomy may be required.

Postabortion Care

Women are counseled regarding pain and bleeding which may persist for a few days. Contraceptive choices are offered. Women are also informed of warning signs and when they need to come back for evaluation.

SEPTIC ABORTION

Septic abortion is any abortion, spontaneous or induced, which is complicated by infection. Unsafe abortions, which usually culminate as septic abortions, are defined by WHO as a procedure for terminating an unintended pregnancy carried out either by persons lacking the necessary skills or in an environment that does not conform to minimal medical standards or both. These include lack of preabortion counseling or advice, involves an unskilled provider, carried out in unhygienic conditions, or by a service provider with inadequate health facilities; abortion is provoked by insertion of objects into the uterus by the woman herself or by unskilled provider, or by other methods. A medical abortion prescribed incorrectly or medication issued by a pharmacist with no or inadequate instructions and no follow-up or an abortion self-induced by ingestion of traditional medication or hazardous substances are also unsafe and can have devastating outcomes. The situation is further worsened by lack of immediate intervention if severe bleeding or other emergency develops during the procedure, failure to provide postabortion checkup and care including no contraceptive counseling to prevent repeat abortions, legal restrictions involved, and sociocultural beliefs linked to abortions. Unsafe abortions contribute significantly to maternal mortality and more than half of abortions in developing countries are unsafe.

Causes

Infections are polymicrobial and the organisms involved in pathogenesis are usually part of the normal vaginal flora. *Peptostreptococcus anaerobius* is the most common blood isolate from cases of septic abortion. Toxin-producing organisms such as *Clostridium perfringens*, group A *Streptococcus* and some strains of *Escherichia coli* proliferate rapidly within dead tissue rendering antibiotic therapy ineffective. *Staphylococcus aureus* is another organism involved in pathogenesis.

Neisseria gonorrhea and *Chlamydia trachomatis* both of which are causative pathogens of pelvic inflammatory disease are also risk factors for septic abortion.

Pathophysiology

Septic abortions, whether induced or spontaneous, occur because of improper, unsafe, or inadequate removal of products of conception. These are usually ascending infections with bacterial infiltration of the uterine contents enabling the infection to invade the myometrium and then cause parametritis, oophoritis and salpingitis, peritonitis, and eventually septicemia. The longer the duration the products are retained, the more chances of developing infections. Duration of pregnancy also correlates with infective morbidity and mortality, both increasing with the gestational age.

Risk Factors

Certain risk factors increase the chances of developing sepsis following an abortion.

- Unsafe abortion
- Sexually transmitted infections such as *Chlamydia*
- Intrauterine device (IUD) insertion
- Tissue from the fetus or placenta retained in the uterus after a miscarriage or elective abortion procedure
- Insertion of foreign body or chemical irritants into the uterus

Clinical Presentation

Typically appear within 24–48 hours following abortion. These include chills, high grade fever, vomiting, malaise, abdominal pain, and foul-smelling vaginal discharge. In some, there may be hemorrhage due to injury to cervix or uterus, undiagnosed cervical pregnancy, uterine atony in advanced gestation, or coagulopathy.

Red Flags

Perforation of the uterus during the abortion typically causes severe abdominal pain and hemorrhage. More concerning are visceral injuries like bowel or bladder injuries which may need urgent laparotomy due to associated hemorrhage. Presence of peritonitis may occur due to spread of infection and present as septic shock.

Evaluation

History

There is history of abortion (medical or surgical) usually carried out by an untrained person or involving use of medicines or substances that have been inserted in the uterus to bring about the abortion. The symptoms arise a few days after use of the abortifacient/surgical procedure. There may be history of other risk factors, chronic diseases, or immunocompromised state. The symptoms may be insidious but progress rapidly as sepsis develops.

Physical Examination

On general examination, the woman has a toxic look with tachycardia, fever, and tachypnoea. If the woman is in shock, hypotension with hypothermia may present. There may be pallor, icterus, ecchymotic patches, anuria, dehydration and altered sensorium.

On abdominal examination, there may be tenderness, and guarding in peritonitis due to visceral injury, or palpable abdominal mass in hematometra (blood accumulation in uterus).

On vaginal speculum examination, there may be evidence of cervical trauma, purulent vaginal discharge, bleeding, or the products of conception may be visible at the cervical os.

On vaginal bimanual examination, there is cervical motion tenderness, uterine and adnexal tenderness, presence of tender adnexal mass suggestive of hematoma. Rectal examination may reveal bogginess due to collection or tenderness and blood staining in cases with bowel injury.

Interpretation of Findings

Pallor and hypotension indicate hemorrhage which may be ongoing. Hyperthermia and tachycardia may present with infection. With onset of sepsis, there is hypothermia and hypotension. Multiorgan involvement may present as renal involvement with anuria or liver involvement with hemolysis. Disseminated intravascular coagulopathy may present with thrombocytopenia and ecchymosis.

Visceral injuries present with tenderness and guarding due to associated peritonitis. Bowel injury due to instrumentation may present as abdominal pain, distension, obstipation, or bloody stools. Injury to urinary bladder may present with suprapubic pain, urinary retention, hematuria, and distension. Hepatic failure and jaundice may ensue due to disseminated intravascular coagulation (DIC) or gangrene. Peritonitis may occur due to spread of infection and present as septic shock with hypothermia, hypotension, oliguria, respiratory distress, or necrotizing infections.

Grading

Based on the extent of spread of infection, septic abortion is graded as follows:

- Grade-I: Infection localized to the uterus
- Grade-II: Infection spreading beyond uterus to pelvic organs and parametrium without signs of generalized sepsis
- Grade-III: Infection spreading beyond pelvis, patients have septicemia with clinical features of fever, hypothermia, tachycardia, tachypnea, and inadequate organ perfusion
- Grade-IV: Patients with septic shock and systolic blood pressure <90 mm Hg.

Investigations

Routine investigations and some specific tests are required to manage cases of septic abortion (**Table 6**). It is important to evaluate for multiorgan dysfunction and development of other complications such as DIC and sepsis.

Laboratory tests may show leukocytosis, thrombocytopenia, hemoconcentration, and intravascular hemolysis (**Table 6**).

Treatment

History and physical examination are crucial for diagnosing septic abortion. Besides routine blood investigations, aerobic and anaerobic blood and vaginal discharge cultures should be obtained to help guide therapy. Ultrasound should also be obtained to look for products of conception in the uterine cavity. In the critical patient, studies looking for DIC are warranted.

TABLE 6: Investigations for septic abortion.	
Routine investigations	
Full blood counts	Serology for HIV, HBsAg, and syphilis
Blood grouping and Rh typing	High vaginal swab culture sensitivity
Renal function test and serum electrolyte	Coagulation profile
Liver function test	Blood culture and sensitivity
Urine microscopy and culture	Blood sugar levels
Ultrasound of abdomen for retained products in uterus, adnexal masses, or free fluid in pelvis	X-ray erect abdomen for gas under diaphragm or multiple air fluid levels in bowel
Special investigations	
Serum lactate—measured within 6 hours of suspected sepsis; ≥4 mmol/L suggests tissue hypoperfusion	
C-reactive protein	
Computed tomography of abdomen and pelvis when ultrasound in inconclusive	
Histopathology and culture sensitivity of products of conception after evacuation	
β-hCG where there is doubt of mismanaged ectopic pregnancy	

(β-hCG: β-human chorionic gonadotropin; HBsAg: hepatitis B surface antigen; HIV: human immunodeficiency virus)

Like other forms of sepsis, resuscitation with intravenous fluids and antibiotics are the mainstay of treatment. Foley catheterization and oxygen support should be given. Vasopressors and blood transfusions are used as needed. The antibiotic regimen selected should cover all potential aerobic and anaerobic pathogens.

Most importantly, prompt evacuation of the infected products is required. This is considered the most critical step in the treatment of septic abortion. Fetal death is inevitable, so procedural intervention should not be withheld even if fetal heart activity is found.

Clinical improvement after fluids, antibiotics, and curettage should be seen within 6 hours. If there is insufficient clinical improvement after such treatment, then a hysterectomy may be necessary. Finally, anti-D immunoglobulin should be administered to all Rh-negative women.

Grade I

Antibiotics should be given as early as possible. Prophylactically antitetanus serum may be given.

Evacuation of the Uterus

As abortion is often incomplete, gentle evacuation should be performed within 24 hours following antibiotic therapy. Early emptying of the uterus not only minimizes the risk of hemorrhage but also removes the nidus of infection. Sedatives and analgesics should be given wherever necessary.

Grade II

Antimicrobial Therapy

A combination of either piperacillin-tazobactam or carbapenem plus clindamycin (IV) gives broadest range of microbial coverage. Empirical therapy is started initially and later changed once culture sensitivity report is available. Other antibiotics such as clindamycin, gentamicin, and metronidazole can also be used as per the clinical scenario.

Surgery

(1) Evacuation of the uterus—Evacuation should be withheld for at least 48 hours when the infection is controlled and is localized, the only exception being excessive bleeding. (2) Posterior colpotomy—When the infection is localized in the pouch of Douglas, pelvic abscess is formed as evidenced by spiky rise of temperature, rectal tenesmus (frequent loose stool mixed with mucus), and boggy mass felt through the posterior fornix. Posterior colpotomy and drainage of the pus relieves the symptoms and improve the general outlook of the patient. (3) Laparotomy—Indicated when uterine perforation, intestinal injury, presence of foreign body, or generalized peritonitis is suspected. Hysterectomy with or without unilateral or bilateral salpingo-oophorectomy may be performed depending upon the pathology. Drainage of pus along with a thorough peritoneal lavage with povidone iodine may be required. Entire bowel length should be examined for any trauma and managed as necessary.

Grade III

Clinical monitoring is to be conducted similar to the management protocols in Grade II. Supportive therapy is directed to treat generalized peritonitis by gastric suction and intravenous crystalloids infusion. Endotoxic shock or renal failure to be managed, if present. Features of organ dysfunction should be carefully guarded against. Patient may need intensive care unit management.

Grade IV

Along with the management protocols of Grade III septic abortion, the patient may even require intensive care, ionotropic or ventilatory support, and other supportive measures like blood transfusion or dialysis which is to be assessed as per the clinical situation.

Complications

Immediate

- *Complications of anesthesia during surgical evacuation*: General anesthesia: Uterine atony leading to severe hemorrhage; local anesthesia: Paracervical block causing accidental intravascular injection of anesthetic agents leading to seizure, cardiopulmonary arrest, and death
- *Neurogenic shock*: Vasovagal syncope produced by stimulation of the cervical canal during dilatation
- *Hemorrhage*: Due to uterine atony in advanced gestational age, cervical laceration, uterine perforation, undiagnosed cervical pregnancy, and coagulopathy
- Acute renal failure

- Pelvic thrombophlebitis
- *Perforation and peritonitis*: Uterine, bladder, and bowel perforation during suction evacuation or dilation of cervix
- Disseminated intravascular coagulation
- Damage to the genital tract and internal organs by the insertion of dangerous objects such as sticks, knitting needles, or broken glass into the vagina or anus.

Sequelae

Septicemia and its associated multiorgan involvement, hepatic failure, paralytic ileus, DIC, and death. Risk of death following complications of unsafe abortions is several hundred times higher.

Remote

- Chronic pelvic pain
- Dyspareunia
- Secondary infertility
- Depression and other psychiatric problems
- Rarely enterovaginal fistula

Prevention and Control

Unsafe abortion can be prevented through:

- Comprehensive sexuality education
- Prevention of unintended pregnancy through use of effective contraception, including emergency contraception
- Provision of safe and legal abortion services
- Maintaining asepsis wherever possible
- Prompt and timely diagnosis and treatment of sepsis

HYPERTENSION IN PREGNANCY

Hypertensive disorders complicate 5–10% of pregnancies and contribute significantly to maternal and perinatal morbidity and mortality worldwide. Not only do these disorders effect pregnancy, they have an important role in long-term disabilities such as cardiovascular and metabolic abnormalities. For the purpose of defining hypertension in pregnancy, the American College of Obstetrics and Gynecology (ACOG) defined criteria of systolic blood pressure ≥140 mm Hg and diastolic blood pressure ≥90 mm Hg is used. Blood pressure should be repeated to confirm the diagnosis, within 15 minutes if systolic blood pressure ≥160 mm Hg and diastolic blood pressure ≥110 mm Hg or over a few hours if lower. According to the International Society for Study of Hypertension in Pregnancy, hypertensive disorders in pregnancy are classified as follows:

- Chronic hypertension (of any etiology)
- Gestational hypertension—definitive evidence for the preeclampsia syndrome does not develop and hypertension resolves by 12 weeks postpartum
- Preeclampsia superimposed on chronic hypertension
- Preeclampsia and eclampsia syndrome

Of these, chronic hypertension either predates pregnancy or is diagnosed before 20 weeks of gestation whereas gestational hypertension and preeclampsia syndromes develop after 20 weeks of pregnancy.

Chronic Hypertension

Chronic hypertension refers blood pressure ≥140/90 mm Hg either preceding pregnancy or recognized <20 weeks in pregnancy and complicates about 3% of pregnancies. It is usually diagnosed at first visits in early months of pregnancy and since most of the women would not have prepregnancy blood pressure recordings, this reading is used to label the woman as a chronic hypertensive. Those women with persistently high blood pressure ≥140/90 mm Hg after 12 weeks postpartum are also labeled as chronic hypertension, as some women may be missed in pregnancy due to physiological lowering of blood pressure in second trimester when they present late to the clinician for the first time. Women with essential hypertension are usually elderly or overweight with a family history. Few have secondary hypertension with causes usually identifiable before conception. There is increased risk of developing superimposed preeclampsia.

Recently, the American Heart Association and American College of Cardiology have lowered the threshold for normal blood pressure levels to 130/80 mm Hg. Although not used by ACOG for defining pregnancy hypertension at present, there will be in the future, a rise in number women with prepregnancy chronic hypertension.

Chronic hypertension per se results in high morbidity and mortality and increases substantively the risk of cardiovascular disease, coronary heart disease, congestive heart failure, stroke, renal failure, and peripheral arterial disease (**Table 7**).

Etiology/Causes

Chronic hypertension may be primary or secondary. Primary hypertension is idiopathic in origin. Causes of secondary hypertension may be:

- Renal artery stenosis
- Renal parenchymal disease
- Primary aldosteronism

TABLE 7: Complications of chronic hypertension on pregnancy.

Maternal complications	***Fetal complications***
Heart failure	Growth restriction
Hypertensive cardiomyopathy	Preterm birth (spontaneous/ iatrogenic)
Myocardial infarction	Intrauterine fetal demise
Stroke	Neonatal morbidity
Pulmonary edema	Perinatal mortality
Acute kidney injury	Anomalies if exposed to fetotoxic drugs
Placental abruption	
Superimposed preeclampsia and HELLP syndrome	
Development of severe hypertension	
Maternal death	

- Pheochromocytoma
- Cushing's syndrome
- Hypothyroidism/Hyperthyroidism
- Coarctation of the aorta
- Obstructive sleep apnea
- Medication

Pathophysiology

As in normal pregnancies, blood pressure drops in most women with chronic hypertension in early pregnancy and rises again in third trimester. This is noted by reduction of antihypertensive medication needed for control. Women with chronic hypertension are noted to have persistently elevated vascular resistance and reduced intravascular volume expansion. The presentation is further complicated by development of superimposed preeclampsia.

Clinical Presentation

Pregnant women present either with diagnosed essential hypertension or they are diagnosed at first presentation. Development of complications depends largely on the duration and severity of hypertension and whether superimposed preeclampsia develops. Blood pressures ≥160 mm Hg systolic or ≥110 mm Hg diastolic is associated with development of complications. Presence of proteinuria at baseline (≥1 + on dipstick or 30 mg/dL) is a risk factor for development of superimposed preeclampsia and other adversities. Superimposed preeclampsia is diagnosed by worsening hypertension, new-onset proteinuria, neurological symptoms such as severe headaches and visual disturbances, generalized edema, oliguria, and certainly, convulsions or pulmonary edema. Laboratory abnormalities are rising serum creatinine or hepatic transaminase levels, thrombocytopenia, or any of the facets of hemolysis, elevated liver enzyme levels, low platelet count (HELLP) syndrome. For women with chronic hypertension and superimposed preeclampsia with severe features, magnesium sulfate for maternal neuroprophylaxis is recommended.

Red Flags

Around 25% cases of chronic hypertension are complicated by superimposed preeclampsia. Diagnosis is made by worsening hypertension and accompanying new onset proteinuria. Preeclampsia is earlier in onset as compared to previously normotensive women.

Evaluation

History

Onset and duration of hypertension and used of antihypertensive medication (drug, dose, and duration) has to be elicited. In cases of secondary hypertension, history regarding other organ involvement and evaluation of function must be enquired. History regarding comorbidities such as diabetes, thyroid disorders, systemic lupus erythematosus, and thrombophilia are important as the treatment may need modification. Family history of hypertension should be elicited.

Physical examination

Thorough physical examination with accurate blood pressure measurement. Systemic examination should be done to rule out end-organ involvement. Obstetric examination is important to assess fetal growth and development.

Interpretation of Findings

Once the diagnosis is accurately established, systemic examination findings will help in evaluation of organ involvement. History of headache and blurring may indicate severe hypertension. Pulmonary edema presents with fine basal crepitations. Ejection systolic murmurs or added heart sounds may be present too. Renal involvement may present with edema due to hypoproteinemia. Growth restriction of fetus may present as size of uterus smaller than the growth expected at that gestation.

Investigations

In addition to routine antenatal investigations, tests for evaluation of end-organ functioning and prediction of complications are recommended (**Table 8**). Obstetric ultrasound should be done to assess the growth and to rule out embryopathies due to fetotoxic medications.

Treatment

All women with chronic hypertension taking angiotensin-converting enzyme inhibitors/angiotensin receptor blockers should be counseled regarding possible teratogenicity (renal failure, oligohydramnios, growth restriction, fetal demise, and skull and limb deformities) of these drugs and be switched to other drugs which are safe in pregnancy. Beta-blockers are not recommended as they are associated with fetal growth restriction when used in latter half of pregnancy. Diuretics too are not recommended for use in pregnancy due to limited data available for safety. Recommended antihypertensive drugs are summarized in **Table 9**.

Women diagnosed first time in pregnancy should have baseline investigations and blood pressure monitoring. They should be advised regarding weight gain, exercise, healthy eating, and dietary salt restriction. Those on medication, if

TABLE 8: Investigations recommended for hypertension in pregnancy.

Test	*Indication*
Full blood counts	Hemoglobin and platelet count
Liver function test	Liver enzymes [aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase (LDH)] and functions tests [international normalized ratio (INR), serum bilirubin, and serum albumin]
Renal function test	Serum creatinine, electrolytes, and uric acid
Urinalysis and microscopy	Proteinuria (protein: creatinine ratio or albumin: creatinine ratio)
Fundoscopy	Hypertensive retinal changes
Echocardiogram/ echocardiogram	Left ventricular function and cardiomyopathy
Renal ultrasound	When serum creatinine or any of the urine testing are abnormal

TABLE 9: Antihypertensives used in pregnancy.

Drug	*Dosage*	*Comments*
Labetalol α1 and nonselective β-blocker	• 200–2,400 mg/day in 2–4 divided doses • Initial dose usually 100 mg twice daily and increased as needed	• Usually well tolerated • Contraindicated in asthma and congestive heart failure
Nifedipine Calcium channel blocker	20–120 mg/day in divided doses (sustained release preparations)	Tachycardia and headache
Methyldopa Centrally acting α2 agonist	500–2,000 mg/day in 2–4 divided doses	Used when there is intolerance to both labetalol and nifedipine

safe in pregnancy can continue the same. For women not on treatment, start medication if systolic blood pressure is ≥140 or diastolic ≥90 mm Hg. Target blood pressure should be 135/85 mm Hg. It may be helpful to admit to investigate and monitor the blood pressure over 48 hours to rule out other severe conditions.

Labetalol is preferred drug for treatment of hypertension. Nifedipine is used where labetalol is not suitable and methyldopa if both labetalol and nifedipine cannot be used. Low dose aspirin 75–150 mg should be offered once daily from 12 weeks, preferably before 16 weeks. Initial dose of labetalol used is 100 mg twice or thrice a day with titration as needed.

Women with poorly controlled hypertension need follow-up every week for antihypertensive dose adjustment. Those with controlled blood pressure may follow up 2–4 weekly or as deemed necessary.

Delivery should be planned after 37 weeks and before 39 weeks in women with blood pressure <160/110 mm Hg with/without treatment. Corticosteroids for lung maturation may be given for planned births. Trial of vaginal birth should be given. Severe hypertension may be treated with intravenous labetalol or hydralazine and magnesium sulfate should be used for seizure prophylaxis. Those with complications may need earlier delivery after consultation with senior obstetrician and neonatologist.

In the postpartum period, these women are prone to develop pulmonary edema as vascular resistance rises and fluid is mobilized into circulation. Prompt management with diuretics along with blood pressure control should be instituted.

Oral hypertensives can be restarted with the aim to keep blood pressure <140/90 mm Hg and on discharge from the facility, review with physician can be done at 2 weeks and 6 weeks postpartum. Diagnosis is confirmed at 12 weeks when blood pressure remains elevated.

Gestational Hypertension

Gestational hypertension is persistent hypertension >140/90 mm Hg in a previously normotensive woman at or after 20 weeks of gestation, in the absence of features of preeclampsia. Final diagnosis is however made at 12 weeks postpartum when blood pressure has normalized. Around 25% cases go on to develop preeclampsia, more so in women diagnosed early. As in chronic hypertension, gestational hypertension is also a risk factor for future cardiovascular disease.

TABLE 10: Risk factors for gestational hypertension.

Age ≥40 years	*Nulliparity*
Family history of preeclampsia	Interpregnancy interval >10 years
Body mass index (BMI) ≥35 kg/m^2	Multiple pregnancy
Preexisting vascular disease	Previous history of gestational hypertension
Preexisting kidney disease	Previous history of preeclampsia

Etiology/Causes

As for other pregnancy-induced hypertensive disorders, there is no definite etiology for gestational hypertensive. Prevalence is more in women with risk factors (**Table 10**).

Clinical Presentation

Pregnant women presents after 20 weeks of gestation with blood pressure >140/90 mm Hg without proteinuria. The diagnosis is confirmed by repeat blood pressure reading after a few hours. If the blood pressure remains >140/90 mm Hg but <160/110 mm Hg, antihypertensive treatment is started to achieve a target blood pressure of 135/85 mm Hg. Laboratory investigations should be done to rule out hematological or biochemical features suggestive of preeclampsia. Blood pressure and proteinuria should be measured at least twice a week. Once blood pressure is controlled, the woman may follow-up every 2–4 weeks.

If there is severe hypertension, the pregnant woman is admitted and treatment instituted. Blood pressure is repeated every 15–30 minutes till it is <160/110 mm Hg. Daily blood pressure monitoring can be done during hospital stay. Once blood pressure is controlled and laboratory findings are normal, patient can be discharged with follow-up every 2 weeks.

Red Flags

Since these women are at an increased risk of development of preeclampsia, development of new onset proteinuria or abnormal laboratory findings may suggest development of the same. At every antenatal visit, home blood pressure recordings should be assessed along with evaluation for headache, blurring of vision, and epigastric pain which may indicate preeclampsia (**Table 11**).

TABLE 11: Differentiating features of preeclampsia and gestational hypertension.

Findings	*Preeclampsia*	*Gestational hypertension*
Onset	>20 weeks	>20 weeks
Proteinuria	Present	Absent
Thrombocytopenia (platelets $<10^5/mm^3$)	Present	Absent
Serum creatinine >1.1 mg/dL	Present	Absent
Liver transaminases twice of normal	Present	Absent
Headache	Present	Absent
Visual disturbance	Present	Absent

Evaluation

History

Assessment regarding risk factors such as family history and hypertension in previous pregnancy should be done. History of any medical comorbidity such as diabetes and vascular diseases should be elicited.

Physical examination

Thorough systemic examination should be done to rule out any end-organ involvement and also to rule out preeclampsia.

Interpretation of Findings

Raised blood pressure may be the only finding in most cases. With severe hypertension or development of preeclampsia, findings suggestive of end-organ damage such as pulmonary edema, proteinuria, and abnormal laboratory findings may be present.

Investigations

Other than routine antenatal investigations, investigations are done at baseline to evaluate disease severity and end-organ damage (**Table 12**). Obstetric examination and assessment of fetal well-being to be done at every antenatal visit and growth assessment by ultrasound at 2–4 weekly.

Treatment

Labetalol is the drug of choice started in twice or thrice a day dosage and titrated as needed. In presence of contraindication, nifedipine or methyldopa may be used. Home blood pressure records should be maintained and warning signs explained. Follow-up every 2 weeks with records is adequate if blood pressure is controlled. Termination can be done after 37 weeks of gestation.

In women presenting with severe hypertension, intravenous labetalol or hydralazine may be used. Once controlled, oral medication may be started. If blood pressure remains elevated or preeclampsia develops and termination is decided, corticosteroid for fetal lung maturation should be given and magnesium sulfate should be considered for neuroprotection. Mode of delivery can be decided according to the obstetric indication. Blood pressures should be controlled during labor. Postpartum period should be watched for development of pulmonary edema and managed.

TABLE 12: List of investigation for gestational hypertension.

Full blood counts	*Urinalysis and microscopy*
Liver transaminases	Lactate dehydrogenase
Prothrombin time	Serum creatinine
Urea and electrolytes	Fundus examination

In postpartum period, antihypertensive treatment may be continued as required. Start medication if >150/100 mm Hg in those not on medication. Medicine should be gradually tapered with physician review at 2 and 6–8 weeks.

Preeclampsia

The most dreaded of all hypertensive disorders in pregnancy, the preeclampsia syndrome, has an incidence of 2–5% though it contributes most to morbidity and mortality related to hypertension. On the global front, it is estimated over 70,000 women and 500,000 babies die each year due to its complications and the burden of near miss is nearly 100-fold. It is a pregnancy-specific disorder that affects every organ system in the body and is associated with cardiovascular complications in later life.

The diagnosis of preeclampsia is made by the presence of new onset hypertension >140/90 mm Hg after 20 weeks of gestation either with proteinuria and/or evidence of maternal acute kidney injury, liver dysfunction, neurological features, hemolysis or thrombocytopenia, and fetal growth restriction. Some cases may be diagnosed for the first time in intrapartum or early postpartum period.

Etiology/Causes

Numerous etiologies have been proposed, yet no definite cause has been established for development of preeclampsia. The most accepted theory is of placental implantation with abnormal trophoblastic invasion of uterine spiral arteries. Unlike in normal pregnancies where placental trophoblasts invade the decidua and extend into the walls of the spiral arteriole replacing the endothelium and muscular walls to create a large caliber low-resistance vessel, in preeclampsia, there is defective placental implantation characterized by incomplete invasion of the spiral arteriolar wall by extravillous trophoblasts. This results in a small caliber vessel with high resistance to flow. Antiangiogenic factors have a role to play in this defective remodeling. With this, there is endothelial damage, intimal hyperplasia, and medial necrosis leading to atherosclerotic changes in placental vessel walls on microscopy. All these culminate in a systemic inflammatory response with clinical onset of hypertension and multiorgan involvement.

Another theory postulated is immune maladaptation of the mother to paternally derived antigens. This leads to graft-versus-host reaction with inflammation at uteroplacental interface. This is supported by incidence of preeclampsia being higher in first pregnancy when the woman is exposed to paternal antigens, and the severity of the disease being more in multiple pregnancy and molar pregnancy where the load of paternally derived antigens is higher.

Endothelial cell dysfunction resulting from release of placental factors due to placental ischemia is another proposed theory for preeclampsia. Antiangiogenic and metabolic factors

TABLE 13: Risk factors for preeclampsia.	
Age >35 years	Nulliparity
Body mass index (BMI) >30 kg/m^2	Multifetal pregnancy
Chronic hypertension	Prior preeclampsia
Diabetes mellitus	Prior abruption
Chronic kidney disease	Assisted reproduction
Systemic lupus erythematosus	Prior stillbirth
Antiphospholipid antibody syndrome	Male fetus

and other inflammatory leukocyte mediators [tumor necrosis factor α (TNFα) and interleukins] are thought to provoke systemic endothelial cell injury. There is formation of reactive oxygen species with toxic free radicals causing endothelial dysfunction leading to prostaglandin imbalance and finally ending in placental atherosclerosis with microvascular coagulation.

Genetic association of preeclampsia is well established and the disease has strong familial predisposition. Numerous genes have been studied for their association, the important ones being methylenetetrahydrofolate reductase, factor V Leiden, angiotensin-converting enzyme gene, various human leukocyte antigens, and many more. The syndrome is usually polygenetic origin with phenotypic expression dependent on environmental influences as well. Certain clinical risk factors if present have strong premonitory significance and need further evaluation (**Table 13**).

Pathophysiology

Abnormal trophoblast invasion in women who develop preeclampsia causes placental ischemia with release of certain antiangiogenic factors and substances which cause injury of systemic endothelial cells and activation which is central to pathogenesis of preeclampsia. This endothelial activation causes endothelial leakage and interferes with many intrinsic functions of the endothelium such as anticoagulation and release of nitric oxide. Activated endothelium releases substances that promote coagulation and reduced prostacyclin and nitric oxide increases sensitivity to vasopressors. Due to widespread arterial vasospasm, there is rise in blood pressure. Along with reduced blood flow and endothelial leak, there is progressive tissue ischemia and necrosis leading to end-organ damage with clinical features.

Endothelial dysfunction, vasospasm, and ischemia lead to the manifestation of pathophysiological changes in all organ systems beginning early in pregnancy which progress throughout pregnancy with multiorgan involvement.

In the cardiovascular system, there is ventricular hypertrophy with diastolic dysfunction as a result of increase in afterload due to hypertension which can be evaluated on echocardiography. Also, there is marked hemoconcentration due to limited volume expansion and endothelial activation which causes a fall in the cardiac preload. These women are extremely sensitive to volume of intravenous fluids transfused and can develop pulmonary edema compounded by these factors.

Overt thrombocytopenia (platelets <100,000/mm^3) and hemolysis result from endothelial disruption with platelet adherence and fibrin deposition (microangiopathic hemolysis). Hemolysis can be evaluated by elevated serum lactate dehydrogenase, reduced haptoglobin levels, increased bilirubin levels, and presence of schizocytes, spherocytes, and reticulocytosis in peripheral blood smear. Together with elevated liver transaminases these form part of the HELLP syndrome.

In the kidneys, there is reduced perfusion due to marked increase in resistance in the afferent glomerular arterioles and decreased filtration due to glomerular endotheliosis. As a result, there is elevated serum creatinine and uric acid. Acute tubular necrosis occurs frequently with coexisting placental abruption HELLP syndrome and postpartum hemorrhage.

Liver involvement ranges from mild periportal hemorrhage to hepatocellular necrosis to massive infarction and liver failure. There may be only mild elevation of aspartate transaminase or alanine transaminase in mild cases whereas levels up to 2,000 U/L have been reported in severe cases. Rarely, a subcapsular hematoma may form and rupture causing hemorrhage.

In the brain, there is cerebral edema due to hyperperfusion with endothelial damage, and, infarction due to vasospasm and ischemia. Rise in blood pressure exceeds the cerebrovascular autoregulatory capacity with forced vasoconstriction and vasodilatation which leads to capillary damage and causes edema. The occipital and parietal lobes are usually involved which is apparent on imaging as posterior reversible encephalopathy syndrome. Cerebral symptoms can present as confusion, lethargy, visual blurring, obtundation, coma, or seizures in eclampsia. Visual symptoms of blurring, diplopia, and scotoma result from either occipital lobe edema or retinal detachment or infarction.

Clinical Presentation

Pregnant woman presenting with blood pressure >140/90 mm Hg after 20 weeks of pregnancy accompanied by proteinuria or any systemic findings is diagnosed as preeclampsia. The blood pressures should be rechecked after a few hours to make a diagnosis. Proteinuria, once the sine qua non of preeclampsia, is now not considered pathognomonic of this condition. In absence of proteinuria, presence of any abnormal laboratory values suggestive of preeclampsia is included in the diagnosis (**Table 14**).

Preeclampsia is classified as nonsevere and severe depending on presence of severe hypertension, rapidly deteriorating laboratory parameters, or features of impending eclampsia (**Table 15**). However, this is now considered redundant as a seemingly "nonsevere" case may rapidly progress to a severe form of the disease.

Red Flags

Blood pressures systolic ≥160 mm Hg or diastolic ≥110 mm Hg or presence of any hematological or biochemical abnormalities are concerning. In presence of symptoms of impending eclampsia, one needs to be more vigilant and institute prompt treatment to prevent worsening of the maternal condition.

Evaluation

History

On presentation, it is important to ask regarding presence of any symptoms indicating features of severity. History of headache

TABLE 14: Criteria of diagnosing the preeclampsia.

Criteria	*Diagnosis of preeclampsia*	*Comments*
Blood pressure	• >140/90 mm Hg after 20 weeks • Confirm by repeat blood pressure measurement in a few hours	Previously normotensive woman
Proteinuria	≥300 mg/24 hours or urine protein: creatinine ratio ≥0.3 or dipstick 1 + persistent	Automated dipstick recommended, if not available visual dipstick used
Hematological complications	Thrombocytopenia—platelet count <150,000/mm^3, disseminated intravascular coagulation (DIC), and hemolysis	
Renal disease	Creatinine level >1.1 mg/dL or doubling of baseline	No history of previous renal disease
Liver involvement	Serum transaminases double of normal	With or without right upper quadrant or epigastric pain
Pulmonary edema		
Cerebral or visual symptoms	Headache or visual disturbances: Eclampsia, altered mental status, blindness, stroke, clonus, severe headaches, and persistent visual scotomata	
Uteroplacental dysfunction	Fetal growth restriction, abnormal umbilical artery Doppler wave form analysis, or stillbirth	

TABLE 15: Indicators of preeclampsia severity.

Systolic blood pressure	*≥160 mm Hg*
Diastolic blood pressure	≥110 mm Hg
Headache	New-onset headache
Visual disturbances	Present
Upper abdominal pain	Epigastric or right upper quadrant pain
Oliguria	<400 mL/24 h
Serum creatinine	>1.1 mg/dL
Serum transaminases	>70 IU/mL
Pulmonary edema	Present
Fetal growth restriction	Present

TABLE 16: Recommended investigations for preeclampsia.

Recommended investigations	*Importance*
Complete blood count	Anemia and thrombocytopenia
Urine proteins	Diagnosis/quantification of proteinuria
Renal function tests	Serum creatinine levels and uric acid levels
Liver function test	Serum transaminases and bilirubin level
Lactate dehydrogenase	Hemolysis for diagnosis of HELLP syndrome
Coagulation profile	With low platelet counts
Fundoscopy	Papilledema and other hypertensive changes
Obstetric ultrasound	Fetal well-being

(HELLP: hemolysis, elevated liver enzyme levels, and low platelet count)

not relieved by medication, visual disturbances, scotomas, flashes of light suggesting aura, blurring of vision, pain in epigastric or right upper quadrant, and recent weight gain need to be inquired. History of presence of risk factors, chronic or gestational hypertension, and use of antihypertensive medicines has to be asked. History of medical conditions such as diabetes, chronic kidney disease, thyroid disorders, lupus, and thrombophilia must be ruled out. One must also ask about family history of hypertension. Obstetric history regarding multiple fetuses, hydramnios or molar pregnancy should be elicited.

Physical examination

Thorough physical examination with measurement of blood pressure, pulse, respiratory rate, temperature, pallor, and edema to be evaluated. It is important to assess the level of consciousness and visual symptoms and evaluate any dyspnea which is out of proportion to that physiologically expected. Measure the weight and assess the weight gain since last visit. Systemic examination to assess for pulmonary edema, congestive cardiac failure such as tachypnoea, presence of basal crepitations, and raised jugular pressure should be assessed. Obstetric examination is done to assess the period of gestation and well-being.

Interpretation of Findings

Presence of any features of severity will label the condition as severe preeclampsia which is ominous.

Investigations

Investigations recommended in preeclampsia, apart from routine, help in establishment of diagnosis as well as classification of severity of the condition (**Table 16**).

Treatment

For women presenting with blood pressures 140/90–159/109 mm Hg, admit if there are any concerns for maternal or fetal well-being such as presence of clinical features

suggestive of severe disease. This will also give an opportunity to investigate and watch for disease progression. Detailed examination should be done with assessment for features of worsening. Daily weight measurement and proteinuria quantification to be done. Blood pressure to be monitored 4 hourly. Start antihypertensive medication to achieve blood pressure <135/85 mm Hg with frequent monitoring (**Table 17**). All relevant investigations must be done. Proteinuria should be reevaluated if new symptoms develop. Fetal assessment with cardiotocography, ultrasound, and Doppler to be done at the time of admission. Once blood pressure is controlled and blood tests are reassuring, the woman can be discharged if the pregnancy is remote from term and there are no immediate indications for delivery, with advice on home blood pressure monitoring and sensitization regarding warning symptoms. Follow-up can be done on fortnightly basis with good control.

Pregnancy can be allowed to progress till 37 weeks with mild preeclampsia with good blood pressure control on medication when delivery by induction or cesarean section for obstetric indication is done.

Women presenting with blood pressure >160/110 mm Hg or symptoms of headache, blurring of vision, epigastric pain, and need urgent admission. Blood pressure should be controlled with injectable labetalol, hydralazine, or oral nifedipine with monitoring every 15–30 minutes. If blood pressure falls <160/110 mm Hg, maintenance therapy with oral antihypertensives to be given with investigations repeated alternate day to assess disease progression. Fetal evaluation to be done once the condition of patient is stable to assess maturity and well-being. Corticosteroid coverage can be advised if <34 weeks of gestation to enhance fetal lung maturity, should it become necessary to terminate the pregnancy earlier. Decision to terminate the pregnancy should be taken only after discussion with the critical care team and neonatologist. If high blood pressure persists despite medication, there are features of impending eclampsia or laboratory reports are ominous, delivery is considered after stabilization of the mother. Magnesium sulfate should be considered for seizure prophylaxis (**Box 3**).

For those women whose blood pressure is controlled on more than one drug and laboratory reports do not indicate immediate need for intervention, pregnancy can be continued up to 34 weeks of gestation when delivery should be planned after corticosteroid cover (**Box 4**). Till the termination is planned, hospital visits should be weekly with blood pressure monitoring and assessment of fetal well-being with obstetric ultrasound and umbilical artery Doppler weekly. Approach to preeclampsia is summarized in **Flowchart 2**.

Eclampsia

Preeclampsia complicated by generalized tonic-clonic seizures is eclampsia and has poor implications for maternal and perinatal outcome. Usually preceded by severe preeclampsia,

BOX 3: Indications for magnesium sulfate prophylaxis in severe preeclampsia.

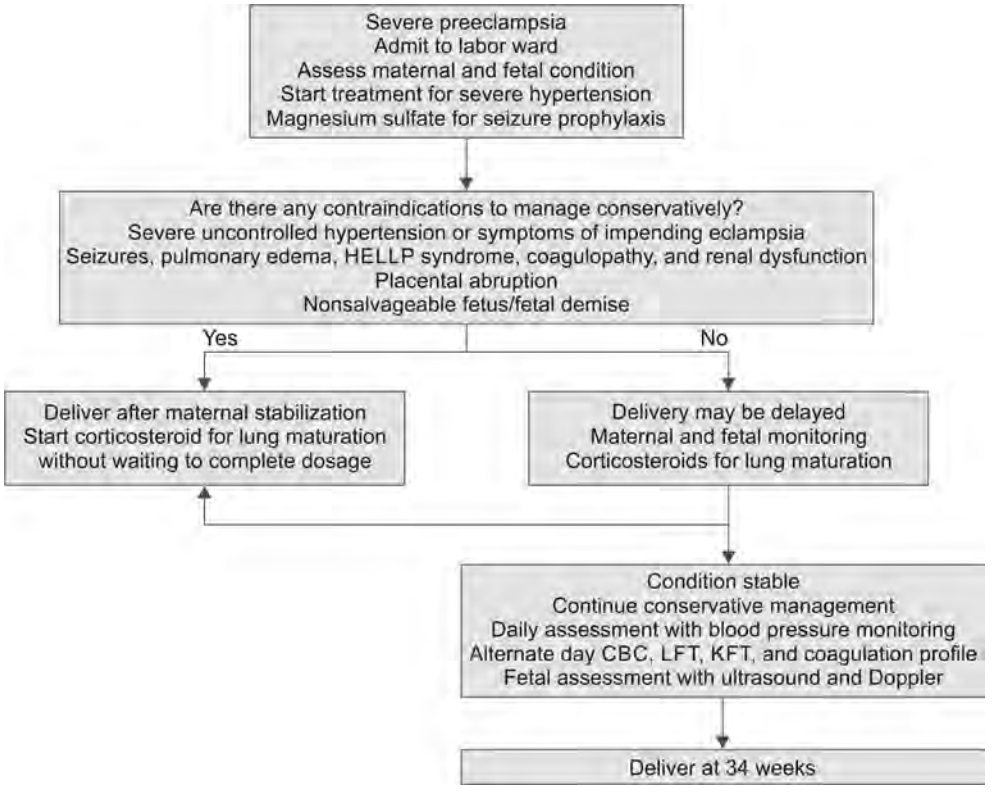
- Systolic blood pressure ≥160 mm Hg or diastolic blood pressure ≥110 mm Hg
- Proteinuria ≥2 + by dipstick in a catheterized urine specimen
- Serum creatinine >1.1 mg/dL
- Platelet count <100,000/mm^3
- Aspartate aminotransferase (AST) elevated two times above upper limit of normal range
- Persistent headache or visual symptoms (scotoma, blurring, and diplopia)
- Persistent epigastric or right-upper quadrant pain

BOX 4: Indications for termination of pregnancy <34 weeks in preeclampsia after maternal stabilization.

- Blood pressure uncontrolled despite using three antihypertensive drugs at optimal dosage
- Presence of pulmonary edema with oxygen saturation (SpO_2) <90%
- Progressive worsening of liver function, renal function, thrombocytopenia, or disseminated intravascular coagulation (DIC)
- Persistent neurological symptoms of headache, visual symptoms, or seizures
- Placental abruption
- Reversal of diastolic flow in umbilical artery on Doppler study, fetal heart rate abnormalities detected on cardiotocography or intrauterine demise

TABLE 17: Therapy for control of severe hypertension.

Drug	*Dosage*	*Side effects*
Hydralazine	• Dilute 20 mg hydralazine in 20 mL of water for injection • Initial 5 mg intravenous (IV) bolus dose, repeat 5 mg dose at 20 minutes. If blood pressure not controlled and third dose of 5 mg after another 20 minutes • Record blood pressure every 10 minutes • If still not controlled after three doses, start infusion at 5 mg/hour dose	Maternal hypotension and fetal distress
Labetalol	• Initial 10 mg dose, repeat at 10–15 minutes as 20 mg and then 40 mg to 80 mg, if no response. Maximum dose of 300 mg • Record blood pressure every 10 minutes	Contraindicated in asthma and congestive heart failure
Nifedipine	• Initial 10 mg immediate release dose, repeat 30–45 minutes with second 10 mg dose • Record blood pressure every 15 minutes • If severe hypertension persists, switch to injectable antihypertensive	Tachycardia and headache



Severe preeclampsia
Admit to labor ward
Assess maternal and fetal condition
Start treatment for severe hypertension
Magnesium sulfate for seizure prophylaxis
Are there any contraindications to manage conservatively?
Severe uncontrolled hypertension or symptoms of impending eclampsia
Seizures, pulmonary edema, HELLP syndrome, coagulopathy, and renal dysfunction
Placental abruption
Nonsalvageable fetus/fetal demise
Yes
No
Deliver after maternal stabilization
Start corticosteroid for lung maturation
without waiting to complete dosage
Delivery may be delayed
Maternal and fetal monitoring
Corticosteroids for lung maturation
Condition stable
Continue conservative management
Daily assessment with blood pressure monitoring
Alternate day CBC, LFT, KFT, and coagulation profile
Fetal assessment with ultrasound and Doppler
Deliver at 34 weeks

(CBC: complete blood count; HELLP: hemolysis, elevated liver enzyme levels, and low platelet count; KFT: kidney function test; LFT: liver function test)

FLOWCHART 2: Approach to preeclampsia.

convulsions can occur in the antenatal or postnatal period. In the antenatal period, eclampsia occurs usually in the last 3 months of pregnancy closer to term. In postnatal period, seizures occur usually within 48 hours of birth though cases have been reported even 7 days after delivery.

All pregnant women presenting with seizures should be considered to be eclampsia until proven otherwise. In women presenting with focal neurological deficits, atypical eclamptic seizures and prolonged comatose state, alternate diagnosis should be sought.

Clinical Presentation

Generalized seizures, sometimes violent enough to injure the woman, last about a minute followed by gradual waning of contraction intensity. The eclamptic phase is sometimes preceded by a state of aura with marked headache, visual symptoms such as flashes or scotomas, confusion or altered consciousness. Post an episode of seizure, the woman may regain consciousness completely in some time or remain unconscious or comatose. In some, there is a state of combative semiconsciousness. Rarely coma may persist and condition deteriorates after further seizures resulting in death. If seizures continue despite all interventions (status epilepticus), there is emergent need for sedation or general anesthesia to prevent anoxia.

Due to spasm of all muscles in the body during a convulsion, tongue bite can occur there, thus, the need to protect the airway. Also, after convulsion, the tongue may fall back and obstruct the upper airway due to secretions. There is also a risk of aspiration of secretions or vomitus postconvulsion leading to aspiration pneumonitis or Mendelson's syndrome. Due to spasm of respiratory muscles, there is anoxia, hypercarbia, and lactic acidosis with transient tachypnoea to compensate for CO_2 retention. Other organs may be affected as in severe preeclampsia.

Pulmonary edema may occur due to ventricular failure from raised blood pressure (cardiogenic edema) or injudicious use of intravenous fluid or aspiration of gastric contents (altered pulmonary capillary permeability).

Cerebrovascular hemorrhage may lead to neurological defects or even cause death if massive. A devastating complication, it is more common in women with chronic hypertension where there are Charcot-Bouchard aneurysms in the deep penetrating arteries of the lenticulostriate branch of middle cerebral arteries which rupture during hypertensive crises.

Visual impairment results from occipital lobe edema or retinal detachment. It is usually reversible within 1–2 weeks.

Posteclamptic convulsion, there is higher chance of onset of labor with rapid progression. Fetal bradycardia is common after seizure due to acidosis and usually recovers by 5 minutes.

Red Flags

Death may occur from status epilepticus nonresponsive to treatment, cerebral edema with transtentorial herniation, massive cerebral hemorrhage, pulmonary edema, pulmonary embolism, hepatic rupture due to subcapsular hematoma, acute hepatic/renal failure, congestive cardiac failure, and DIC.

Treatment

Delivery of the fetus is the definitive treatment of preeclampsia and eclampsia. However, when the woman has convulsed, it is important to stabilize her condition before termination of pregnancy which is done irrespective of ability of the fetus to be salvaged.

When a pregnant woman presents with seizures, immediately check the vitals and turn in lateral decubitus position to prevent aspiration. Care should be taken to prevent the woman from injuring herself should a seizure recur. A mouth gag or padded tongue blade can be inserted to prevent tongue bite during fit. Airway assessment for patency to be done and suctioning to clear any secretions is done. Respiratory rate and oxygen saturation are assessed and endotracheal intubation is done for those not able to maintain saturation. Oxygen is given at 8–10 L/min if saturation in low. A quick history is obtained and examination done. Magnesium sulfate is given to prevent further seizures along with medicine to control blood pressure. Per urethral catheterization is done. Obstetric assessment for mode of termination of pregnancy is done. Cesarean section is done for obstetric indications and status epilepticus nonresponsive to treatment, if immediate vaginal delivery is not possible. It is a good practice to deliver an eclampsia patient in 12 hours to improve maternal outcome.

The mainstay of eclampsia treatment is use of magnesium sulfate to prevent further convulsions or even forestall convulsions in severe preeclampsia. It is administered either by intramuscular route as intermittent injections or intravenous route as continuous infusion; the doses used are same for eclampsia and preeclampsia. The treatment has to be continued till 24 hours after delivery or last seizure, whichever is later (**Table 18**).

Importance of assessment of deep tendon reflexes cannot be overemphasized. At serum magnesium levels >10 mEq/L which may be the only indication of levels above normal range. At levels >12 mEq/L, respiratory depression (respiratory rate <10 or SpO_2 <92%) and arrest ensues. Treatment with calcium gluconate or calcium chloride, 1 g intravenously (10 mL of 10% over 10 minutes), along with discontinuation of further magnesium sulfate, usually reverses mild-to-moderate respiratory depression and these should be readily available in labor ward settings.

Urine output monitoring (>30 mL/hour) gives an idea of renal function and thus monitored every 4 hours. Since $MgSO_4$ is renally excreted, magnesium toxicity can occur with impaired renal function. Even with suboptimal renal function, loading dose should not be skipped as it helps in achieving a therapeutic serum level. Maintenance doses, however, will depend upon renal function, and when serum creatinine is >1 mg/dL, it is advisable to do serum magnesium levels to monitor toxicity and guide further dosage.

With administration of $MgSO_4$, there is transient fall in vascular resistance and mean arterial pressure with increase in cardiac output presenting as flushing.

Magnesium sulfate readily crosses over to the fetus and causes transient fetal heart rate changes such as reduced variability and decelerations. Few other adverse effects have been reported such as hypotonia yet overall, it has been found to be protective against development of cerebral palsy, especially in low birth weight babies.

Another important facet of eclampsia management is treatment of severe hypertension which may result in cerebral hemorrhage or hypertensive encephalopathy or even cause convulsions in severe preeclampsia. It is recommended that therapy be started to bring systolic blood pressure <160 mm Hg and diastolic blood pressure <110 mm Hg. Labetalol, hydralazine, and nifedipine (oral) are used for management of severe hypertension as discussed previously.

Diuretics must be used judiciously in cases with pulmonary edema, which is probably the only indication for use in preeclampsia and eclampsia.

TABLE 18: $MgSO_4$ regimen for eclampsia treatment.

	Intramuscular regimen (Pritchard regimen)	***Intravenous regimen (Zuspan regimen)***
Loading dose	• 4 g $MgSO_4$ as 20% v/w solution intravenously at rate not exceeding 1 g/min • Follow promptly with 10 g $MgSO_4$ 50% v/w solution, 5 g as deep intramuscular in upper outer quadrant of each buttock by 3 inch 20-gauge needle	4–6 g $MgSO_4$ in 100 mL normal saline over 15–20 minutes
Repeat convulsions after 15 minutes	Give additional 2 g $MgSO_4$ as 20% v/w solution intravenously at rate not exceeding 1 g/min	
Maintenance dose	Every 4 hours, 5 g $MgSO_4$ 50% v/w solution as deep intramuscular in alternate buttock	1–2 g/hour maintenance in 100 mL intravenous fluid/infusion
Prerequisites for maintenance doses	• Patellar reflex is present • Respiration is not depressed • Urine output over last 4 hours is >100 mL	• Deep tendon reflexes present • Serum magnesium levels done 4–6 hourly to maintain between 4 and 7 mEq/L • Serum magnesium levels if creatinine >1 mg/dL
Maternal observations	Respiratory rate and blood pressure every 30 minutes, maternal pulse hourly, urine output hourly, deep tendon reflexes 2 hourly, and fetal heart rate continuous monitoring	
Pain relief	1 mL of 2% lidocaine can be added to the intramuscular preparation	
Discontinue	24 hours after delivery or last fit whichever is later	24 hours after delivery or last fit whichever is later

Both vaginal birth and cesarean section are possible in cases of eclampsia. For vaginal birth, intravenous fluids should be used cautiously to avoid any fluid overload when using oxytocin infusion for labor augmentation. Second stage of labor has to be cut short by using vacuum or forceps for assisting birth. For the purpose of cesarean section, general, epidural, and combined spinal-epidural are acceptable provided that careful approach is adopted to manage the complications arising due to each method. Due to limited plasma volume expansion of pregnancy, these women may not be able to tolerate moderate amount of blood loss at childbirth and second stage has to be managed well to prevent excessive bleeding. Blood loss can be estimated from hematocrit and managed appropriately with crystalloids and blood transfusion.

HELLP SYNDROME

HELLP syndrome is an acronym for hemolysis, elevated liver enzymes, and low platelet counts and occurs in about 7.5% of all pregnancies, more commonly in those complicated by severe preeclampsia and eclampsia. It may develop during the antepartum period more so in the third trimester and also in the postpartum period. Majority (80%) of women with HELLP have hypertension and proteinuria.

Two classification systems are used for grading of HELLP syndrome as follows:

1. *Tennessee classification*:
   i. Complete syndrome—platelets <100,000/mm^3, liver transaminases >70 IU/L, and lactate dehydrogenase >600 IU/L
   ii. Incomplete syndrome—one or two of platelets <100,000/mm^3, liver transaminases >70 IU/L, and lactate dehydrogenase >600 IU/L
2. *Mississippi classification:*
   i. Class 1—platelets < 50,000/mm^3, liver transaminases >70 IU/L, and lactate dehydrogenase >600 IU/L
   ii. Class 2—platelets 50,000–100,000/mm^3, liver transaminases >70 IU/L, and lactate dehydrogenase >600 IU/L
   iii. Class 3—platelets 100,000–150,000/mm^3, liver transaminases >40 IU/L, and lactate dehydrogenase >600 IU/L

Etiology

Similar to the pathogenesis of preeclampsia, there is endogenous release of factors leading to endothelial injury with activation of the coagulation and complement cascade. There is also decrease in endothelium-derived prostacyclin and nitrous oxide increasing the response to vasopressors. There is widespread microvascular injury with hemolytic anemia, elevated liver enzymes due to periportal hepatic necrosis and thrombocytopenia due to consumption by microthrombi.

Pathophysiology

Microangiopathic hemolysis results in abnormal forms of red cells in peripheral smear (schizocytes, burr cells, and fragmented cells). There is compensatory haematopoiesis which can be seen as reticulocytosis. Due to hemolysis, there is an increase in lactate dehydrogenase level, fall in hemoglobin, low haptoglobin, and rise in unconjugated bilirubin levels. Liver enzymes (aspartate and alanine transaminases) are elevated as a result of hepatic necrosis and increased hemolysis. Thrombocytopenia results from consumption due to platelet aggregation and microthrombi formation.

Clinical Presentation

Majority of cases being associated with hypertensive disorders are diagnosed in these women by laboratory investigations. There may be no symptom at all and diagnosis is made on the basis of presence of anemia, platelet count <100,000/mm^3, raised liver transaminases, and bilirubin and elevated lactate dehydrogenase levels.

In symptomatic women there may be hypertension and proteinuria with epigastric or right upper quadrant pain, nausea, vomiting, headache, edema, weight gain, and rarely jaundice.

Maternal complications such as eclampsia, acute renal failure, disseminated intravascular coagulopathy, placental abruption, cerebral hemorrhage, pulmonary edema, hepatic infarction or parenchymal hemorrhage, and subcapsular hematoma may occur. Mortality can occur in 1–3% cases.

Neonatal morbidity and mortality are also increased. There is a higher incidence of growth restriction, prematurity, perinatal asphyxia, and stillbirths. Neonatal thrombocytopenia also occurs in a few cases. Mortality is higher in preterm deliveries.

Red Flags

Large hepatic hematoma can even rupture and cause shock and death. Epigastric pain radiating to shoulder, transaminases >1,000 IU/L, presence of fever, and abdominal distension warrant imaging and prompt management.

Treatment

Management of HELLP is largely supportive. Careful observation of parameters and correction of anemia and coagulopathy is required. Antihypertensives to control blood pressure in women with preeclampsia are needed to prevent worsening. Delivery is the definitive therapy for HELLP. In mild cases, pregnancy may be continued with meticulous monitoring till reasonable fetal maturity is achieved. Corticosteroids for fetal lung maturation should be used in pregnancy <34 weeks of gestation. Those presenting early on with HELLP (<26 weeks of gestation) are advised termination. Prolonged conservative management may have poor fetal and maternal outcomes.

Large hepatic hematomas or those presenting with rupture and hemodynamic instability may need surgery or hepatic artery embolization for management. Liver transplant is a last resort in those who do not respond to standard management.

PLACENTA PREVIA

Placenta previa is placental implantation in the lower uterine segment. This may be near or even cover the internal cervical os. Placental location may change during pregnancy as the lower uterine segment grows in the latter half, and so the diagnosis. Moreover, lack of any defined landmark makes it even more challenging to correctly locate the placental edge which may vary falsely with the bladder filling. Placenta previa is defined using ultrasonography as a placenta developing within the lower uterine segment.

Classification

Conventionally, placenta previa has been graded according to the relationship between the lower placental edge and the internal os of the uterine cervix.

- *Grade I or minor previa*: Lower edge inside the lower uterine segment;
- *Grade II or marginal previa*: Lower edge reaching the internal os;
- *Grade III or partial previa*: Placenta partially covered the cervix;
- *Grade IV or complete previa*: Placenta completely covered the cervix.

Grades I and II are categorized as "minor" placenta previa whereas grades III and IV are "major" placenta previa.

A newer classification which is widely accepted now is as follows:

- *Placenta previa*—the internal os is covered partially or completely by placenta
- *Low-lying placenta*—implantation in the lower uterine segment and placental edge is <2 cm from the internal os
- *Partial previa*—placental edge reaches but does not cover the internal os
- *Total previa*—placenta covers the internal cervical os.

Partial and total previa are considered as major degrees of previa and a high cesarean section rate is associated with these.

Any class of placenta previa may change in labor with cervical dilatation due to relative change in relation of the placental edge with cervical margin.

Epidemiology

The incidence of placenta previa varies from 0.3 to 1 out of 300–400 births.

Etiology

There are many theories about development of placenta previa.

Dropping Down Theory

The fertilized ovum drops down in uterine cavity and is implanted in the lower segment. Poor decidual reaction in the upper uterine segment and failure of zona pellucida to disappear in time can be a possibility. Persistence of chorionic activity in the decidua capsularis and its subsequent development into placenta results in formation of lesser degrees of placenta previa. Defective decidua results in spreading of the chorionic villi over a wide area in the uterine wall to get nourishment which forms membranous placenta encroaching onto the lower segment, common with morbidly adherent placentas. Big surface area of the placenta as in multiple fetuses may encroach onto the lower segment. Placenta previa is associated with many risk factors (**Table 19**).

TABLE 19: Risk factors for placenta previa.

Advanced maternal age	Cigarette smoking
Increasing parity	Cocaine use
Multiple pregnancy	Endometritis
Previous placenta previa	Tumors of uterus distorting contour
Prior cesarean delivery	Assisted reproduction
History of uterine curettage	Short interpregnancy intervals

Clinical Presentation

Placenta previa may be asymptomatic and only an incidental finding on routine ultrasonography. In symptomatic patients, painless bleeding is the most characteristic event. Bleeding usually begins without warning or pain in a woman who has had an uneventful pregnancy course (sentinel bleed/warning hemorrhage) and rarely profuse. There is no associated pain unless labor starts simultaneously. There is no associated inciting factor such as fall, trauma, or coitus. Many cases present for first time in labor, more often with major degrees of previa, due to inevitable shearing of placenta as cervix dilates. Fetal distress is unusual unless the hemorrhage is severe enough to cause maternal hypovolemic shock. The first episodes with small bleeds occur < 30 weeks in a third of cases, between 30 and 35 weeks in another third and beyond 36 weeks in the remaining.

Red Flags

Presence of pain that is usually continuous, symptoms of pre-eclampsia such as raised blood pressure, headache, visual disturbances or epigastric pain, sudden decompression of an overdistended uterus as in hydramnios, history of hypertension, and thrombophilias, all may be suggestive of an ominous form of antepartum hemorrhage "placental abruption" where the separation of placenta occurs leading to hemorrhage.

In 10% cases, both these forms of antepartum hemorrhage may coexist.

Massive hemorrhage may cause exsanguination and present as hypovolemic shock which needs prompt management with resuscitation, blood transfusion, and termination of pregnancy even if the fetus is nonviable, which if not done, can even result in death of the pregnant woman.

Evaluation

History

Unprovoked, painless, apparently causeless, and recurrent bleeding usually points to the diagnosis of placenta previa. Establish the amount, color of bleed, and history of any precipitating factors. Obstetric history should be established regarding past pregnancies, previous cesarean sections, hemorrhage in previous pregnancies, gestational age at present, multiple fetuses, preeclampsia in current or previous pregnancies, and placental localization on ultrasonography. Enquire about any hypertensive disorders, thrombophilia, and uterine fibroids. Ask about perception of fetal movements as the fetus may be dead in case of heavy bleeding.

Physical Examination

A quick examination is done to assess the general condition of the woman. Shock with altered sensorium presents when bleeding has been heavy. The woman is pale and the pallor is usually proportionate to the amount of blood loss which should be estimated. Check for vitals, blood pressure, pulse rate, and temperature. Assess for need of blood transfusion. Start resuscitation simultaneously with intravenous fluid through two wide bore cannulas and draw blood for grouping and crossmatching and other investigations.

Systemic examination is done followed by obstetric examination. Abdominal examination is done to determine the size of uterus, contour, consistency, and presence of tenderness. Fetal presentation, uterine contractions, and presence of fetal heart sound are established. Vulval examination to assess any ongoing bleeding and a gentle speculum examination to rule out any local causes of bleeding are done. Per vaginal digital examination is best avoided for fear of torrential hemorrhage.

Interpretation of Findings

As the dictum goes, all cases of vaginal bleeding in late pregnancy are presumed to be placenta previa unless proven otherwise. Shock out of proportion suggests alternate diagnosis such as placental abruption or rupture uterus. Preeclampsia and hypertension, when present, may mask the shock and give a false impression of the amount of blood lost.

Uterus height corresponds to the period of gestation in previa, whereas, if more, may suggest concealed abruption. Uterus tone is increased in cases of placental abruption along with tenderness and fetal parts are felt with difficulty. Uterus may not be palpable in cases of rupture and fetal parts are superficially felt. Malpresentations with nonengagement of fetal head are common in cases of placenta previa. Fetal heart sounds may be absent in massive hemorrhage in previa or concealed abruption and rupture uterus. After initial resuscitation and stabilization of patient, investigations are done (**Table 20**).

Treatment

Antenatal care, including hospitalization, should be tailored to individual woman's needs and social circumstances depending on distance from hospital and availability of transportation, previous bleeding episodes, laboratory reports, and acceptance of receiving donor blood or blood products.

Women with *asymptomatic* placenta previa confirmed on ultrasound in late pregnancy and managed at home should be counseled about risks of obstetric hemorrhage, preterm delivery, and need access to the hospital in case bleeding starts.

Significance of "warning hemorrhage" should not be ignored. A course of antenatal corticosteroid therapy is recommended prior to 34 weeks of gestation in women at higher risk of preterm birth. Counseling should also include need for blood transfusion and need of intensive care monitoring. Delivery should be considered between 36 and 37 weeks of gestation. Prevention and treatment of anemia during the antenatal period is recommended for women with placenta previa or a low-lying placenta as for any pregnant woman. Minor degrees of placenta previa may have uneventful vaginal delivery but cesarean section in recommended for major previas.

Those who are *symptomatic* may be managed depending on whether the bleeding is continuing, amount of bleeding, and effects of bleeding on the woman.

TABLE 20: Investigations for placenta previa.

Full blood counts	Bleeding time and clotting time
Blood urea and serum creatinine	Clot retraction time
Blood sugars	PT and aPTT
Urine routine and microscopy	Fibrin degraded products
Liver function test	Kleihauer–Betke test in Rh negative
Ultrasonography for localization of placenta—transabdominal/transvaginal or transperineally	
Doppler or magnetic resonance imaging in cases with previous uterine scars to diagnose morbidly adherent placenta	

(aPTT: activated partial thromboplastin time; PT: prothrombin time)

Expectant Management

The aim is to continue pregnancy for fetal maturity without compromising the maternal health. Expectant management can be offered only if there is availability of blood transfusion and facilities for cesarean section round the clock.

The pregnant woman should be in good health (hemoglobin >10 g/dL; hematocrit >30%) and pregnancy <37 weeks with no ongoing vaginal bleeding. Fetal well-being muse be assured using cardiotocography and ultrasound. Routine assessment for blood loss and fetal surveillance is done. Hemoglobin is built up and the blood loss is replaced by adequate crossmatched blood transfusion. This is ideal in hospital setting but some prefer home care when there is compliance and weekly follow-up is possible. This can be continued up to 37 weeks of pregnancy when the fetal maturity is achieved. Expectant management is discontinued if there is recurrent/continuing brisk hemorrhage, fetus is dead or congenitally malformed on investigation, labor onset and where another cause of bleeding such as abruption is identified. Steroid therapy is indicated when the duration of pregnancy is <34 weeks.

Acute Management

Definitive management (delivery) is done if patient is in exsanguinated state on presentation, bleeding occurs ≥37 weeks of pregnancy, onset of labor, there is continuing moderate bleeding, fetal distress or fetal death/congenital malformation incompatible with life, and any obstetric indication where vaginal delivery is contraindicated.

Initial resuscitation with intravenous fluids and blood transfusion is done. Clinical assessment is important to decide the mode of delivery. Cesarean delivery is preferred for all women with major degrees of placenta previa, in women with profuse bleeding, or obstetric contraindication for vaginal birth.

Vaginal delivery may be considered where placenta edge is clearly away from the internal cervical os on sonography after vaginal examination in a double setup arrangement in the operation theater prepared for cesarean section. Should vaginal delivery be considered safe, artificial rupture of membranes with oxytocin augmentation is done with careful watch for bleeding and vitals.

For cesarean section, informed consent is taken for surgery and performed in presence of a senior obstetrician and senior anesthetist. Uterine incision should be decided depending on placental localization or presence of adherent placenta. Elective sections are associated with better maternal and perinatal outcomes and are preferred. Regional anesthesia is considered safe and is associated with lower risks of hemorrhage than general anesthesia for cesarean delivery in women with placenta previa or a low-lying placenta. Blood loss should be assessed and crossmatched for possible transfusion.

Hysterectomy may be done as a life-saving procedure in some cases.

Complications

Morbidly adherent placentas are serious complication associated with placenta previa. Venous thromboembolism is associated with prolonged inpatient care. Other complications include malpresentations, intrapartum and postpartum hemorrhage, preterm labor, and sepsis. Coagulation defects are rare complications of placenta previa. Fetal hemorrhage, low birth weight, prematurity, intrauterine asphyxia, or birth injury.

PRELABOR RUPTURE OF MEMBRANES

"Prelabor rupture of membranes" (PROM) is the rupture of the fetal membranes before onset of labor. This is classified further depending on duration of pregnancy as: *Preterm prelabor rupture of membranes (PPROM)*—before 37 completed weeks and before onset of labor, *term prelabor rupture of membranes (term PROM*)—after 37 completed weeks but before onset of labor, and *previable prelabor rupture of membranes (previable PROM)*—rupture of membranes before onset of labor and before period of viability (23 weeks completed). PROM complicates nearly 10% of all pregnancies. Approximately two-thirds of the patients with PROM are deliver within the next 4 days and the rest within 1 week. An estimated 80% of term PROM begin labor within 24 hours and nearly 95% within 72 hours. Though the exact etiology can be a combination of various factors, following are the risk factors associated with PROM (**Table 21**).

Pathophysiology

Prelabor rupture of membranes may occur because of an alteration in structure or tensile strength of membranes or an alteration in the biochemical milieu of the membranes although the exact pathogenesis is still unclear. The amniotic membranes are a connective tissue structure and their tensile strength depends on the composition, degradation, and quality of their collagen, which increases until 20 weeks and then plateaus until week 39 when it starts to dramatically decrease. Incidence is high in women with connective tissue disorders, tobacco smoking, nutritional deficiencies, and intra-amniotic. Prostaglandins, glucocorticoids, and relaxin hormone facilitate rupture of the membranes.

TABLE 21: Risk factors of prelabor rupture of membranes (PROM).

Maternal factors	Maternal smoking, caffeine intake, and low socioeconomic status
Nutrition	Deficiency of copper/vitamin C, and low body mass index
Immunological	Collagen vascular disorders
Infectious	Vaginal colonization by *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and group B streptococci
Previous pregnancy	History of preterm delivery or PROM
Present pregnancy	Vaginal bleeding in the first and second trimesters, short cervix (<2.5 cm) on ultrasonography, positive fetal fibronectin in cervicovaginal fluid

Clinical Presentation

The characteristic presentation is complaint of watery discharge per vagina which may be continuous or intermittent. There is no associated pain, fever, itching, or odor associated with the discharge.

Red Flags

Prolonged rupture of membranes can lead to ascending infection in the uterus and development of chorioamnionitis (**Table 22**). This requires early delivery to prevent development of maternal and fetal sepsis. This may present with a nonreactive fetal cardiotocography and absence of fetal breathing movements.

Evaluation

History

History should include duration of leaking, type of discharge, associated foul smell, fever, abdominal pain, and presence of infection elsewhere. One must also confirm the duration of pregnancy by dates and early scans. Enquire about fetal well-being and perception of movements. Ask regarding previous preterm births or premature membrane rupture in a prior pregnancy. Presence of any chronic illness or connective tissue disorders should be ruled out.

Physical Examination

A general physical examination is to be done with recording of blood pressure, pulse rate, temperature, and respiratory rate. A systemic examination should be done. Obstetric examination should include abdominal examination to confirm the uterus size, presentation and lie, presence of uterine contractions, and assess for any tenderness. Fetal heart rate auscultation is to be done. A vaginal speculum examination is done to confirm the diagnosis and to assess the characteristics of the fluid. Digital vaginal examination should be avoided unless the woman is in labor.

Interpretation of Findings

Presence of watery discharge through cervical os is characteristic. Fever, tachycardia, uterine tenderness, and foul-smelling discharge are suggestive of chorioamnionitis.

TABLE 22: Clinical features of chorioamnionitis.

Fever (>100°F)	Fetal tachycardia >160 bpm
Maternal tachycardia >100/min	Uterine tenderness
Foul odor of the amniotic fluid	Nonreactive fetal cardiotocography
Laboratory features of chorioamnionitis	
Maternal leukocytosis >15,000	C-reactive protein >2.7 mg/dL
High vaginal swab may show microbial growth	Ultrasonography may suggest absent fetal breathing movements

Investigations

Other than routine antenatal investigations, some specific tests may be done in cases of PROM—full blood count (including total and differential leukocyte count), C-reactive protein, and high vaginal swab for culture. Ultrasonography for fetal well-being may also show reduced amniotic fluid measurement which is suggestive but not diagnostic of PROM.

Some laboratory tests are available to diagnose PROM which include placental alpha macroglobulin-1 (PAMG-1), insulin-like growth factor binding protein-1 (IGFBP-1), and pH of amniotic fluid to help diagnose PROM and are helpful but not easily available.

Treatment

Essentially involves inpatient management. After assessment of fetal well-being and ruling out infection, further management includes antibiotics, corticosteroids for fetal lung maturity, monitoring for features of chorioamnionitis and other possible complications, and, delivery if indicated. Decision to deliver will depend upon gestational age, presence of infection, uterine contractions, fetal well-being, lung maturity, and availability of facility for newborn care.

Antibiotics

Erythromycin 250 mg 6 hourly for 10 days or earlier if labor onset or intravenous ampicillin followed by oral amoxicillin or erythromycin is recommended for prevention of infection.

Corticosteroids

The predominant risks for patients with PROM between 24 and 34 weeks are respiratory distress/hyaline membrane disease, sepsis, and intraventricular hemorrhage. Administration of glucocorticoids is beneficial if there is no clinical or subclinical chorioamnionitis.

Neuroprophylaxis

Magnesium sulfate should be given for neuroprophylaxis in PROM before 32 weeks of pregnancy, given up to 24 hours.

Tocolysis

Tocolytic agents do not significantly prolong the latency period in patients with PROM, may be useful in patients with contractions at the time of admission who may deliver before receiving the benefit of glucocorticoid treatment.

For patients with PROM before 34 completed weeks, management should be expectant unless an indication for delivery is present. The risk of expectancy is infection, but in the majority of cases infection is diagnosed early and has no serious effects on mother or fetus.

Those women who present beyond 34 weeks need to be evaluated and management has to be individualized depending upon the fetomaternal condition and presence of infection or risk factors. Termination has to be done at 37 completed weeks.

When PROM presents after 24 weeks, expectant management should be offered.

Expectant management will include the above and daily maternal and fetal monitoring. Investigations should be done biweekly to diagnose infection and include leukocyte counts, C-reactive protein, and vaginal swabs weekly.

Contraindications for expectant management are chorioamnionitis, abruptio placenta, labor onset, and fetal distress.

Delivery

In most cases of PROM, labor tends to begin spontaneously in a few hours to days. Tocolysis should be given and labor augmentation avoided in preterm PROM to give the room for steroid cover. In case of PROM, or preterm PROM where membrane rupture has been for a long duration and corticosteroid coverage has been done, or preterm RPOM crossed 34 completed weeks, vaginal delivery can be achieved by induction with oxytocin or prostaglandins. Cesarean section should be reserved for obstetric indications such as fetal distress or malpresentations. Antibiotic coverage should be done with observation for signs of chorioamnionitis. For cases of previable PROM, counseling regarding the prognosis is important. Induction of labor can be done if the woman is well counseled and desires so. If the woman opts for expectant management, antibiotics should be given while watching for chorioamnionitis and steroids can be given once the pregnancy crosses period of viability. It is important to counsel that two-thirds will deliver within 1 week of PROM and survival rate of extremely premature babies is extremely poor (**Table 23**).

PRETERM LABOR

Preterm labor is presence of uterine contractions of sufficient intensity and frequency to bring about changes in the uterine cervix (dilatation and effacement) before 37 completed weeks of pregnancy and after the period of viability. "Suspected preterm labor" is when there are signs and symptoms of possible preterm labor but labor has not established yet. "Diagnosed preterm labor" is suspected preterm labor with a diagnostic test positive for preterm labor. "Established preterm labor" is when cervical dilatation is ≥4 cm with regular uterine contractions. The prevalence widely varies and ranges between 10% and 15% and contributes majorly to perinatal morbidity and mortality. Many factors contribute to development of preterm labor (**Table 24**).

TABLE 23: Complications of prelabor rupture of membranes (PROM).

Maternal complications	*Fetal complications*
Chorioamnionitis	Preterm labor and prematurity
Abruptio placenta	Pulmonary hypoplasia
Cesarean section due to malpresentations/cord prolapse	Intraventricular hemorrhage and cerebral palsy
Postpartum endometritis	Neonatal sepsis
Maternal sepsis	Fetal skeletal malformation
Retained placenta	Risk of trauma due to operative interference
Rarely maternal death	Death due to prematurity, sepsis, and cord prolapse

Pathophysiology

The components contributing to preterm labor are cervical changes, activation of the decidual membranes, and uterine contractions. The whole process may progress rapidly or develop over weeks. Cervical changes are evident as effacement of the cervix and membrane activation results in the presence of fetal fibronectin in the cervicovaginal secretions (**Fig. 1**).

Clinical Presentation

Women who develop preterm labor may have some nonspecific warning features a few days prior to onset of labor. Clinically, preterm labor is the occurrence of regular uterine contractions (≥4 in 20 minutes or ≥8 in 1 hour) and cervical changes (effacement ≥80% and dilatation ≥1 cm) in women with intact fetal membranes and gestational age <37 weeks.

Threatened preterm labor is characterized by regular and frequent (10/hour) uterine contractions, cervical dilatation <1 cm, and short cervix (<2.5 mm) by transvaginal ultrasound examination.

TABLE 24: Etiology of preterm labor.

Maternal factors	• Stress, smoking, substance and alcohol abuse, maternal age <18 or >40, low body mass index, low prepregnancy weight, poor nutrition, and low socioeconomic status • Medical and surgical illness such as acute fever, acute pyelonephritis, diarrhea, and acute appendicitis • Chronic diseases such as hypertension, nephritis, diabetes, decompensated heart lesion, and severe anemia • Genital tract infection such as bacterial vaginosis, beta-hemolytic *Streptococcus*, *Bacteroides*, *Chlamydia*, *and Mycoplasma*
Past pregnancy related	Previous preterm labor, cervical incompetence, cervical surgeries, multiple induced second trimester abortions, uterine anomalies, and multiple pregnancies
Present pregnancy	Multiple gestation, antepartum hemorrhage, premature rupture of the membranes, chorioamnionitis, polyhydramnios, inadequate prenatal care, and extrauterine infections

Red Flags

Chorioamnionitis, as a result of prolonged membrane rupture or itself a cause of preterm labor, may present with fever >100.4°F, tachycardia, foul-smelling discharge, uterine tenderness, fetal tachycardia (>160/min), increases C-reactive protein and leukocytosis, and may need augmentation of labor (**Table 25**). Presence of massive placental abruption also may need augmentation if coexistent with preterm labor. Medical conditions such as uncontrolled diabetes may also be a contraindication to arrest preterm labor.

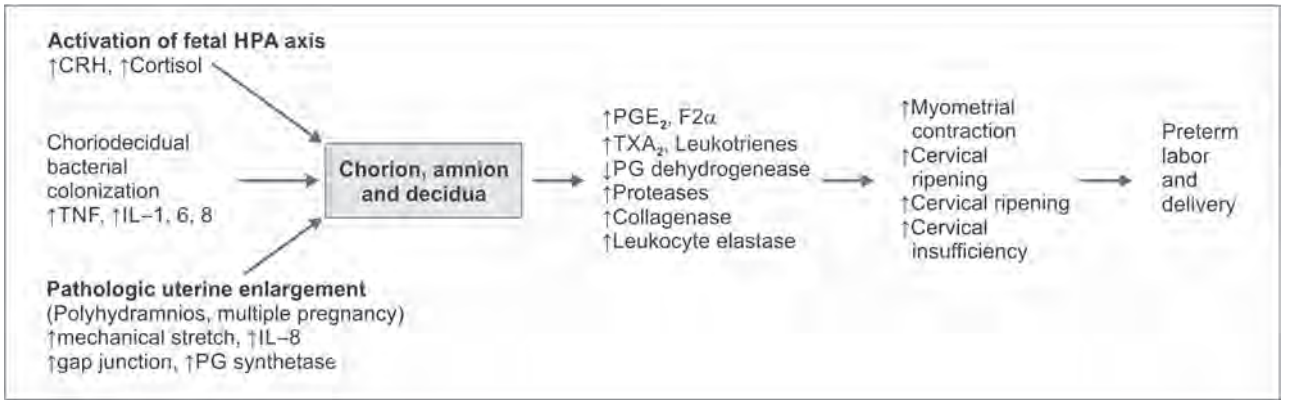
Evaluation

History

Ask regarding onset and progress of pain, duration and frequency of contractions, heaviness or dragging sensation, perception of fetal movements, complaints of discharge or leaking per vagina, and fever. Confirm the duration of pregnancy by dates and early scans. Ask about previous pregnancies and whether there has been any previous preterm delivery. Enquire about any chronic illnesses and previous surgeries, especially cervical procedures such as conization, cervical amputation, large loop excision of transformation zone (LLETZ), or previous cervical cerclage. Personal history of smoking, substance abuse, and physical abuse should be elicited.

TABLE 25: Red flags of preterm labor.

Warning symptoms	***Warning signs***
Lower abdominal cramps	Uterine contractions
Low and dull backache	Leaking per vagina
Pressure/heaviness	Shortening of cervix
Increase/change in vaginal discharge	Thinning/effacement of lower uterine segment
Abdominal cramps	Engagement of presenting part



(CRH: corticotropin-releasing hormone; HPA: hypothalamic–pituitary–adrenal; IL: interleukin; PG: prostaglandin; PGE_2: prostaglandin E_2; TNF: tumor necrosis factor; TXA_2: thromboxane A_2)

FIG. 1: Etiopathogenesis of preterm labor.

Physical Examination

A quick and thorough general examination is done with assessment of vitals followed by systemic examination. Obstetric assessment is done to ascertain the uterine fundal height which should correspond to the gestational age of pregnancy, fetal lie and presentation, uterine contractions and fetal heart sound. Vaginal examination is done to assess the status of membranes, cervical dilatation, and effacement.

Interpretation of Findings

Presence of regular uterine contractions and cervical dilatation and thinning are suggestive of labor.

Prediction of Preterm Labor

Some clinical, biochemical, and radiological investigations are used to identify high risk of preterm birth (**Table 26**).

Investigations

Other than routine investigations in pregnancy, some specific investigations may be required in cases of preterm labor (**Table 27**).

Management

The management includes: (1) To prevent preterm onset of labor, if possible; (2) To arrest preterm labor, if not contraindicated; (3) Appropriate management of labor; and (4) Effective neonatal care.

Bed rest is advisable to prevent premature rupture of membrane. Delivery by lower segment cesarean section (LSCS) does not prevent periventricular-intraventricular hemorrhage compared with vaginal birth. Intensive clinical monitoring with continuous cardiotocography (CTG) is ideal. Repeated digital examinations should be avoided to prevent infection.

TABLE 26: Prediction of preterm labor.

Fetal fibronectin	Swabs from cervicovaginal secretions tested for fetal fibronectin between 24 and 37 weeks, if positive, predict preterm labor in next 2–3 weeks
Salivary estradiol levels	Increases levels of salivary estradiol can predict preterm labor
Cervical length measurement by transvaginal scan	Short cervical length <25 mm can predict preterm labor risk

TABLE 27: Investigations for preterm labor.

Full blood count	Cardiotocography for fetal heart rate
Urine routine microscopy	Ultrasonography for fetal well-being
High vaginal swab for culture	Cervical length estimation
Vaginal fluid pH	C-reactive protein

Corticosteroids

Steroid administration reduces the incidence and severity of respiratory distress syndrome and hence, neonatal morbidity and mortality. Recommended corticosteroids are injection betamethasone 12 mg, two doses 24 hours apart or injection dexamethasone 6 mg, four doses 12 hours apart. Delivery should be delayed using tocolysis for minimum 12 hours for maximum effect of steroid, although optimal benefit begins 24 hours after therapy and lasts for 7 days, but first dose should be administered irrespective of possibility of administration of a second dose. Single course of steroids is recommended.

Tocolytic Agents

These are used to delay delivery to achieve lung maturity or facilitate transfer to another facility, but maintenance tocolysis is not recommended in routine practice. Commonly used ones are presented in **Table 28**. Before starting tocolytic agent one should rule out any contraindication to tocolytic therapy (**Table 29**).

Antibiotics

In case of preterm labor, antibiotics are recommended when there is associated rupture of membranes (prevention of group B *Streptococcus* infection in fetus). Erythromycin 250 mg every 6 hours is preferred for maximum of 10 days or till labor sets in. Those allergic to erythromycin may be given oral penicillin. 5–10% of patients in preterm labor may have infection outside uterus, mostly in the urinary tract and they should be treated by appropriate antibiotics.

Rescue Cervical Cerclage

It is a surgical procedure where stitch is applied to the cervix in women with cervical dilatation with unruptured membranes to prevent preterm births. There should not be any uterine contractions, bleeding, infection, and fetus should be viable.

Prophylactic Vaginal Progesterone and Cervical Cerclage

Prophylactic vaginal progesterone can be offered to women diagnosed as having short cervical length on ultrasound but no history of preterm births. Cervical cerclage is offered to women with cervical length is ≤25 mm on transvaginal sonography and are at risk of preterm birth (previous history of preterm birth, uterine anomalies, and symptomatic).

Management of Preterm Labor

- Bed rest advisable to prevent rupture of membranes
- Strong sedatives avoided
- Repeat vaginal examinations to be avoided
- Ideally continuous fetal heart tracing
- Fetal scalp electrodes should be avoided
- Delivery preferably in a hospital with specialized neonatal unit in presence of senior obstetrician and pediatrician
- Episiotomy should be considered to minimize head compression
- Prophylactic forceps should not be used
- Cord clamping to be done early if resuscitation is needed or may be delayed for up to 3 minutes

TABLE 28: Commonly used tocolytic drugs.

Drug	*Dosage*	*Comments/side effects*
Nifedipine (calcium channel blocker)	• 20–30 mg orally stat followed by same dose after 30 minutes, if contractions persist • Maintenance 10–20 mg 6 hourly for 48–72 hours (maximum 160 mg/24 hours)	Contraindicated in maternal heart disease and hypotension; stop if pulse rate >120/min, blood pressure <100/60 mm Hg or SpO_2 <95%
Terbutaline (β agonist)	0.25 mg subcutaneous (S/C) every 20 minutes to 3 hours	Tachycardia, chest pain, palpitations, and headache
Isoxsuprine (β agonist)	• 4 ampules (40 mg) in 500 mL of 5% dextrose 0.2–0.5 mg/min intravenous (IV) over 10 hours • Maintenance 0.1–0.3 mg/min IV over 12 hours	Tachycardia, chest pain, palpitations, and headache
Magnesium sulfate	• 4–6 g IV over 20 minutes followed by 2–3 g/hour as continuous infusion for 24 hours/delivery • Neuroprotective at <32 weeks	Monitor with urine output, respiratory rate, and deep tendon reflexes
Atosiban (oxytocin receptor antagonist)	• 6.75 mg intravenously stat over 1 minute followed by infusion of 18 mg/hour for 3 hours and then 6 mg/hour for up to 45 hours • Maximum duration 48 hours and maximum dose 330 mg	Chest pain, palpitations, tachycardia, hypotension, dyspnea, nausea, vomiting, and headache

TABLE 29: Contraindications of tocolytic therapy.

Advanced labor (cervix >4 cm dilated)	Fetal demise
Abruptio/placenta previa	Fetal maturity >34 weeks
Features of chorioamnionitis	Acute fetal distress
Severe preeclampsia and eclampsia	Congenital malformations
Severe anemia	Hyperthyroidism

TABLE 30: Neonatal complications in preterm babies.

Respiratory system	Hyaline membrane disease and apnea of prematurity
Central nervous system	Intraventricular hemorrhage and hypoxic–ischemic encephalopathy
Biochemical changes	Hypoglycemia, hypocalcemia, and hypomagnesemia
Cardiovascular system	Patent ductus arteriosus
Hepatobiliary system	Jaundice and necrotizing enterocolitis
Ocular	Retinopathy of prematurity
Systemic complications	Hypothermia, septicemia, hypoxia, and acidosis

Neonatal Complications in Preterm Babies

Preterm neonates are predisposed to many complications and need intensive monitoring (**Table 30**). Particularly important are hyaline membrane disease due to lung immaturity and septicemia. The neonate may need intensive care with ventilatory support, oxygen, and surfactant therapy. Prevention of sepsis, acidosis, and electrolyte imbalance should be practiced to prevent morbidity.

Prevention

Primary care is aimed at reducing the incidence of preterm labor by treating the high-risk factors. Secondary care includes screening tests for early detection and prophylactic treatment (tocolytics and cervical cerclage in women with short cervix). Tertiary care is aimed to reduce the perinatal morbidity and mortality after the diagnosis (use of corticosteroids/surfactant therapy).

SUMMARY

Obstetric emergencies can arise at any point in time and it is important to diagnose the condition and institute prompt treatment as needed. The early half of pregnancy can have complications related to miscarriages or infection arising as a result of unsafe abortions. Nearly 10 lakh abortions are carried out in India annually and almost 10 women die per day due to related complications. Diagnosis of abortion and treatment of related complications is thus, of utmost importance. Since the patient is first attended by the emergency physician, it is imperative that early pregnancy complications be addressed. Pregnancy is often missed or overlooked so it is advisable to ask regarding the last menstrual period in a woman of reproductive age group and carry out a urine pregnancy test whenever in doubt. Liaising with the on-call gynecologist can be helpful.

157 CHAPTER

Comorbid Conditions and Pregnancy

Laxman Bhusal, Rabin Bom

INTRODUCTION

Many medical conditions can present in pregnancy, either as a preexisting condition or arising during pregnancy. As a result of the complex interactions between the mother, fetus, disease, and the treatment many medical problems become complicated. Chronic medical conditions if not managed well pose a serious threat to the mother's health and poor fetal outcome. The mother is the first priority in any medical emergency since the fetus is dependent on her for physiologic support. Complex demography and lifestyle factors are responsible for increasing prevalence of medical problems in pregnancy. Older women are more likely to have acquired medical disorders. Medical conditions are the leading causes of maternal death. The physiologic changes occur in pregnancy makes symptom onset or rapid decompensation of previously present medical illness during pregnancy. Certain chronic medical condition poses a serious threat to the mother health or result in a poor fetal outcome. The incidence of pregnancy with chronic disease is increasing day by day. The following medical conditions pose a serious threat to both mother and fetal outcome (**Table 1**).

DIABETES

Diabetics cause various complications in pregnancy and also give rise to acute complications of diabetes. The incidence of diabetes with pregnancy is increasing day by day. Three-fourths of pregnant patients with diabetes have either gestational diabetes or type 2 diabetes mellitus (T2DM) diagnosed through prenatal screening. Of the remaining 25%, 1% has preexisting type 1 diabetes mellitus (T1DM) and the remaining are T2DM patients. Pregnant diabetes women are at increased risk for spontaneous abortion, particularly patients with poor glycemic control in pregnancy, preexisting vascular disease, and preeclampsia. Preexisting diabetes and gestational diabetes are at increased risk for complication during pregnancy. The common complications occurring because of diabetes in pregnancy are: Pregnancy-induced hypertension (PIH), preterm labor, spontaneous abortion, pyelonephritis, and diabetic ketoacidosis (DKA). The American College of Obstetrician and Gynecologists recommends the following goals for maintaining euglycemia in pregnant diabetic patients: A fasting blood glucose concentration of <95 mg/dL and a 2-hour postprandial glucose concentration <120 mg/dL. Initial stage of gestational diabetes can be managed with diet and if it is high then there is need of oral hypoglycemic drugs like metformin. Insulin therapy is necessary for some patients with gestational diabetes and for preexisting diabetes. Among patients with preexisting T1DM and T2DM patients, the need for insulin increases throughout the courses of pregnancy. Usually all T2DM patients are switched to insulin as soon as possible to ensure appropriate glycemic control. There are concerns over the safety of oral hypoglycemic agent in pregnancy. In general, during the first trimester, the initial insulin requirement is 0.7 units/kg/day. By late pregnancy, patients generally require 1 unit/kg/day. Neutral Protamine Hagedorn (NPH)/regular insulin combination are still first-line insulin therapy.

Pregnant patients are at increased risk of DKA, and DKA can occur more rapidly, and at lower glucose levels, than in nonpregnant patients. DKA should be considered for any pregnant diabetic patient who is ill appearing and/or has a blood glucose level ≥180 mg/dL. Treatment of DKA in pregnancy includes supplemental oxygen, left lateral decubitus positioning, and usual DKA care: Isotonic fluid resuscitation to correct volume deficits, administration of continuous insulin, correction of electrolyte abnormalities, and treatment of the underlying cause.

Mild hypoglycemia (glucose <70 mg/dL and able to follow commands) is treated with some oral feed. Severe hypoglycemia (glucose <70 mg/dL with unable to follow command) should

TABLE 1: Comorbid conditions of concern during pregnancy.

Endocrine	• Diabetes • Thyroid diseases
Cardiovascular	• Chronic hypertension • Gestational hypertension • Peripartum cardiomyopathy • Thromboembolism
Central nervous	Epilepsy
Respiratory	Asthma

be treated with 50 mL of 50% dextrose in water intravenous (IV), with 1–2 mg of glucagon given intramuscular (IM), or subcutaneous if IV access is delayed. Subsequently, the patient should be given 5% dextrose solution IV at 50–100 mL/h.

THYROID DISEASES

Hyperthyroidism

Hyperthyroidism in pregnancy increases the risk of preeclampsia, congenital anomalies, and neonatal morbidity. Treatment is with propylthiouracil (PTU). Patients on PTU are at risk for purpuric rash and agranulocytosis. Thyroid storm can presents with fever, volume depletion, or cardiac decompensation manifesting as high-output heart failure.

Hypothyroidism

The most common cause of hypothyroidism worldwide is iodide deficiency. In iodine-replete areas, the most common cause is postautoimmune thyroiditis, such as Hashimoto's thyroiditis. Overt hypothyroidism is often associated with infertility, so most cases seen during pregnancy are less severe. When signs and symptoms do occur, they are generally the same as those in the nonpregnant state. Myxedema coma is extremely rare, but should be considered along with other causes of coma in a pregnant patient. There is an increased incidence of adverse maternal and fetal effects such as preeclampsia, placental abruption, low birth weight, and an increased risk of stillbirth in women with clinical hypothyroidism. Postpartum thyroiditis is characterized by transient hyperthyroidism and/or hypothyroidism in the postpartum period. The diagnosis of hypothyroidism during pregnancy should be suspected when the patient exhibits edema, dry skin, hair loss, and a prolonged relaxation phase of deep tendon reflexes. Confirmation of hypothyroidism is based on an elevated serum thyroid-stimulating hormone (TSH) level, relying on trimester-specific TSH reference ranges.

CARDIOVASCULAR DISEASES

Hypertensive disorder is the most frequent cardiovascular events occurring in 6–8% of pregnancies. Older pregnant women experience an increased rate of antepartum and intrapartum complication mainly in comorbid with cardiovascular diseases. Cardiac disease in pregnant women can be worsened in pregnancy due to increase in blood volume, along with the increases in preload, cardiac output, and oxygen consumption.

Chronic Hypertension and Hypertensive Emergencies

Hypertension is the most common medical problem in pregnancy occurring in 6–8% of pregnancies. In normal pregnancy, blood pressure falls by around 10 mm Hg in the first half of pregnancy, and then gradually returns to prepregnancy levels by term. High blood pressure in pregnancy can be in two forms. It may be a preexisting hypertension called chronic hypertension or it can develop during pregnancy as PIH. Treatment is often considered for chronic hypertension if blood pressure >140/90 mm Hg measured on two occasion before 20 weeks of gestation. Chronic hypertension is associated with adverse perinatal outcome including preeclampsia, intrauterine growth restriction (IUGR), and placental abruption. The severity of maternal blood pressure at 20 weeks is associated with worse outcome. Treatment of mild-to-moderate chronic hypertension in pregnancy has no proven fetal benefit. Excessively lowering of the blood pressure is not recommended because it causes adverse perinatal outcome due to decreased placental perfusion. Pharmacological treatment is indicated if blood pressure is persistently >150–160/100–110 mm Hg in order to prevent maternal end-organ damage.

Chronic hypertension during pregnancy is usually treated with labetalol, nifedipine, or methyldopa. Drugs such as angiotensin receptor blockers and angiotensin-converting enzyme (ACE) inhibitors are avoided. The β-blocker atenolol has been associated with IUGR. Thiazide diuretics can exacerbate the intravascular fluid depletion of preeclampsia so in such case it should be discontinued.

Gestational Hypertension

Gestational hypertension is a provisional diagnosis used for a heterogenous group of women including: (1) Those that will eventually develop proteinuria during the pregnancy and be diagnosed with preeclampsia, (2) Those who will have persistent hypertension after 12 weeks postpartum and be diagnosed with chronic hypertension, and (3) Those who do not develop preeclampsia and whose blood pressures normalize postpartum.

Preeclampsia is associated with increased risk of developing new onset hypertension, coronary artery disease, cerebrovascular disease, and chronic kidney disease. If preeclampsia develops before 34 weeks, the risk is increased up to eightfold. If pharmacological treatment is required, labetalol (nonselective α- and β-blocker) or modified-release nifedipine (calcium channel blocker) are the first-line drugs in pregnancy. Methyldopa and amlodipine are second-line options. Drugs such as ACE inhibitors, angiotensin II receptor blockers, and spironolactone are contraindicated in pregnancy and during preconception should be switched to an alternative agent. However, ACE inhibitors can be reintroduced postpartum and are safe when breastfeeding.

Peripartum Cardiomyopathy

The incidence of peripartum cardiomyopathy (PPCM) is between 1 in 3,000 and 4,000 births. Mortality of PPCM is high from 5 to 20%. By definition, PPCM is heart failure developing in the last month of pregnancy or within 5 months of delivery in a woman without another identifiable cause of the heart failure. The etiology of PPCM remains unknown but evidence points to myocarditis, perhaps due to a weakened immune response to viral infection of the myocardium. Initial diagnosis may be delayed because the sign and symptoms of systolic dysfunction including dyspnea, fatigue, tachypnea, and lower extremity edema are common in the last month of pregnancy and immediate postpartum period. Standard congestive heart failure treatment (includes ACE inhibitors) is contraindicated in pregnancy and excess diuresis (risk of uteroplacental insufficiency) should be avoided in pregnancy. Future pregnancies are at risk for recurrent and life-threatening

PPCM. Women whose cardiac function does not recover fully should be discouraged from conceiving again.

Thromboembolism

Deep venous thrombosis (DVT) and pulmonary embolism (PE) are the common diseases causing maternal morbidity and mortality. Venous thromboembolism (VTE) refers to both DVT, a blood clot in the venous system of the lower extremities, and PE, a clot that breaks loose and lodge in the pulmonary arteries. Advance maternal age, increasing parity, multiple gestation, operative delivery, prolong bed rest, and obesity are the risk factors to thromboembolism during pregnancy. The relative risk of VTE in pregnancy is increased fourfold to sixfold compared with the general population. Cesarean section further increases this risk. DVT and PE are treated with unfractionated or low molecular weight heparin at usual doses. Warfarin is contraindicated during pregnancy as should direct oral anticoagulant such as rivaroxaban. Thrombolysis is considered in massive life-threatening PE; however, pregnancy is not a contraindication to thrombolysis.

Valvular Heart Disease and Pregnancy

Mitral stenosis and regurgitation followed by aortic valve disease are the common valvular comorbid conditions associated with pregnancy. Effects of coexisting valvular disease on pregnancy depend on the type and severity of the valvular lesions. Mild-to-moderate valvular lesions with the New York Heart Association (NYHA) Class I/II are generally associated with good outcome for mother and fetus. Advanced valvular lesions such as mitral stenosis (NYHA more than class I) and severe aortic stenosis are associated with ventricular dysfunction and pulmonary hypertension (**Table 2**). Significant maternal mortality is observed in patient with prosthetic valve and on anticoagulants. Expert cardiologist consultation and directed therapy required in valvular heart disease and pregnancy.

TABLE 2: Risk stratification in pregnant women with valvular heart disease.

Low risk	• Aortic stenosis with EF > 50% mean gradient <25 asymptomatic • Aortic or mitral regurgitation asymptomatic or mild symptoms • Mitral valve prolapses EF > 50% with mild/moderate regurgitation • Mild/moderate stenosis without severe pulmonary stenosis • Mild-to-moderate pulmonary stenosis
High risk	• Symptomatic mitral stenosis NYHA Class II–IV • Severe aortic stenosis (irrespective of symptoms) • Mitral/aortic regurgitation NYHA Class III–IV • Severe LV dysfunctions <40% • Severe pulmonary hypertension • Mechanical prosthetic valve

(EF: ejection fraction; LV: left ventricular; NYHA: New York Heart Association)

ASTHMA

Asthma is one of the most common chronic medical problems in pregnancy, with a prevalence of between 3.7 and 9.4 %. Maternal asthma is associated with an increased risk of preeclampsia or eclampsia, premature contractions, cesarean section, low birth weight, and small for gestational age status. Maternal respiratory function changes can make it more difficult to recognize the decompensating pregnant asthmatic patient. During the course of pregnancy, tidal volume, and minute ventilation increase by 45% resulting in an average partial pressure of carbon dioxide (pCO_2) of 32 mm Hg. The kidneys compensate and maintain an average bicarbonate level of 19 mEq/mL, which results in a compensated respiratory alkalosis with a serum pH between 7.40 and 7.45. Many adverse perinatal outcomes caused by asthma are thought to be due to fetal hypoxia. Both the American College of Obstetrics and Gynecology (ACOG) and National Asthma Education and Prevention Program have clearly stated that it is safer to use asthma medications to treat pregnant women than to allow severe asthma symptoms and exacerbations to occur during pregnancy. Acute asthma presents with cough, wheezing, and dyspnea. The standard treatment for a pregnant asthmatic patient is the same as that for a nonpregnant patient with an asthma exacerbation. Supplemental oxygen should be given to all mothers with oxygen saturation below 95%. Inhaled short-acting β2-agonists are the first-line treatment for an asthma exacerbation and can be given continuously, if needed, for a severe exacerbation. Long-acting selective β2-agonists and inhaled corticosteroids, with budesonide being the preferred agent, can be added as controller medications on discharge from the ED. Nonselective β-agonists such as epinephrine are generally avoided because of concern for their effect on placental blood flow. Terbutaline sulfate 0.25 mg subcutaneous can also be used when not better with above treatment. Second-line agents for asthma control (e.g., cromolyn sodium) are considered safe in pregnancy. Magnesium has been shown to improve respiratory function in pregnant females with severe asthma exacerbations without adverse fetal outcomes.

EPILEPSY

Management of epilepsy in pregnancy has two main aspects. First, epilepsy may have adverse outcome on pregnancy (and vice versa); secondly, antiepileptic drugs (AEDs) exposure may adversely affect the fetus as well. Maternal mortality is 10-fold higher in patients with epilepsy than in those without the disorder. Epilepsy is also associated with an increased risk of obstetric hemorrhage, hypertensive disorders of pregnancy, and fetal growth restriction. Hepatic and renal clearance of many drugs is increased in pregnancy. Lamotrigine, in particular, may require significant dose increases in pregnancy. All AEDs are teratogenic but the risks of uncontrolled epilepsy almost always outweigh the risks to the fetus posed by these medications. Sodium valproate should be switched to an alternative drug preconception because sodium valproate carries the highest risk of fetal malformations. Even if alternate antiepileptics are used through pregnancy, careful monitoring and counseling are required to communicate the benefits and risks to the mother.

SUMMARY

Maternal mortality and morbidity resulting from treatable medical conditions is increasing day by day, despite a marked decrease in overall maternal mortality. Preconception counseling is the most important part to explain them about the continuation of the same medication or to change in medication with risk benefit background. Prompt recognition of acute illness and optimal treatment of chronic conditions is of clear benefit, and most drugs and many radiological investigations can be used in pregnancy to manage medical conditions in pregnancy.

158
CHAPTER

Emergency Delivery

Sangeeta Kaushik Sharma

INTRODUCTION

Emergency department (ED) is challenging and dynamic place where time bound emergencies are imminent. The management of childbirth is usually the responsibility of obstetricians and is not always available in-house in most of EDs, as they need to be called from outpatient department (OPD) or operation theater (OT) in daytime and from their home in nighttime. So, emergency physician should be prepared of managing obstetric emergencies and procedures of labor and basic steps of parturition, if situation occurs. Apart from this, emergency physician should be aware of various possible complications during labor such as malpresentation, shoulder dystocia, multiple deliveries, and be able to perform various maneuvers for shoulder dystocia and breech presentation. Labor is a process that begins with the onset of repetitive and forceful uterine contractions sufficient to cause dilation of the cervix and ends with delivery of the infant and placenta.

PREHOSPITAL CARE

If such a situation occurs outside the hospital then arrangements must be made to transport the pregnant to the nearby hospital safely and promptly. Under Janani Suraksha Yojana for pregnant, Indian Government is providing free transport facility to all pregnant women in labor pains, to nearby hospital for urgent delivery round the clock 24 hours. During prehospital care: (1) Provide oxygen, (2) Obtain intravenous (IV) access, (3) Transfer the patient in left lateral recumbent position, use this position especially if the expectant mother's blood pressure is low (pressure on vena cava reduces the return to the heart), and (4) Prepare for field delivery, because little can be done to prevent the birth.

EMERGENCY DEPARTMENT CARE

Evaluation of Pregnant Female

Apart from history and physical examination of pregnant female few points to be noted such as prenatal history, frequency of contractions, any vaginal discharge or bleeding, and focused examination to determine fetus presentation (**Fig. 1**).

Abdominal Examination and Steps to Ascertain the Presentation

This is very important to know which part of the fetus is near the birth canal. Sterile vaginal examination is carried out to know which part of fetus body (head, shoulder, buttock, and feet) is the presenting part. Shoulder will be the presentation in transverse lie. Abdominal examination carried out by Leopold maneuver (**Figs. 2A** to **D**).

Vaginal Examination

Lithotomy position is maintained while doing vaginal examination. Prepare the part (cleaning with povidone-iodine); vulva and perinial area for examination. Sterile gloved hand should be used to examine the vagina and effacement (**Figs. 3A** to **C**—measured through 0–100%) and cervical dilatation is assessed (10 cm cervical os indicate full dilatation). After examination of cervix, head of fetus [station of head –5 to +5 (**Fig. 4**)] is determined in relation to ischiatic spine. When the head is at the level of ischial spine this is leveled as 0 and as head progress further to birth canal it is levels as +5.

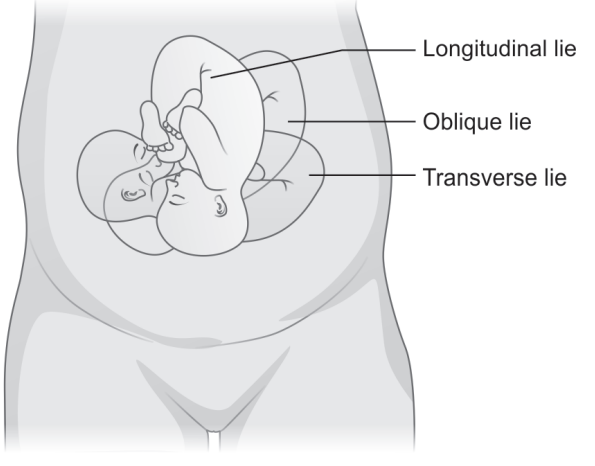

FIG. 1: Various presentation of fetus.

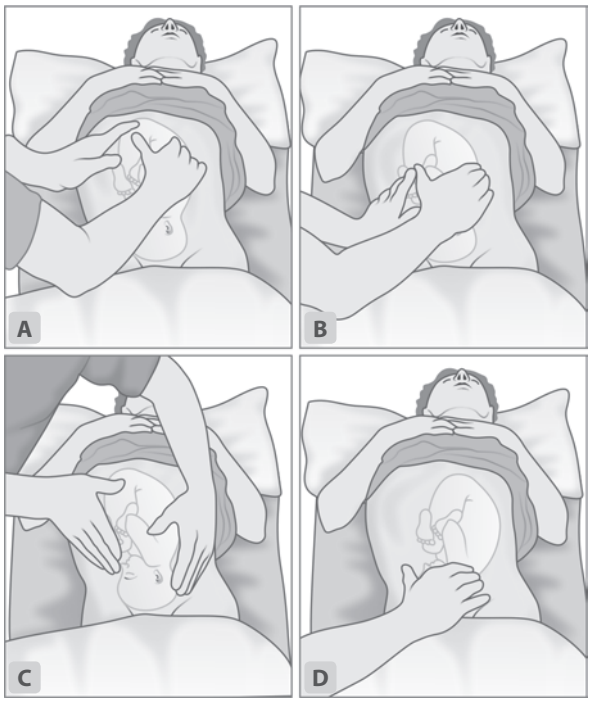
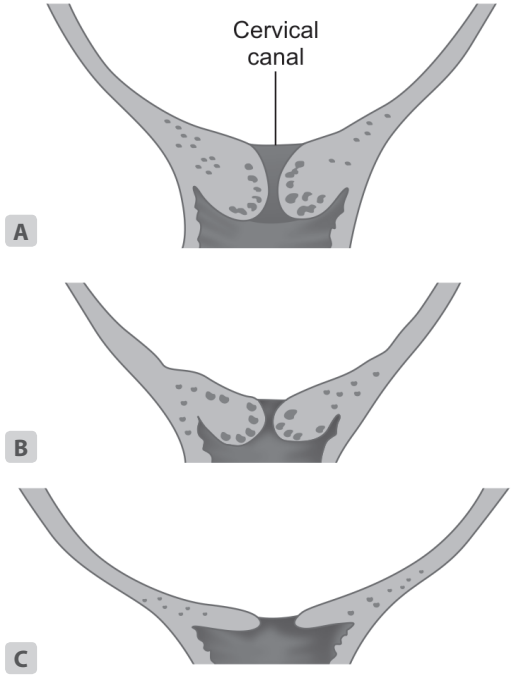


FIGS. 2A TO D: Leopold maneuver for abdominal examination in pregnant female. (A) Palpate fundus part; (B) Palpate lateral part of abdomen to find the back of fetus; (C) Palpate other lateral part; (D) Palpate presenting part.



FIGS. 3A TO C: Effacement of cervix. (A) 0%; (B) 50%; (C)100%.

Emergent Vaginal Delivery/Labor

Labor is defined as the initiation of regular and rhythmic contractions that results in serial cervical dilatation and effacement and categorized into four stages. *First stage (stage of cervical dilatation)* begins with onset of regular contraction and end with complete dilatation; latent (0–3 cm) → active (4–7 cm) → transitional (8–10 cm). *Second stage (stage of expulsion)*

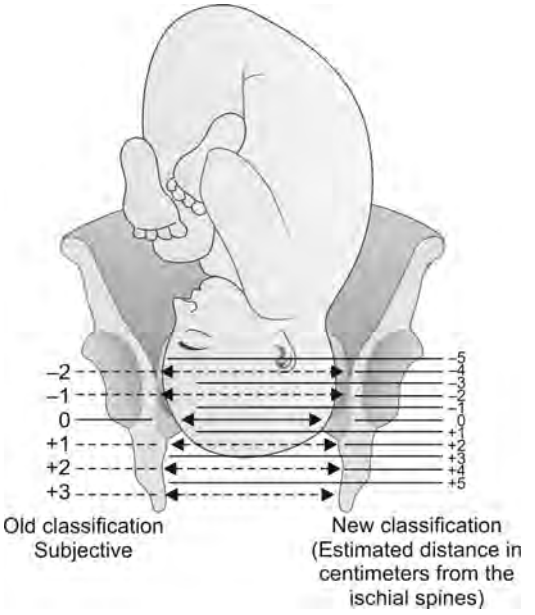


FIG. 4: Station of head.

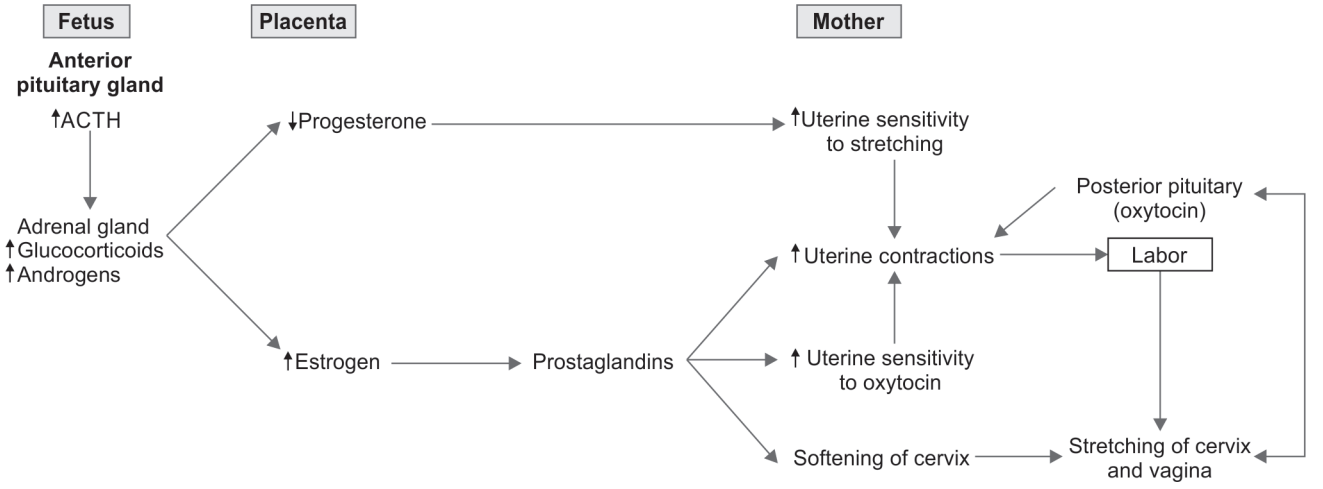
begins with complete cervical dilatation and end with delivery fetus. *Third stage (placental stage)* begins immediately after fetus is born and ends when placenta is delivered. *Fourth stage (maternal stabilization stage)* begins after delivery of the placenta and continues for 1–4 hours after delivery. Various hormonal factors are believed to have role in initiation of process of labor as shown in **Figure 5**.

A reliable sign of impending child labor is shown. The appearance of a slight amount of vaginal blood-tinged mucus is a good indication that labor will begin within the next 24 hours and sequence of labor will start and obstetrics and pediatric consult should be requested without delay. The loss of more than a few milliliters of blood at this time, however, must be regarded as being due to a pathological process like placenta previa or abruptio placenta. Adequate equipment should be arranged easily accessible for use at any time. List of equipment for labor is given in **Box 1**.

Patient should be placed in lithotomy position, if head is visible in vaginal opening or vulvar area (crowning), physician should be ready for the emergency delivery. Once the fetus head is crowning, delivery is performed by using the Ritgen maneuver. Important steps for safe delivery are shown in **Figure 6**.

Neonate neck should be checked for the umbilical cord around the neck, gently pull it around the head if cord around the neck is present. Deliver the child and shoulder by giving gentle traction and then rest of the baby will come out quickly. Be careful at this time as baby is slippery at this time. Suction the mouth and nose of the baby. Place the double clamp on the cord about 7–10 cm away from the baby and cut the clamp between the cord. If the child starts breathing and moving and appears to be in good health, hand over the baby to nursing personnel. In case of thick meconium, intubate the baby with 3.0 size endotracheal tube, then perform suction and stimulate the baby. Guide the placenta for delivery, do not try to pull the placenta. Mother and baby can be moved to the obstetrics ward for follow-up care if both are healthy and do not require further resuscitation.



(ACTH: adrenocorticotrophic hormone)

FIG. 5: Possible role of hormonal factors in labor.

- Neonatal warmer

Placenta Delivery

This may take 5–15 minutes after the delivery of fetus; bleeding is inevitably occurred when placenta separates and give uterus massage for contraction. Manual removal is mandatory if placenta does not descend and mother asked to push down or cough to increase the intra-abdominal pressure. Once placenta is delivered, stop abdominal massage and start the oxytocin infusion [20 U (2 mL/L)] at the rate of 10 mL/minute until uterus is well contracted and bleeding is stopped. Infusion of oxytocin titrated to 1–2 mL/minute until to shifted recovery unit. Mother should be kept under careful observation for 1 hour as bleeding may reoccur.

Episiotomy

Episiotomy is the incision given to the posterior vaginal wall to enlarge the vaginal introitus and facilitates smooth passage of fetal head (**Fig. 7**). Earlier it was thought that episiotomy can prevent vaginal tear and head trauma, but it is not showing better outcome and associated with bleeding, hematoma, infections incontinence, and lacerations. Now selective approach is used and only recommended in selective cases such as breech presentation, shoulder dystocia, preterm labor, and imminent perineal tear.

After the fetal delivery episiotomy can be repaired. Vaginal canal should be inspected closely for any other reason of bleeding and should be corrected and hemostasis achieved first before repair of episiotomy. Site is adequately prepared and cleaned and sutured with 2-0 or 3-0 absorbable sutures.

COMPLICATED DELIVERY

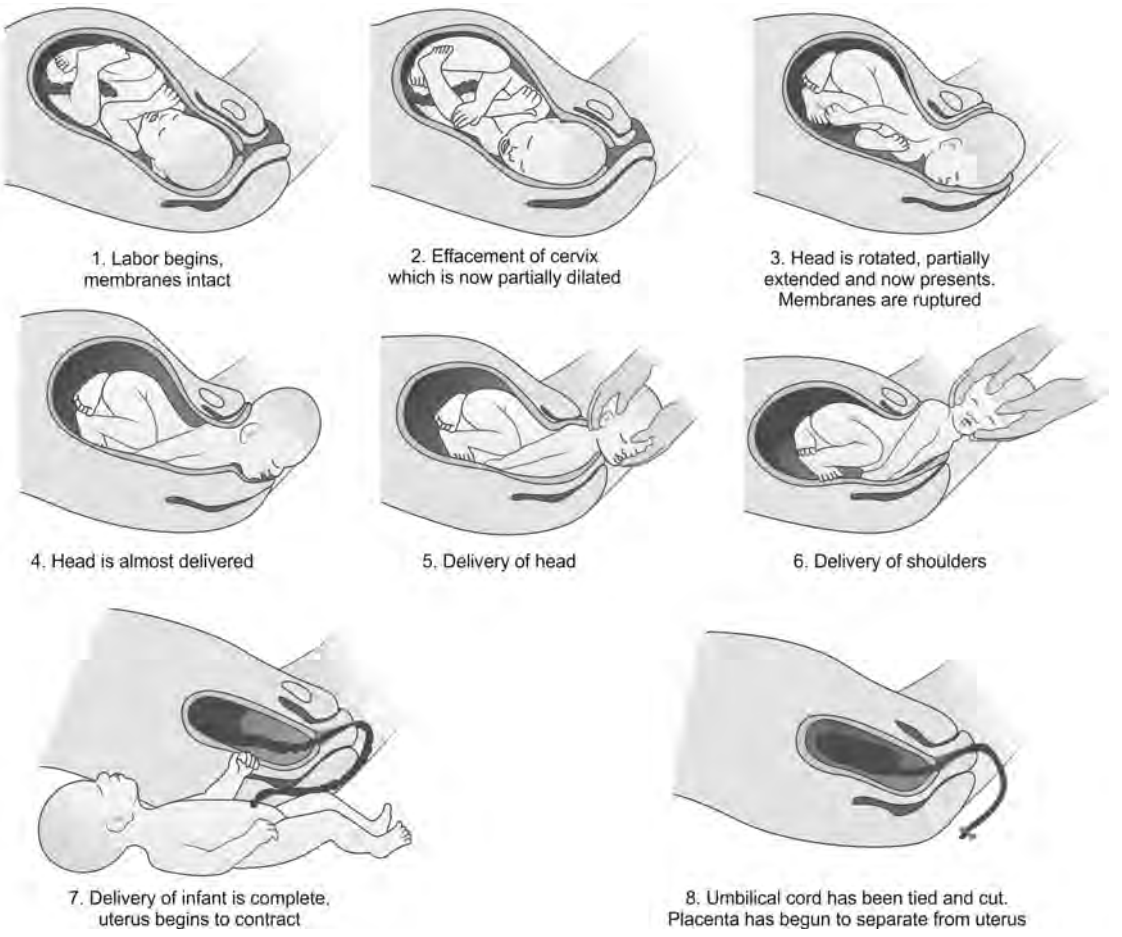
Often high-risk deliveries occur in ED in higher population of without access of care, those of unaware and denial of pregnancy. Obstetric patient presenting to ED usually have little or no prenatal care.

The emergency physician needs to expect the unexpected during a delivery, including precipitous delivery, shoulder dystocia, malpresentation, umbilical cord emergencies, hemorrhage, and multiple gestations. Additional ED nursing staff, doctors, obstetrician, and pediatrician should be called to ED. Arrange and open the kit for delivery and neonatal care, turn on infant warmer, and prepare resuscitation equipment. Wear personal protective equipment (gown, mask, eye protection, gloves, and shoe covers). Obtain IV access in the mother so that oxytocin, fluids, blood, and other medications may be administered as needed during the delivery. Keep the patient and family well informed.

If the infant is not crowning (head bulging at the perineum), a brief vaginal examination performed with a sterile–gloved hand. Various abnormal presentations of abnormal deliveries such as face, foot, hand, arm, or breech presentations are obvious on palpation (**Fig. 8**). These unexpected presentations can be problematic for the delivery in the ED, because they require special expertise.

UMBILICAL CORD PROLAPSE

Obstetrician should be called and the mother prepared for emergency cesarean section. However, if labor has progressed far enough that vaginal delivery is imminent, it should be performed as the most rapid method of delivery. If delivery is not imminent, as arrangements are being made for the



1. Labor begins, membranes intact
2. Effacement of cervix which is now partially dilated
3. Head is rotated, partially extended and now presents. Membranes are ruptured
4. Head is almost delivered
5. Delivery of head
6. Delivery of shoulders
7. Delivery of infant is complete, uterus begins to contract
8. Umbilical cord has been tied and cut. Placenta has begun to separate from uterus

FIG. 6: Steps for safe delivery in emergency department.

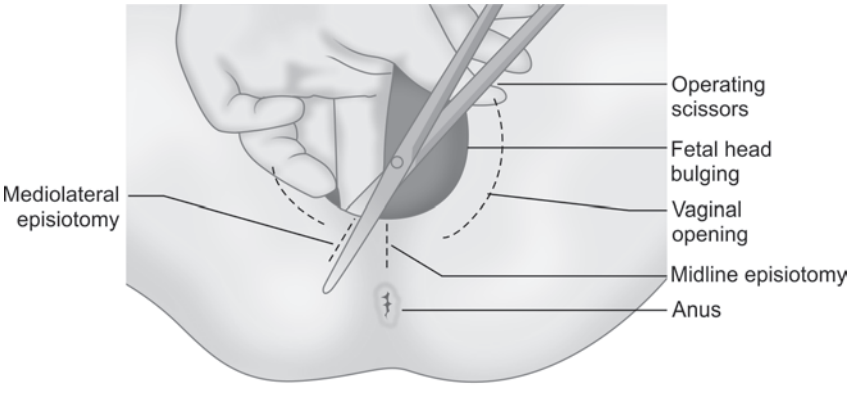


FIG. 7: Episiotomy modalities.

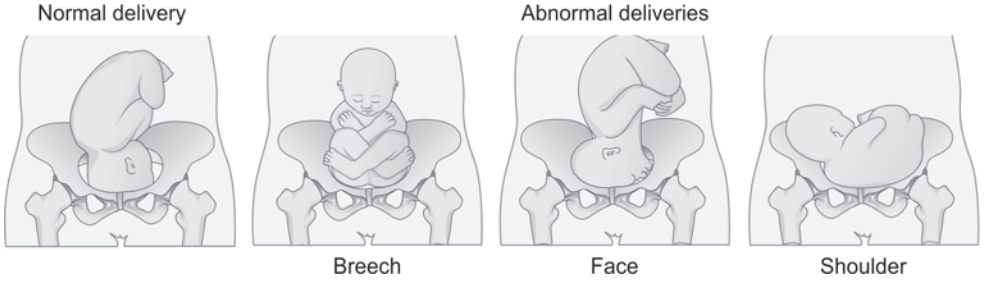

FIG. 8: Abnormal presentations of deliveries.

operation room, care should be focused on reducing pressure on the prolapsed cord. The cord should not be manipulated as this can induce vasospasm and subsequent fetal hypoxia. Instruct the mother not to push. The patient should be transported to the operating room and prepared for surgery with the provider's hand still in the vagina. Instillation of 500–700 mL normal saline into the bladder via Foley catheter may also help lift any presenting fetal parts off the cord.

CESAREAN SECTION

It is one of the oldest surgical procedures to preserve the fetal life. Every emergency physician must be aware of this procedure. Though most experience obstetrician should perform this procedure and neonatologist presence is mandatory.

Common indications for cesarean section procedures are malpresentation such as breech, brow, face posterior or transverse lie, and cord prolapse. Medical conditions where cesarean section such as cardiac, pulmonary, thrombocytopenia, active herpes simplex virus, human immunodeficiency virus infection, congenital anomalies, pelvic tumor, placenta previa, placental abruption, and vasa previa. Emergent cesarean section is indicated in perimortem condition (mother in cardiac arrest). Prolonged resuscitation is not beneficial to mother and fetus, so every attempt should be made to complete this surgical procedure within 4 minutes to save the fetal life. Decrease in time from maternal death to delivery, enhanced the possibility of neonatal survival. Rapid extraction of infants while avoiding any injury to mother and infants is the primary goal in perimortem condition. When this is so important, emergency physician should be aware of the minimum equipment required for the procedure. Essential equipment for perimortem cesarean section are retractors, clamps, vascular clamps or hemostats, neonatal resuscitation kit: neonatal air bag, intubation tray, suction bulb, warmer, curved scissors, blades #10, blood gas syringe, and suture. Perimortem cesarean section technique is described in **Figure 9**.

First a vertical incision is made in ventral aspect of the abdomen. Second, identify the bladder, place a bladder retractor. Third vertical incision made with the scalpel in the uterus. With a scissors, extend the incision inferiorly. Extract the fetus head, suction the pharynx, and deliver the fetus completely. Important to note complications of cesarean section surgical procedure are bladder injury (common) followed by bowel injury, fetal injury, neonatal neurological injury, maternal bleeding, and infections.

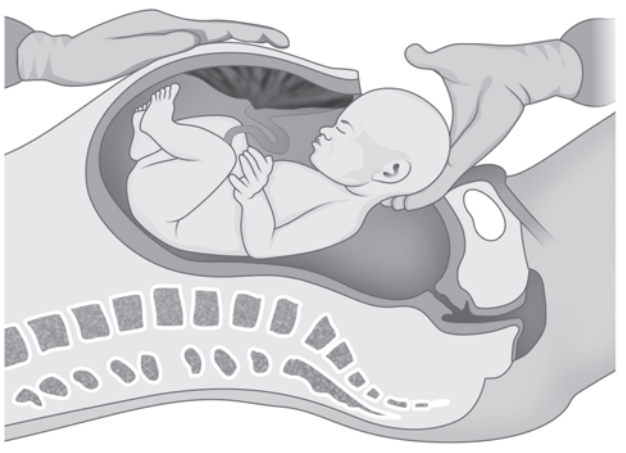

FIG. 9: Perimortem cesarean section.

POSTPARTUM COMPLICATIONS

Risk factors for the postpartum complications are cesarean delivery, prolonged rupture of membrane, prolonged labor, and bladder cauterization. These risk factors described earlier leads to complications such as mastitis, upper respiratory infection, urinary tract infection, thrombophlebitis, hematoma, abscess formation, endometritis, perineal cellulitis, and hemorrhage.

Postpartum Hemorrhage

An emergency physician should give attention to amount of blood loss during and after the delivery. Bleeding can be subtle and constant and can be life-threatening if go unnoticed. More than 500 mL of maternal blood during vaginal delivery is considered as postpartum hemorrhage. Multiple risk factors are identified for this condition such as prior history of postpartum hemorrhage, multiple deliveries, polyhydramnios, prolonged labor, and coagulopathy. Differential diagnosis includes uterine atony, cervical or uterine laceration/rupture, and retain products of conception. Management includes hemodynamic evaluations, initiation of blood products, volume expanders, and identify cause and their treatment.

Uterine Atony

Uterine atony is the most common cause of postpartum hemorrhage after prolonged labor and overdistension. Uterus feels soft and boggy with vaginal bleeding. Treatment of choice is uterotonic drug oxytocin 10–40 U in 1 L of crystalloid and given in infusion. Second-line drugs are methylergonovine 0.2 mg intramuscular and carboprost (prostaglandin derivatives) 0.25 mg intramuscular. Two-hand uterine massage can also be done. If these measures fail to control the postpartum hemorrhage, invasive measures such as embolization and surgery are indicated.

Placenta Previa

Placenta previa is a third trimester obstetric complication in which placenta abnormally (partially or completely) covers the internal cervical os. *Symptoms*: Bright red painless recurrent vaginal bleeding. S*igns:* Soft pain-free uterus easy to feel fetus, often high head breech or transverse lie no fetal distress. No recommendations for digital per vaginum (PV) examination, often fetus is not affected by the first small bleed, but because of high risk after emergency resuscitation shift immediately to obstetric department.

Abruption of Placenta

It means premature separation of placenta. *Symptoms*: Abdominal pain, bleeding, and severe shock. *Signs*: Shock spasm of uterus fetal part hard to feel, often no fetal heart sound. All emergency protocol should be considered to shift the patient to obstetric emergency unit.

Uterine Inversion

Forceful traction of umbilical cord during placental delivery causes uterine inversion. Although uterine inversion is uncommon but present with severe abdominal pain and produce shock due to vaginal bleeding and can be life-threatening if left untreated. Physical examination reveals absence of palpable uterus and protruding mass on vaginal examination. Hemodynamic stabilization and repositioning of the uterus is required in this situation.

SUMMARY

Every emergency physician should have sound knowledge of the emergency delivery and common obstetrics complications and emergencies. First principles of obstetrics emergencies are the same as with any other emergency, maintain circulation, airway, and breathing. Left uterine displacement of gravid uterus to prevent aortocaval compression. If patient is in second stage of labor, deliver the baby with all due precautions. If time permits, shift the patient to obstetric unit after primary resuscitation.

159 CHAPTER

Resuscitation in Pregnant

Vijaya Banu Mohan, Dodiy Herman, Benita Florence

INTRODUCTION

Resuscitation in pregnancy has few unique aspects and consideration when to compared to normal adult resuscitation as it involves resuscitation of two patients—pregnant woman and fetus. It is important to be familiar with the physiological changes in pregnancy which impact the resuscitation.

PHYSIOLOGICAL CHANGES IN PREGNANCY

The resuscitation modifications begin as early as in first trimester which peak at the second trimester and stays the same until labor. These are based on the anatomical and physiological and anatomical changes during the course of pregnancy. The changes during pregnancy and their implications are tabulated in **Table 1**.

CRITICALLY ILL MATERNAL PATIENTS

Any patient requiring admission to intensive care unit (ICU) because of pregnancy-specific conditions (sepsis, hemorrhage, and hypertensive emergencies in pregnancy), medical or surgical conditions unrelated to pregnancy (asthma, diabetes, and trauma), and conditions worsening in pregnancy (cardiac conditions, anemia, and autoimmune conditions). The crucial part in the prevention of cardiac arrest in critically ill patient is the prompt quick response.

MATERNAL COLLAPSE

It is an acute critical event due to cardiorespiratory or central nervous system involvement leading to reduced or absence conscious level during any stage of pregnancy up to 6 weeks after labor. If maternal collapse is not managed effectively then it can lead to cardiac arrest.

TABLE 1: Anatomical and physiological changes in pregnancy and their associated implications.

Systems	*Changes during pregnancy*	*Implications*
Airway	Edema/friability of upper airway	Difficult to perform bag mask ventilation
	Edema to pharynx and larynx	• Difficulty in laryngoscopy • Small diameter • ET tube may be needed
Breathing	• Diaphragm elevation by 4 cm • Reducing FRC	• High thoracostomies • Hypoxia can develop quickly
	Oxygen consumption is increased by increased by 20% to meet the oxygen demands of maternal and fetal organs	Hypoxia develops soon, hence maintain saturation > 94%
	Increased tidal volume and minute ventilation	Partial pressure of carbon dioxide is reduced leading to respiratory alkalosis. Normal $PaCO_2$ can mean impending respiratory failure
Circulation	• Cardiac output increased by 30–40% • Increased heart rate • Plasma volume increased by 30% • Uterine blood flow increased by 10–20% • Blood pressure reduces in the second trimester	Masking the effecting of sepsis

Continued

Continued

Systems	*Changes during pregnancy*	*Implications*
	Aortocaval compression starting from 20 weeks	• Hypotension on supine position • Avoid access in lower extremities • Decreases the effectiveness of CPR
	Diaphragmatic elevation and apex of heart moved to left	• Changes in ECG—left axis deviation • Q waves in lead III • ST depressions in inferolateral leads • T-wave changes—flattened or inverted
Other changes	Relaxation of lower esophageal sphincter	Risk of aspiration
	Changes in bile composition (lithogenic)	Prone for cholelithiasis
	Plasma volume increase by 50% and 30% increase in red cell mass	Physiological anemia leading to reduced oxygen carrying capacity to tissue, more impact during CPR
	Increase in clotting factors and vWF	Hypercoagulable state—increased risk of venous thromboembolism
	Dilatation of ureteropelvic system—physiological hydroureteronephrosis and increased vesicoureteric reflux	Increased pyelonephritis
	Vaginal pH decreases	Increased chance of chorioamnionitis

(CPR: cardiopulmonary resuscitation; ECG: electrocardiogram; FRC: functional residual capacity; $PaCO_2$: partial pressure of carbon dioxide; vWF: von Willebrand factor)

MATERNAL CARDIAC ARREST

Cardiac arrest in pregnancy is rare. It occurs in 1:30,000 pregnancies. Resuscitation in cardiac arrest in pregnancy is unique and has few modifications as it involves two patients—mother and fetus. Effective resuscitation of the mother is often the best way to improve fetal outcome. It may need resuscitative hysterotomy if return of spontaneous circulation (ROSC) is not obtained in 4 minutes. One of the study done in UK revealed about one-fourth of the cardiac arrest in pregnancy were secondary to anesthesia and the all those patients survived.

Causes

The causes of maternal collapse or cardiac arrest can be classified as obstetric causes and nonobstetric cause (**Table 2**).

TABLE 2: Causes of maternal cardiac arrest.

4H	**H**ypoxia	• Acute myocardial infarction (MI) • Cardiomyopathy • Anaphylaxis • Aortic dissection • Aspiration
	Hypovolemia	Hemorrhage: • Antepartum hemorrhage • Postpartum hemorrhage • Uterine rupture • Coagulopathy • Surgical • Trauma Other shocks like: • Anesthesia • Septic • Neurogenic
	Hypo/hyperkalemia Other electrolyte imbalance	• Less likely • Oxytocin can cause hyponatremia
	Hypothermia	Less likely
4T	**T**hromboembolism	• Amniotic fluid embolism • Pulmonary embolism • Acute myocardial infarction • Air embolism
	Toxicity	• Magnesium • Local anesthesia
	Tension pneumothorax	Trauma
	Tamponade	Trauma
Preeclampsia/eclampsia		

APPROACH TO CRITICALLY ILL OBSTETRIC PATIENT

Like any standard approach, initial assessment should be done in airway, breathing, circulation, disability, and exposure (ABCDE) approach. Good maternal resuscitation provides good fetal care. So, it is imperative to follow the general standards of resuscitation. Resuscitation has the highest priority than the evaluation of the cause.

- Oxygen to maintain saturation >95%
- Insert two large bore intravenous (IV) access above the level of diaphragm
  - Treat hypotension with isotonic IV fluids and care should be taken that volume resuscitated is 50% more than the fluid required by nonpregnant person
  - If fluid unresponsive vasopressor should be considered as uterine blood flow is pressure dependent

- Early antibiotics, if sepsis is considered
- *Investigations*:
  - Bloods—full blood count (FBC), urea and electrolyte (U&E), liver function test, coagulation profile, crossmatch, fibrinogen, and fibrin degradation products
  - Chest X-ray—to look for pulmonary edema and acute respiratory distress syndrome (ARDS)
  - Electrocardiogram (ECG)
- Involve obstetrician, anesthetist, and neonatologist at the earliest
- If hemorrhage—crossmatch four to six units of blood
- If coagulopathy—liaise with hematologist to correct with platelet fresh frozen plasma (FFP) and cryoprecipitate transfusion
- Early transfer to intensive treatment unit (ITU)
- Deliver the baby

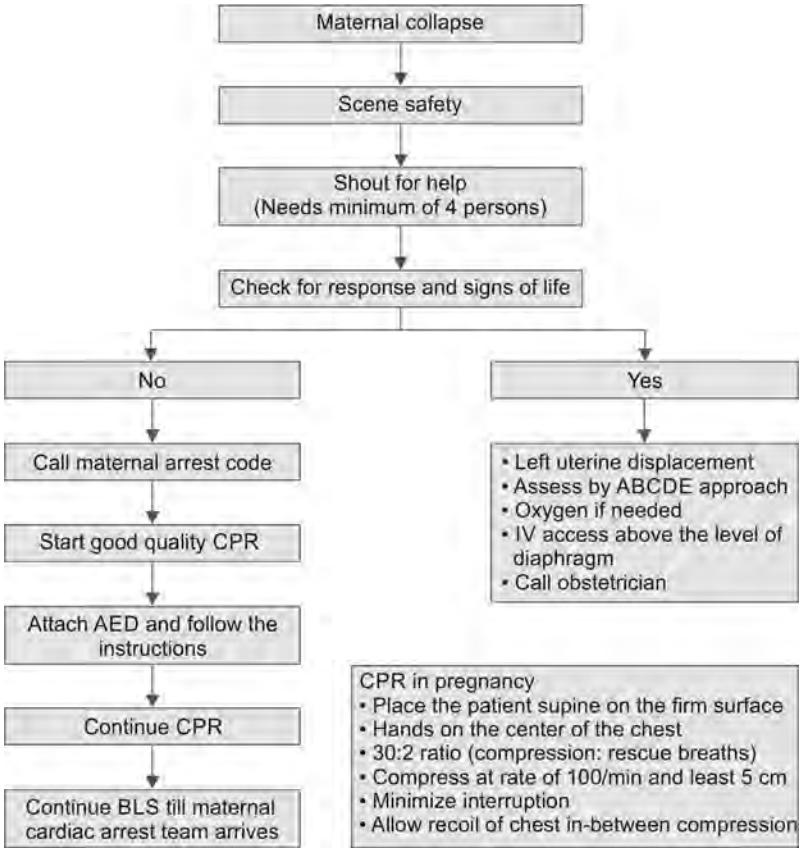
APPROACH TO MATERNAL CARDIAC ARREST

Whenever there is a maternal cardiac arrest, basic life support (BLS) (**Flowchart 1**) should be commenced immediately as basic emergency care is crucial with few modifications. Make the patient lie in supine position over the back board. Check for the response. If the patient is unresponsive with no breathing or abnormal breathing, obstetric emergency code should be activated. For BLS, minimum of four persons are needed. Automated external defibrillator (AED) and crash cart to be obtained. Check for pulse for not >10 seconds. If no pulse palpable then start chest compression as per standard adult resuscitation guidelines. Care should be taken to ensure good quality CPR with minimal interruptions. Bag mask ventilation (BMV) with 15 L of oxygen using two-hand technique to be provided—two breaths for 30 compressions each lasting for 1 second. Care should be taken to avoid excessive ventilation. AED should be used to analyze the rhythm and provide shock. If the patient is above 20 weeks of gestation, aortocaval compression can restrict the effectiveness of CPR, manually displace the uterus to left (pull the uterus to left) (**Fig. 1**). Left lateral tilt between 15° and 30° if feasible. This can be achieved with Cardiff wedge, pillow, or sand bags.

Advanced Life Support

Every hospital should have the specific method to activate the maternal cardiac arrest code [advanced life support (ALS)] (**Flowchart 2**). One code call to all necessary resuscitation responders is needed. Ideal maternal cardiac arrest team should consist of:

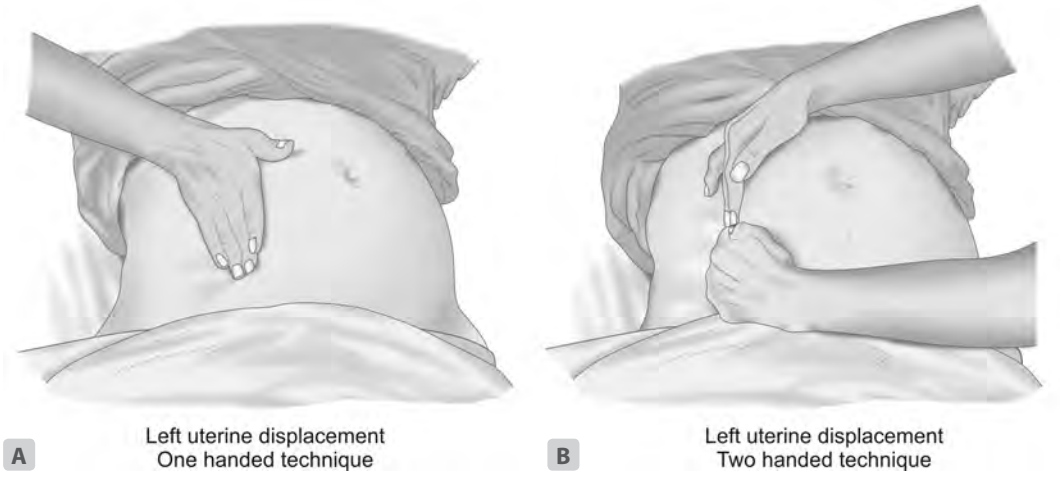
- Emergency physician and nurse/critical care physician and nurse/internal medicine physician and nurse
- Obstetrician and obstetric nurse
- Anesthetist, especially if obstetric anesthetist if available and nurse
- Neonatologist and nurse



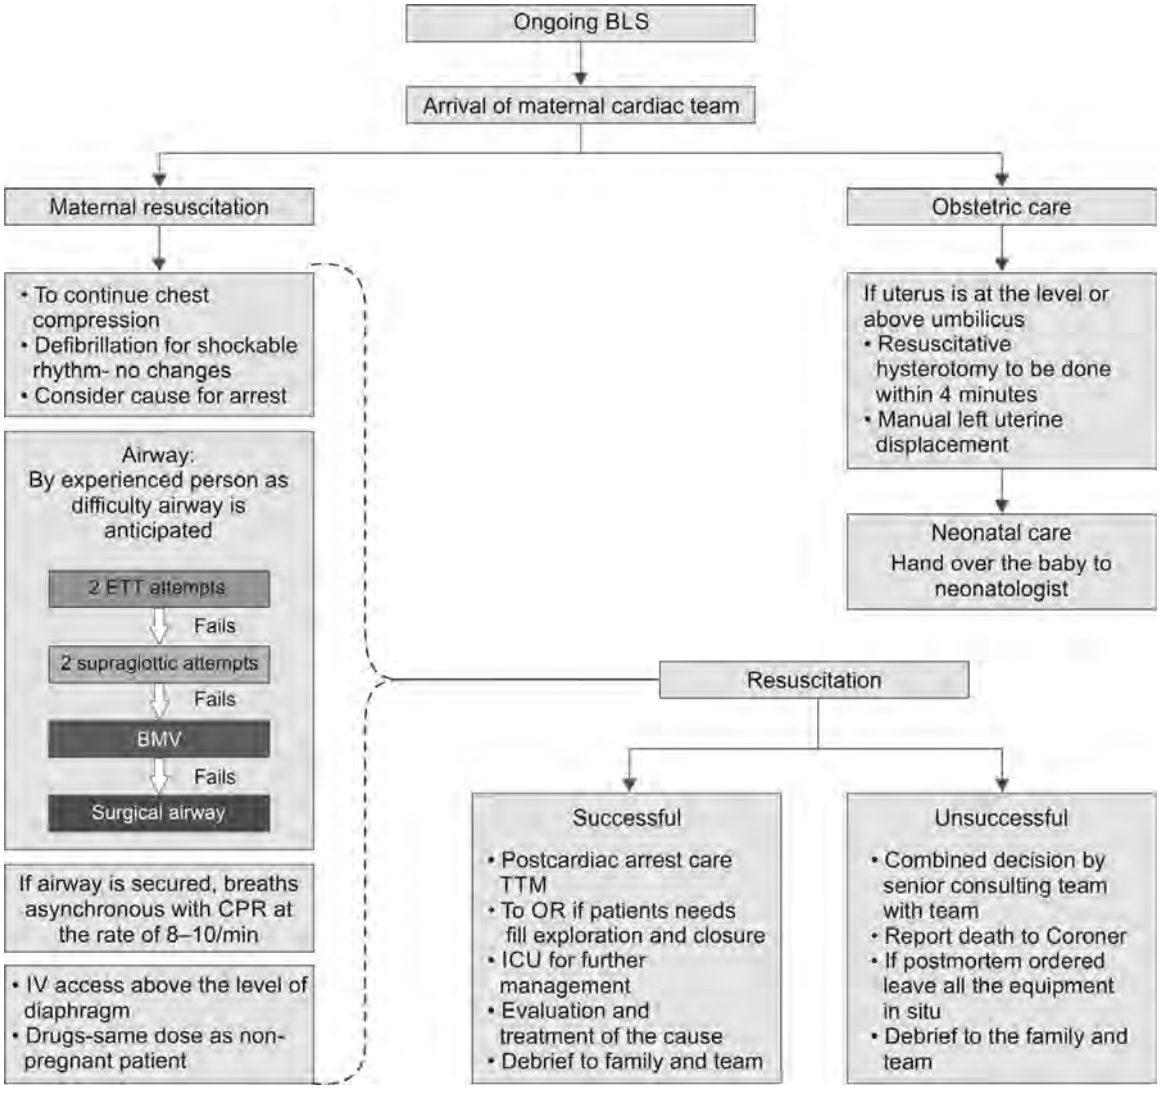
Maternal collapse
Scene safety
Shout for help
(Needs minimum of 4 persons)
Check for response and signs of life
No
Yes
Call maternal arrest code
Start good quality CPR
Attach AED and follow the instructions
Continue CPR
Continue BLS till maternal cardiac arrest team arrives
• Left uterine displacement
• Assess by ABCDE approach
• Oxygen if needed
• IV access above the level of diaphragm
• Call obstetrician
CPR in pregnancy
• Place the patient supine on the firm surface
• Hands on the center of the chest
• 30:2 ratio (compression: rescue breaths)
• Compress at rate of 100/min and least 5 cm
• Minimize interruption
• Allow recoil of chest in-between compression

(ABCDE: airway, breathing, circulation, disability, and exposure; AED: automated external defibrillator; BLS: basic life support; CPR: cardiopulmonary resuscitation; IV: intravenous)

FLOWCHART 1: Basic life support algorithm for pregnant.



FIGS. 1A AND B: (A) Left Uterine displacement, one hand technique. (B) Two hand technique (More than 20 weeks gestational size or uterus is palpable or visible).



Ongoing BLS
Arrival of maternal cardiac team
Maternal resuscitation
Obstetric care
• To continue chest compression
• Defibrillation for shockable rhythm- no changes
• Consider cause for arrest
If uterus is at the level or above umbilicus
• Resuscitative hysterotomy to be done within 4 minutes
• Manual left uterine displacement
Neonatal care
Hand over the baby to neonatologist
Airway:
By experienced person as difficulty airway is anticipated
2 ETT attempts
Fails
2 supraglottic attempts
Fails
BMV
Fails
Surgical airway
Resuscitation
If airway is secured, breaths asynchronous with CPR at the rate of 8–10/min
• IV access above the level of diaphragm
• Drugs-same dose as non-pregnant patient
Successful
• Postcardiac arrest care TTM
• To OR if patients needs fill exploration and closure
• ICU for further management
• Evaluation and treatment of the cause
• Debrief to family and team
Unsuccessful
• Combined decision by senior consulting team with team
• Report death to Coroner
• If postmortem ordered leave all the equipment in situ
• Debrief to the family and team

(BLS: basic life support; BMV; bag mask ventilation; CPR: cardiopulmonary resuscitation; ETT: endotracheal tube; ICU: intensive care unit; IV: intravenous; OR: operating room; TTM: targeted temperature management)

FLOWCHART 2: Advanced life support (ALS) for pregnant.

As maternal cardiac arrest involves adult resuscitation, obstetric care and neonatal resuscitation, team leader for each should be allocated. Overall a team leader for the cardiac arrest should communicate with all the team leaders.

Airway: Maternal cardiac arrest is one of the situations in adult resuscitation which requires definitive airway at the earliest by an experienced person. Alternate measures if definitive airway fails, surgical airway should be followed.

Breathing: BMV connected to 15 L oxygen.

Circulation: IV access above diaphragm.

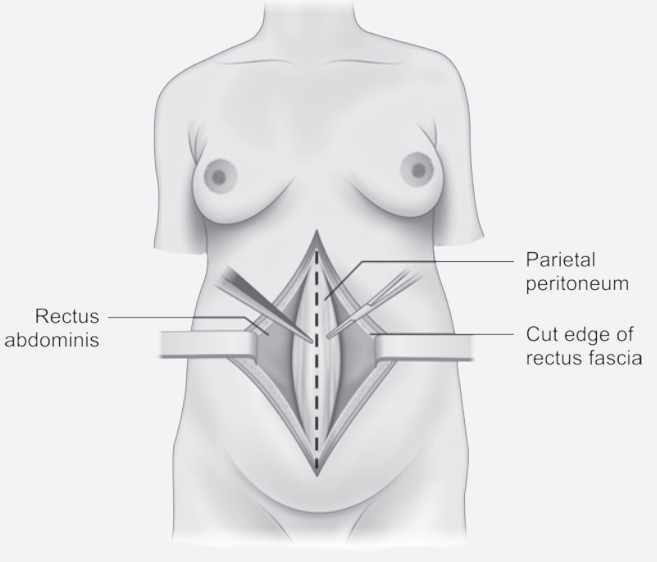
Defibrillation and drugs: Standard resuscitative guidelines should be followed as there are no modifications. Reversible causes for the cardiac arrest should be considered.

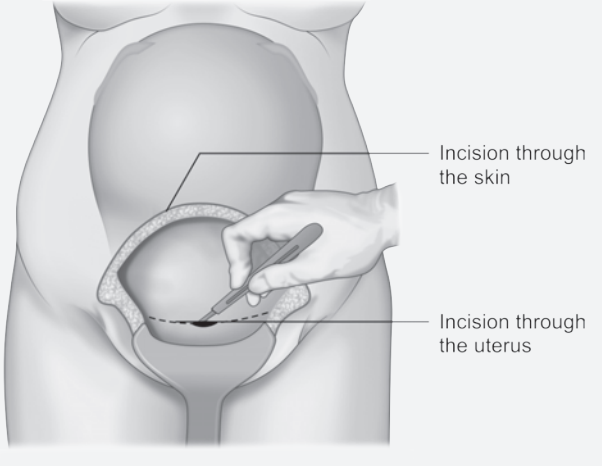
Resuscitative Hysterotomy

It is also called as perimortem cesarean delivery (PMCD) (**Table 3**). It is usually done in patients who are >20 weeks pregnant or uterus is above the level of umbilicus. During maternal cardiac arrest, if ROSC is not obtained within 4 minutes, it is necessary to deliver the baby as this relieves the occlusion of inferior vena cava (IVC) by the uterus and thereby improving the cardiac output. Delivery also improves the thoracic wall compliance and this improves CPR effectiveness. It is preferred to do it in the place where the maternal resuscitation is carried out. Shifting the patient to the operating room (OR) will cause delay in all the crucial resuscitations. It can be carried out with a scalpel and scissor as waiting for the surgical equipment will cause unnecessary delay.

TABLE 3: Resuscitative hysterectomy.

Recommended equipment	***Steps of resuscitative hysterotomy***
• Sterile gloves • Fixed blade scalpel • Sterile scissors • Umbilical cord clamps • Antiseptic	• With continuing maternal resuscitation and manual left uterine displacement, if antiseptic solution is available, pour over the abdomen • Make an incision over the abdomen—vertical incision (preferred over Pfannenstiel) from xiphisternum to pubic symphysis as it allows more space for visualization • Incision from skin to peritoneum • Make vertical incision over the uterus from fundus to lower segment of uterus • Stretch the uterine incision through fingers to allow the easy access to the delivery • Deliver the baby after cutting the cord between the two umbilical clamps. Hand over the baby to neonatologist • Deliver the placenta • Uterus to be closed in layers followed by closure of abdomen as done in regular manner • Oxytocin and antibiotics can be considered • Foley's catheter can be placed
Incisions	
	
	





MANAGEMENT AFTER RESUSCITATIVE HYSTEROTOMY

It depends on the outcome of resuscitation. If ROSC obtained after resuscitative hysterotomy, the patient should be managed in the ICU unless an operation is need. In that situation, patient has to be shifted to OR for full exploration and closure. Target temperature management has to be maintained along with other standard ICU care. Cause of arrest should be evaluated and treated. If the resuscitation is unsuccessful, a combined decision to be made by the senior consulting team in liaison with the team leader. This should be informed to the coroner and if postmortem is required all the equipment should be left in situ. If the abdomen is open with uterus and placenta in situ, it should be left open and covered with dressing. Team and family debriefing have to be done irrespective of the outcome. Neonatal resuscitation is beyond the scope of this chapter.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism (AFE) is one of the rare causes of cardiac arrest in pregnancy. AFE is an obstetric condition characterized by the triad of cardiovascular collapse, hypoxic respiratory failure, and coagulopathy. It is also commonly associated with neurologic symptoms (encephalopathy/coma/seizures) with persistent neurologic deficits in survivors. Low incidence of syndrome is may be due underestimation and diagnosis by exclusion and also due to underreporting. Significant mortality and morbidity is associated with AFE, and emergency physician should be aware about this clinical situation as resuscitation considerations differ slightly from other causes of cardiopulmonary collapse.

Risk Factors

Risk factors associated with increased risk of AFE include advanced maternal age (35 years or older), placental abnormalities (previa, accreta, abruption, and rupture), medical induction of labor, operative deliveries (cesarean delivery, forceps-assisted delivery, vacuum-assisted delivery, and termination of pregnancy), amniocentesis, trauma, eclampsia, cervical lacerations, prolonged gestation, male fetus, and multiple gestations.

Pathogenesis

The traditional theory of developing the AFE start with any stressful factors which causes breach in the physical barriers between mother and fetus, with amniotic fluid entering the maternal circulation, amniotic fluid embolization into the pulmonary vasculature, resulting in mechanical obstruction of pulmonary capillaries, but this is not observed in all cases of AFE nor proven in multiple animal studies.

More recent studies suggest that AFE is similar to abnormal immunologic response with complement activation and release of endogenous proinflammatory mediators. This abnormal host response is similar to those found in anaphylactic shock or endotoxin-mediated septic shock. Some experts use the term "anaphylactoid syndrome of pregnancy" more accurately describes the physiologic diagnosis, although it has not been widely accepted.

Timing and Clinical Presentation

Most of AFE occurs during labor, but can occur during immediate postpartum period till 48 hours postpartum period also.

Cardiovascular Collapse

Pulmonary vasoconstriction, followed by severe pulmonary arterial hypertension and right ventricular (RV) failure (cor pulmonale) is the initial response to hypoxia. Echocardiographic evidence of RV strain and leftward deviation of the intraventricular septum may be present. Hypoxia, acidosis, and hypercapnia if not treated timely may further worsen pulmonary vasoconstriction. Specific treatments for pulmonary hypertension (sildenafil, inhaled nitric oxide, and inhaled or IV prostacyclin) and RV support with inotropes (dobutamine and milrinone) are effective. As a result of RV failure or due direct effect from amniotic fluid or other mediators left ventricular (LV) failure may also occur. LV failure may clinically present as hypotension and pulmonary edema, which can be treated with vasopressors and diuretics, respectively, along with inotropes for increased cardiac contractility.

Hypoxic Respiratory Failure

More than 90% of patient may present as hypoxia which is an early finding. Severe ventilation and perfusion mismatch from the initial embolism and cardiogenic pulmonary edema cause early hypoxia. Later hypoxia may be due to noncardiogenic pulmonary edema from alveolar capillary leakage of a proteinaceous exudative edema containing amniotic fluid debris, consistent with acute respiratory distress syndrome. Encephalopathy and neurologic injuries can also be observed due to hypoxia in survivors. Bradycardia may be observed on fetal monitoring due to hypoxia.

Coagulopathy

Amniotic fluid embolism-induced coagulopathy is most likely multifactorial. Disseminated intravascular coagulation (DIC) is present in 80–85% of cases. Amniotic fluid activates platelet aggregation decreases whole blood clotting time. Extrinsic pathway of the clotting cascade is also get activated by procoagulant components of amniotic fluid (namely tissue factor III), leading to a consumptive coagulopathy. Hemorrhage caused by DIC may be manifested by bleeding from venipuncture or surgical sites, and vaginal bleeding with concomitant uterine atony.

Diagnosis

Amniotic fluid embolism represents a clinical syndrome; there are no clear diagnostic laboratory markers. Diagnosis is by exclusion rather than being based on histopathologic examination. Tests such as a complete blood count, coagulation, and cardiac biomarkers are nonspecific. Laboratory manifestations of DIC (such as prolonged prothrombin and partial thromboplastin times, and decreased fibrinogen levels) may be present. Chest radiographs reveal nonspecific findings such as diffuse bilateral opacities. Evidence of RV strain and leftward deviation of the intraventricular septum can be noted on echocardiogram examination. Differential diagnoses

to consider include puerperal sepsis, thromboembolic pulmonary embolism, air embolism, aspiration pneumonitis, myocardial infarction, and eclampsia.

Management

Patient should be treated in ICU, treatment is supportive and should include multidisciplinary team including maternal-fetal medicine, critical care, anesthesia, and respiratory therapy. Critical care management is focused on hemodynamic support (mechanical ventilation, vasopressors, and inotropes). Avoid excessive crystalloid fluid administration. In the case of cardiac arrest, a presumptive diagnosis of AFE standard high-quality CPR with advanced cardiovascular life support (ACLS) protocols should continue. Both medical and surgical management may be required in AFE coagulopathy. Medical management includes transfusion strategies to maintain a platelet count >50,000/mm^3, a normal activated partial thromboplastin time and international normalized ratio, and a fibrinogen level >200 mg/dL. Early and aggressive transfusion, including activation of a massive transfusion protocol (hemostatic resuscitation in a 1:1:1 ratio) in severe hemorrhage could improve outcomes. Other pharmacologic therapies such as recombinant factor VIIa, fibrinogen concentrates, tranexamic acid, and prothrombin complex concentrates can also be considered. Massive crystalloid resuscitation may result in a dilutional coagulopathy and increased intravascular hydrostatic pressures, which could worsen bleeding.

Mortality and Outcome

Multiorgan failure, massive hemorrhage, and cardiac arrest are the main causes of death.

SUMMARY

Resuscitation of the pregnant patient presents unique challenges. Being knowledgeable about maternal physiologic changes and the distinctive underlying etiology of cardiac arrest in pregnancy is essential in providing high-quality and potentially lifesaving care for both mother and fetus. Maternal resuscitation needs teamwork among adult resuscitation team, cesarean delivery of the fetus, and neonatal resuscitation within 5 minutes. Simulation training and drills can help in improving the teamwork, communication, and belief in managing the maternal cardiac arrest and resuscitative hysterotomy.

160
CHAPTER

Pediatric and Neonatal Transport

Trevor L Tredway

INTRODUCTION

Of the several hundred million emergency department (ED) visits across the United States (US), about 20% of those involve pediatric patients. A great majority of the seriously ill or injured pediatric patients are treated at EDs in community hospitals. When the medical care and/or resources for the patient exceeds what is available at these community hospitals that necessitates transfer to a higher level of care. These situations have helped lead to the development of pediatric and neonatal transport medicine. As more children undergo interfacility transport, it is important to understand the basic concepts of pediatric and neonatal transport.

REFERRING AND RECEIVING HOSPITAL RESPONSIBILITIES

The federal government established the Emergency Medical Treatment and Labor Act (EMTALA) in the Consolidated Omnibus Budget Reconciliation Act (COBRA) of 1985. EMTALA states that every hospital must examine, treat, and stabilize anyone presenting to the ED for medical care. After the medical screening is completed, it may be determined that the patient requires care that exceeds the hospital's existing capabilities. At this time, they can make the decision to transfer the patient to a higher level of care. This decision to transfer cannot be based on the patient's ability to pay and must be within the hospital's own guidelines as well as state and federal regulations.

The referring hospital is responsible for contacting the receiving hospital to arrange the transfer. This initial contact should occur as early as possible in the case. The referring hospital needs to discuss with the family the reason for the transfer and should obtain verbal consent that they are in agreement with the transfer. All appropriate forms, records, labs, and imaging should also be transferred with the patient to comply with EMTALA regulations. The best practice is for these referring hospitals to have established policies and agreements with the receiving hospitals.

The EMTALA also states that any hospital cannot refuse to accept appropriately transferred patients when they have the capacity to treat and manage the patient. Most tertiary care pediatric hospitals have existing policies and procedures to expedite transfers from referring hospitals. In addition, a majority of tertiary care pediatric hospitals have their own pediatric and neonatal transport teams in-house.

CRITERIA FOR TRANSFER

It is up to the referring facility to determine which pediatric or neonatal patient must be transferred to a higher level of care. Again this is most commonly when the patient's needs have exceeded the medical care and resources for their facility. Below is a list of common situations that would require transfer (**Box 1**).

MODE OF TRANSPORT

The mode of transport for the patient should be determined in the communication between the referring and receiving facilities. The mode of transportation should take in account the condition of the patient and their risk for deterioration, the distance between facilities, the weather conditions, and the cost. Air transport of a stable patient a short distance is likely

BOX 1: Criteria for transfer.

- Status post cardiopulmonary arrest
- Respiratory distress or failure
- Depressed or deteriorating neurologic exam or status
- Shock that is not responding adequately to treatment
- Serious cardiac rhythm disturbances leading to inadequate perfusion
- Children with severe electrolyte or metabolic disturbances (i.e., DKA)
- Children with life threatening ingestion or exposure to toxic substances
- Children that have sustained major traumatic injuries leading to circulatory, respiratory, or neurologic compromise

(DKA: diabetic ketoacidosis)

not necessary or cost effective. The main modes of transport are ground ambulance, rotor-wing aircraft (helicopter), or fixed-wing aircraft.

Ground ambulance is the most often used mode of pediatric and neonatal transport. The major advantages to this mode are that it provides a stable working space for the transport team and it is relatively safe in most weather conditions. The major disadvantage to ground ambulance is the speed at which the patient can be brought from the referring hospital to the receiving hospital. If the distance between the two facilities is large, it may take several hours to transport the patient via ground. For a patient that is critically ill or injured a long transfer between facilities may increase their risk of morbidity or mortality.

Over the past several years, rotor-wing transport has become a more popular way to transport patients to the ED. This includes transfers from referring facilities as well as patients brought directly from accident scenes. Rotor-wing ambulances have the main advantage of providing an expeditious transport of the most critically ill or injured patients. However, this mode is limited significantly by weather conditions. This includes the weather near both facilities in addition to the weather at the time of departure and the time of the return trip. The safety of the aircrew and the transport team takes priority when determining whether this mode of transport can be used.

Fixed-wing transport of patients is less commonly used and mainly for those patients that are being transferred between facilities that are very long distances apart. This mode of transportation requires the availability of an airport for landing in addition to ground transportation to and from the hospitals. Thus, fixed-wing transport carries additional costs compared to ground ambulance or rotor-wing aircraft.

TRANSPORT TEAM

Together with determining the mode of transport, the type of team to transport the patient should be discussed between the referring and receiving facilities. These teams may be basic life support (BLS), advanced life support (ALS), or specialized pediatric and neonatal transport teams. All involved in this discussion should have adequate knowledge of the capabilities of the particular teams in terms of pediatric equipment as well as procedural skills.

The advances in interfacility transport of pediatric patients have led to the development of specialized teams. These specialized teams are designed to safely and effectively transport and render care to patients. The specialized teams are usually staffed by dedicated pediatric critical care nurses and respiratory therapists or paramedics. All team members undergo education and training in pediatric and neonatal ALS. It is the responsibility of the medical director for the transport team to confirm all transport team personnel have received appropriate training and are maintaining their procedural skills.

Depending on the needs during the transport of the patient an emergency medicine or critical care physician can be added to the team. These specialized teams are able to bring advance pediatric care to the patient rapidly and provide continuous care during the transport to the receiving facility. Transport team members have to be able to communicate well with their medical control and must be able to work in highly stressful situations. It has been shown that transport between facilities by specialized pediatric and neonatal transport teams were associated with improved outcomes including survival rates as well as fewer unplanned events during the transport.

PATIENT MONITORING AND CARE

Current technology allows most pediatric and neonatal transport teams to provide hospital-based monitoring. Standard monitoring of the patient during transport includes continuous monitoring of heart rate, respiratory rate, pulse oximetry, and blood pressure. Additionally, most teams also provide continuous monitoring of end-tidal CO_2. Certain aspects of patient monitoring may be determined by the patient's underlying condition and/or their status during transport.

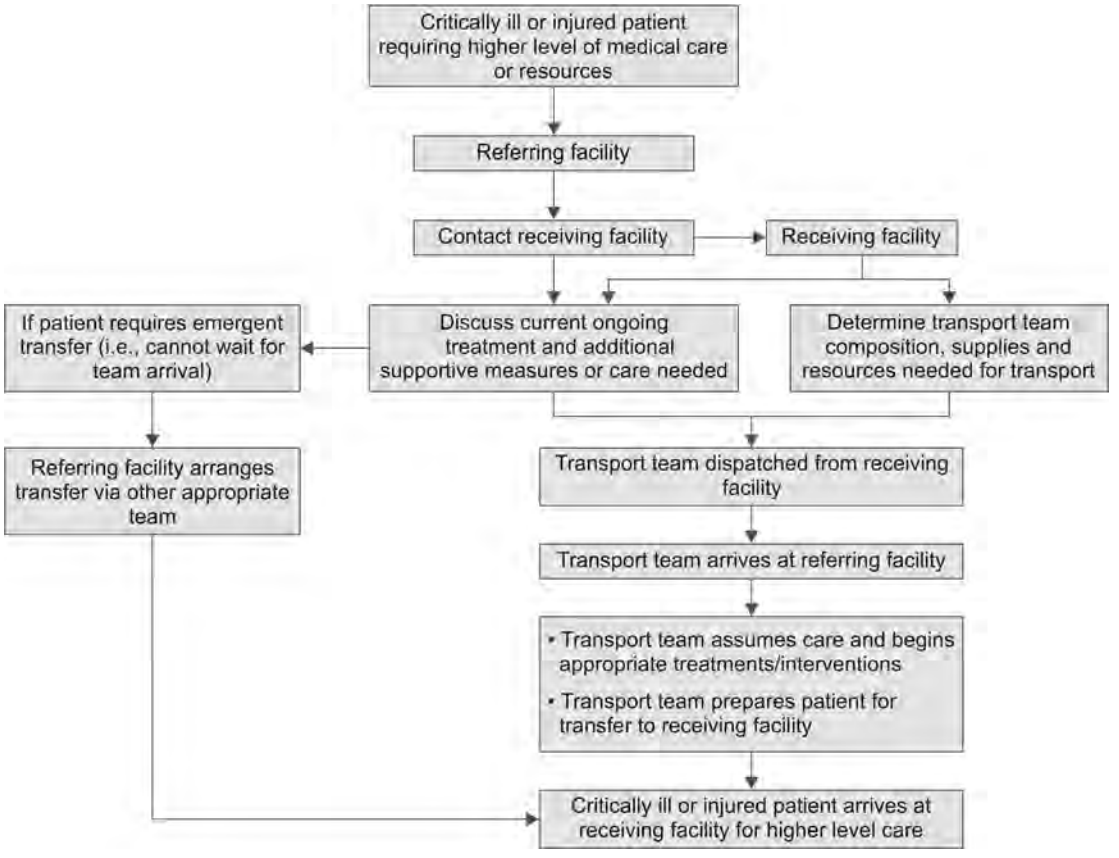
Newborns and neonates provide a unique situation for transport between facilities. In these situations, it is extremely important to maintain the body temperature of the infant during the transport. Therefore, many of these transports take place with specialized teams and the use of transport incubators. The transport incubator with its portable power supply functions like an incubator in the ICU and allows the transport team to have a limited temperature gradient within small environment.

During transport of a patient the teams should be able to provide appropriate specialized critical care treatment and interventions. Teams must have the essential medical equipment, medical devices, and medications immediately available and accessible to them during the transport of the ill or injured patient. Since many hospitals do not own or operate their own ambulances or aircraft, all of the above items need to be easily portable and checked prior to departure for the transport.

The teams need to be able to manage the airway, provide sedation, manage shock, and provide resuscitative efforts if required. Much of the care is determined by the patient's underlying condition along with their current clinical status. Point of care laboratory monitoring is also important during transport between facilities. Laboratory values such as serum glucose, serum electrolytes, hemoglobin, hematocrit, and blood gas measurements are necessary during long transports. Since many of these patients are critically ill or injured continuous and accurate monitoring is required as their clinical status can change rapidly.

SUMMARY

The transfer of children between facilities requires the team to provide continuous stabilization and care throughout. This is different from most emergency medical service (EMS) providers who routinely transport patients from the medical scene to the hospital. The ultimate goal is to bring ED/intensive care unit (ICU) care to the patient sooner. With the appropriate knowledge, preparation, and skills, the interfacility transfer (**Flowchart 1**) of critically ill or injured pediatric or neonatal patients can take place safely and expeditiously to attain improved outcomes.



Critically ill or injured patient requiring higher level of medical care or resources
Referring facility
Contact receiving facility
Receiving facility
If patient requires emergent transfer (i.e., cannot wait for team arrival)
Discuss current ongoing treatment and additional supportive measures or care needed
Determine transport team composition, supplies and resources needed for transport
Referring facility arranges transfer via other appropriate team
Transport team dispatched from receiving facility
Transport team arrives at referring facility
• Transport team assumes care and begins appropriate treatments/interventions
• Transport team prepares patient for transfer to receiving facility
Critically ill or injured patient arrives at receiving facility for higher level care

161 CHAPTER

Pediatric Resuscitation

Mohammad Anzal Rehman, Thiagrajan Jaiganesh

INTRODUCTION

Across the world, 6.2 million children under 15 years of age lost their lives in 2018. While this represents a relative decline from previous years (14.2 million in 1990), pediatric mortality remains considerably high, with many deaths still occurring due to preventable causes.

In the United States alone, approximately 20% (28 million of a total of 139 million) of all emergency department visits in 2017 comprised patients aged under 15. Therefore, emergency physicians around the world as frontline healthcare providers have to be proficient in identifying, assessing, and managing critically ill children.

SYSTEMATIC APPROACH TO THE CRITICALLY ILL CHILD

Initial Assessment and Evaluation of the Sick Child

Children are unique. Triage parameters ordinarily implemented for adults may not appropriately gauge the severity of the disease due to their continually evolving anatomy and physiology. Signs and symptoms could be subtle and could easily mask an impending deterioration. Vital signs could be falsely reassuring, and an over-reliance could result in an untoward outcome.

In 2000, the American Academy of Pediatrics (AAP) introduced a unique method of evaluating the pediatric patient: the pediatric assessment triangle (PAT) (**Fig. 1**). The three elements of the triangle: (1) Appearance, (2) Work of breathing, and (3) Circulation, can be used to reliably identify the "sick" child with underlying states of shock and cardiopulmonary compromise.

Assessing PAT could be carried out from a distance without upsetting the child, potentially eliminating the difficulties and confounders associated with examining a crying, fidgety child.

- *Appearance*: Inspect the child's appearance and evaluate the level of consciousness by assessing *T*one, *I*nteractiveness, *C*onsolability, *L*ook/gaze, and *S*peech/cry *(TICLS)*.
- *Work of breathing*: Observe for audible breath sounds (stridor and wheezing), positioning (e.g., sniffing or tripod position can indicate respiratory distress), retractions, breathing patterns, and rate.
- *Circulation*: Assess the child's perfusion status by checking skin color (pallor, mottling, and cyanosis), surface temperature and any signs of bruising or bleeding.

Any abnormality noted in one or more segments of the PAT necessitates immediate action and intervention. If, however, no significant abnormalities are found in the initial impression, subsequent triage, and evaluation should attempt to obtain the following vital sign measurements alongside initiation of the primary survey:

- Respiratory rate
- Blood pressure
- Heart rate
- Temperature
- With the possible inclusion of:
  - Pulse oximetry
  - Point-of-care blood glucose, particularly in children with altered level of consciousness

PRIMARY SURVEY

Proceed with primary survey in children when there is no obvious life-threatening condition on initial impression. The primary survey is designed as a sequential airway, breathing,

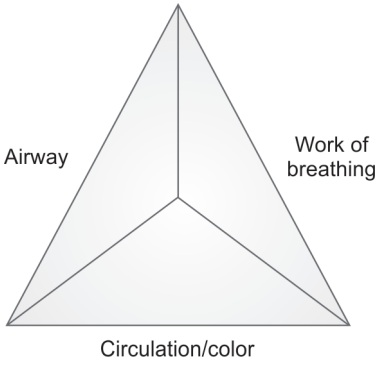

FIG. 1: Pediatric assessment triangle (PAT).

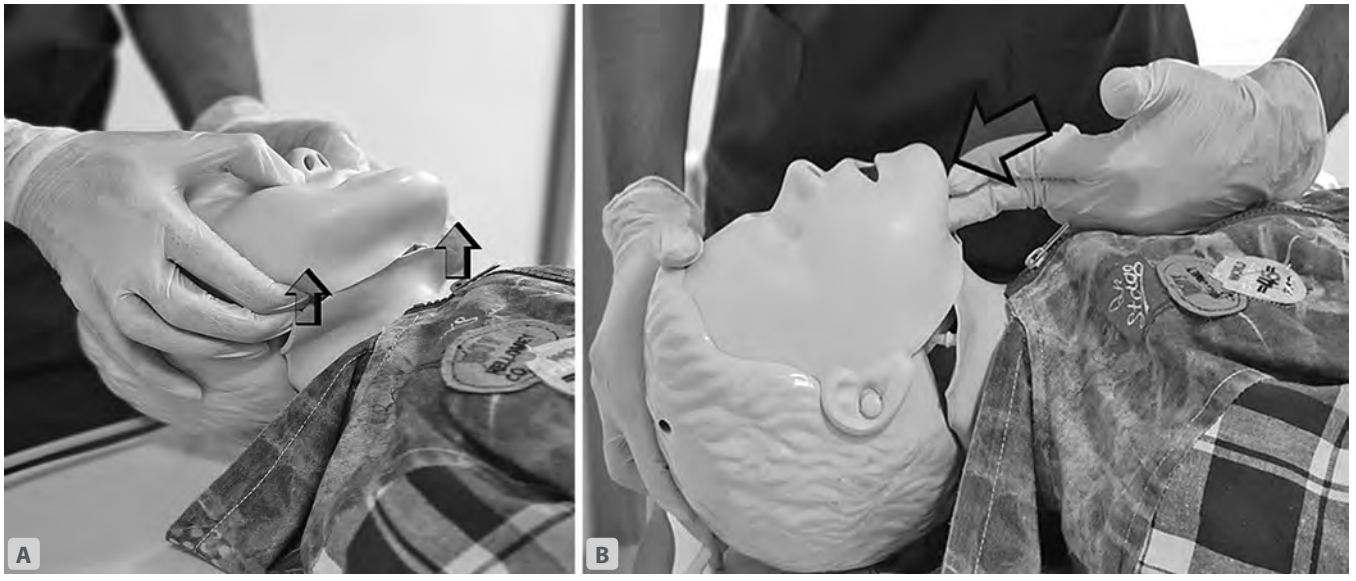


FIGS. 2A AND B: (A) Jaw thrust; (B) head tilt–chin lift.

circulation, disability, and exposure (ABCDE) approach to assessment and evaluation. Note that the correction of any abnormalities identified during the primary survey takes priority over the completion of the survey and/or vital signs measurement.

Airway

Evaluation of the airway primarily revolves around the assessment of its patency. To determine if the airway is patent (open):

- Observe for chest rise or abdominal breathing
- Listen or feel near the mouth and nose for breath sounds or air movement
- Assess for signs of upper airway obstruction such as hoarseness or stridor

If you determine that the patient is not breathing or is gasping, continue with pulse check and proceed with pediatric advanced life support (PALS) protocols for respiratory/cardiac arrest.

If you find signs suggestive of upper airway obstruction, such as increased respiratory effort, retractions, interspersed periods of apnea, abnormal sounds such as snoring or stridor, you may open and maintain the airway using the following interventions:

Simple Measures

- Positioning—a responsive child is made more comfortable with the elevation of the bed. **Figures 2A** and **B** depict the opening of the airway of an unresponsive child, either using the head tilt–chin lift or jaw thrust maneuvers (use this if a cervical injury is suspected). During these maneuvers, apply pressure only on bony prominences as depicted and not on soft tissues. Alternatively, the unconscious child can be turned to their side to aid the airway opening. Assess the effectiveness of any airway maneuver that has been carried out.
- Use appropriately sized airway adjuncts such as oropharyngeal and nasopharyngeal airways to maintain patency. Blood and or vomitus (noisy, gurgling respiratory effort) can be suctioned off under direct vision using a Yankauer catheter to restore airway patency. If a foreign body is suspected as the cause of obstruction, the same can be removed using McGill's forceps and direct laryngoscopy.
- *Foreign body obstruction*: Children <1 year of age can be given five back slaps alternating with five chest thrusts to relieve the obstruction (**Flowchart 1**). In comparison, children >1 year can be given abdominal thrusts (**Flowchart 2**). In the case of an unresponsive patient, proceed with the initiation of the emergency response system, and start basic life support.

Advanced Measures

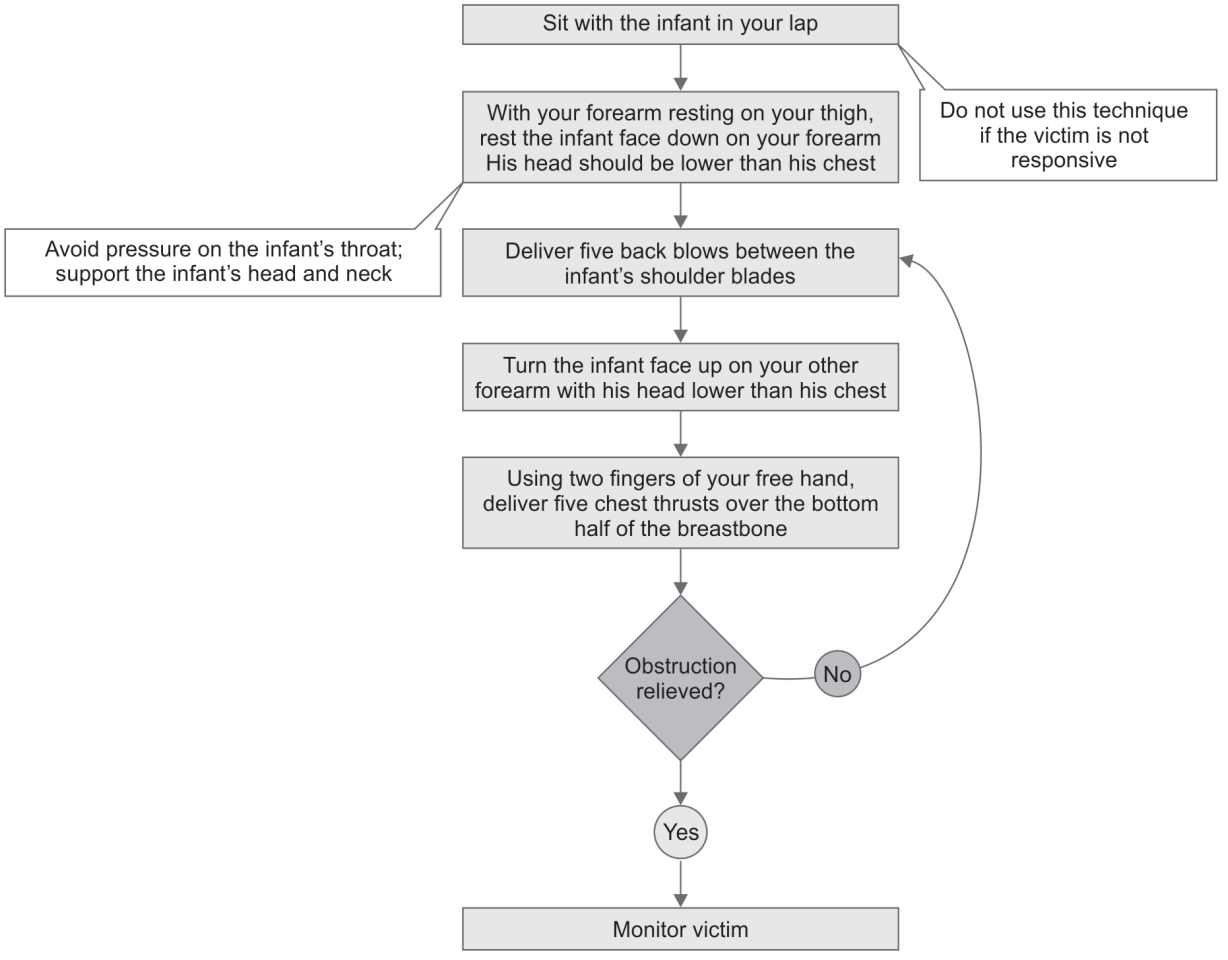
Advanced airway management techniques may be required if the child is unable to protect their own airway and or there is a risk of aspiration. These involve the insertion of an advanced airway devices, such as a laryngeal mask airway or endotracheal intubation and cricothyrotomy and require expertise.

Several anatomic and physiologic differences come into play with the pediatric airway, particularly in the first 2 years of life, compared with conventional variables in an adult airway. These unique characteristics include a large occiput, head, tongue, tonsils, adenoids and stomach, more anterior airway, narrow subglottic region, and small cricothyroid membrane, creating potential challenges during airway management, such as difficulties with positioning, obstruction, vocal cord visualization, and bleeding risk.

Breathing

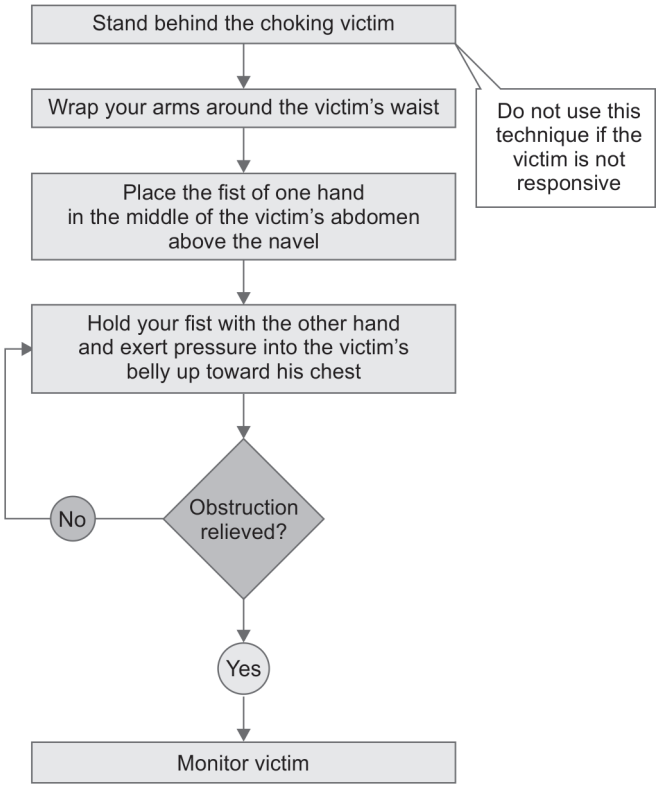
Consider the following components during the assessment of breathing in the pediatric patient:

- Respiratory rate and pattern (normal respiratory rate differs with age)—irregular patterns, fast (tachypnea), slow (bradypnea), or absent respiration (apnea) indicates underlying abnormality and may even signal impending arrest. **Table 1** shows the normal resting respiratory rate for different age groups.
- Increase in respiratory effort—nasal flaring, retractions, head bobbing, or "seesaw respirations" (chest and abdomen



Sit with the infant in your lap
Do not use this technique if the victim is not responsive
With your forearm resting on your thigh, rest the infant face down on your forearm His head should be lower than his chest
Avoid pressure on the infant's throat; support the infant's head and neck
Deliver five back blows between the infant's shoulder blades
Turn the infant face up on your other forearm with his head lower than his chest
Using two fingers of your free hand, deliver five chest thrusts over the bottom half of the breastbone
Obstruction relieved?
No
Yes
Monitor victim

FLOWCHART 1: Infant choking algorithm.



Stand behind the choking victim
Do not use this technique if the victim is not responsive
Wrap your arms around the victim's waist
Place the fist of one hand in the middle of the victim's abdomen above the navel
Hold your fist with the other hand and exert pressure into the victim's belly up toward his chest
Obstruction relieved?
No
Yes
Monitor victim

FLOWCHART 2: Child choking algorithm.

TABLE 1: Normal resting respiratory rate.

Age range	*Normal respiratory rate*
0–12 months	30–60/min
1–3 years	24–40/min
4–5 years	22–34/min
6–12 years	18–30/min
13–18 years	12–16/min

move with inverse proportion during respiration), all of which could imply underlying issues with airway resistance, obstruction or lung compliance.

- Chest expansion and air movement—check for asymmetric chest rise and listen for any sounds of abnormal air entry, such as inspiratory stridor (suggestive of tracheal or laryngeal airway obstruction), expiratory wheezing (suggestive of lower airway obstruction), crackles, or grunting (expiration against a partially closed glottis).
- Central cyanosis is a late sign and occurs when oxygen saturations are below 70%.
- Pulse oximetry may be incorporated here to assess oxygen saturation and guide administration of supplemental oxygen, with care taken to interpret readings in conjunction with your assessment as well as clinical signs and symptoms of the patient.

- CO_2 monitors help to identify hypercapnia which could result in drowsiness or unconsciousness. They help monitor both ventilation and confirm endotracheal tube placement.

Circulation

The approach to assessing circulation involves the evaluation of the following parameters:

- *Heart rate, rhythm, and pulse*: The management of abnormal (tachycardia and bradycardia) or absent pulse (cardiac arrest) is discussed in more detail later in this chapter. Briefly, a central pulse should ideally be assessed. In infants, feel for the brachial artery and in older children feel for the carotid or femoral pulse. Tachycardia can be a sign of pain, respiratory distress, infection, or shock. Bradycardia is often a late sign of shock and suggestive of a preterminal state. **Table 2** depicts the normal heart rate for different age groups. In the absence of a palpable pulse, or a rate of <60 beats/min, chest compressions should be started immediately. This assessment should take no longer than 10 seconds.
- *Central capillary refill time*: Checked over the sternum and normal is <2 seconds.
- *Skin color and temperature*: A change in color (pallor, mottling, and cyanosis) with or without changes in surface temperature can indicate problems with perfusion.
- The blood pressure may be incorporated here, with care taken to reference normal variances with age, usually to check for hypotension, which is an important marker for shock or impending arrest.

TABLE 2: Normal heart rate.

Age range	*Normal heart rate*
0–3 months	80–205/min
4 months–2 years	75–190/min
2–10 years	60–140/min
Over 10 years	50–100/min

TABLE 3: Glasgow coma scale (GCS)—total score/15.

Motor response (best) Score/6	• Spontaneous movement, obeys commands—6 • Localizes pain—5 • Withdraws from pain—4 • Flexion with pain (decorticate) —3 • Extension with pain (decerebrate) —2 • No motor response—1
Verbal response (best) Score/5	• Oriented—5 • Confused—4 • Inappropriate words—3 • Incomprehensible sounds—2 • No verbal output—1
Eye opening score/4	• Spontaneous eye opening—4 • Opens to speech—3 • Opens to pain—2 • No eye opening—1

Disability

This component of the primary survey integrates a rapid assessment of the child's level of consciousness and responsiveness, indirectly correlating with cerebral perfusion and neurologic status.

Two popular methods of pediatric rating level of consciousness are the AVPU (alert, voice, painful, and unresponsive). Response scale and the more widely used Glasgow coma scale (GCS) (**Table 3**).

In addition to the above, pupillary assessment and response to light can provide information regarding brainstem function. Very dilated or pinpoint pupils with sluggish reactions are suggestive of a possible overdose of benzodiazepines or opiates, respectively. Unreactive dilated pupils following trauma may indicate raised intracranial pressure and compression of the ophthalmic nerve. A blood glucose test should be incorporated in this segment to detect and guide management for potential hypoglycemia. Hypoglycemia may present as seizures, while hyperglycemia may present vomiting and malaise or concurrent infection.

Exposure

Finally, all assessments should involve undressing the child to expose and examine the entire body adequately. However, it is crucial to be conscious that children lose heat rapidly due to their high body surface area. Pyrexia and or hypothermia could suggest an infective cause. Petechiae and or purpura could suggest life-threatening bacteremia. Bruising (patterned, multiple areas and stages, particular sites), cigarette burns, etc., could indicate a nonaccidental injury.

Upon completion of the primary survey and when all life-threatening conditions have been addressed, proceed to secondary assessment.

SECONDARY SURVEY

Once a primary assessment is complete, with the child not requiring any immediate action or intervention, evaluation should proceed to the secondary survey, which includes a focused history and physical examination. We are emphasizing repeated assessments for any changes in clinical status during the examination.

Focused history: *SAMPLE mnemonic*:

- *S*igns and symptoms at onset of condition (e.g., dyspnea, fever, and vomiting)
- *A*llergies to food and/or drugs
- *M*edications taken regularly at home and/or accessible to child, including last dose of known medication
- *P*ast medical history—Overview of comorbid conditions, past surgeries, underlying health issues, and immunization status
- *L*ast meal consumed, with time elapsed since up to presentation
- *E*vents leading up to current illness

Focused Physical Examination

Based on the patient's clinical signs and presumed cause of illness, the physician should attempt to focus his examination primarily to areas of suspected dysfunction or injury (e.g., a patient that is in respiratory distress should have an

FIG. 3: Broselow—length-based resuscitation tape.

examination focused around the chest and upper airway, including heart and breath sounds).

Adjuncts to Initial Assessment

Various tools can help provide specific information alongside an evaluation of the critically ill pediatric patient, so long as they do not interfere with or delay emergent intervention. These include, but are not limited to, the following: electrocardiograms (ECG), chest X-rays (CXR), arterial or venous blood gases (A/VBG).

The majority of critically ill children present with conditions that do not allow for conventional measurement of body weight. Therefore, it is recommended to utilize the length-based resuscitation (Broselow tape) (**Fig. 3**) to guide the selection of appropriate medication dosage and equipment size.

PEDIATRIC SHOCK—IDENTIFICATION AND MANAGEMENT

"Shock" is a life-threatening physiologic mismatch between oxygen or nutrient delivery and metabolic demand. Failure to meet cellular demand is usually a consequence of hypoxemia or hypoperfusion. It results in decreased energy production with a concomitant increase in lactic acid, disruption of cellular biochemical pathways, and, eventually, cell death.

Shock is a major worldwide contributor to morbidity and mortality in children, especially those under 5 years of age. In the developing countries, shock most commonly results from sepsis or hypovolemia and is complicated by a significantly higher mortality rate than children who present without shock.

In compensated shock, the body physiologic response allows for the maintenance of end-organ function and normal blood pressure. In uncompensated shock, inadequate tissue perfusion leads to hypotension and end-organ decline. If left untreated, this can progress to organ failure, cardiovascular collapse, and death.

Classification of Shock

Shock can be broadly classified into two categories—(1) distributive and (2) resistive. The major classes of shock are outlined below:

- *Hypovolemic shock* occurs when there is a significant decrease in intravascular blood volume. The two leading causes of reduced blood volume are—intravascular volume loss such as from gastrointestinal (e.g., vomiting and diarrhea secondary to gastroenteritis), skin (e.g., burns), or interstitial (third-spacing) causes. Hemorrhage—from traumatic or nontraumatic bleeding.
- *Distributive shock*: Four major causes of distributive shock are:
  i. Neurogenic shock—neurologic injury resulting in dysfunction of the sympathetic chain of the autonomic nervous system. A consequent parasympathetic-mediated peripheral vasodilation leads to hypotension. Classically, a neurogenic shock is associated with bradycardia and hypotension.
  ii. Anaphylactic shock—mast cell degranulation secondary to allergic trigger causes the release of vasodilatory cytokines
  iii. Drug-induced shock—secondary to vasodilatory effects (e.g., calcium channel blockers) or toxicity (e.g., cyanide toxicity)
  iv. Septic shock—secondary to the severe infectious state. Systemic inflammatory response, immune dysregulation, circulatory compromise, and end-organ deterioration results thereof.
- *Cardiogenic shock* is the inability of the heart to maintain sufficient cardiac output. Pediatric heart failure is often secondary to congenital disease or myocarditis.
- *Obstructive shock* refers to an impedance of blood flow in either the pulmonary or systemic circuit that results in reduced cardiac function. Examples, pericardial tamponade, tension pneumothorax, massive pulmonary embolism, cardiomyopathies, and congenital cardiac defects with outflow tract obstruction.

Recognition of Pediatric Shock

Prompt recognition and early treatment of shock are crucial in children as early intervention is associated with improved outcomes. Children often compensate for shock by increasing heart rate and systemic vascular resistance (delayed capillary refill time) to redirect blood flow toward vital organs.

Point-of-care ultrasonography (PoCUS) can augment the assessment of a shocked child (volume status, cardiac function, and locations of fluid loss in cases of shock secondary to trauma).

Management of Pediatric Shock

The following sections outline key principles of therapy for pediatric shock. Supplemental oxygen, attach cardiac monitor and pulse oximetry. Gain two large bore IV access.

Fluid Resuscitation

Current guidelines recommend isotonic crystalloid solutions as the initial fluid therapy of choice in pediatric shock treatment. At present, no significant difference exists between the use of lactated Ringer's solution and normal saline. Management should proceed with an initial IV bolus of fluid delivered rapidly (push) at 20 mL/kg, with the dose adjusted to 10 mL/kg when a cardiogenic shock is suspected. Additional boluses are given until the patient's perfusion status improves. Care taken to reassess the patient for signs of volume overload frequently (e.g., crackles on lung auscultation or appearance of B lines in lung ultrasound). Although shock may require fluid

up to 200 mL/kg, the shock that persists at 60 mL/kg of fluid therapy would require vasopressor and airway support in the form of endotracheal intubation to improve oxygen delivery and reduce the work of breathing.

Vasoactive Drugs

Initiate vasoactive medications in children with a fluid-refractory shock through an existing peripheral IV site rather than delay administration pending a central venous line placement. The vasoactive drug of choice varies depending on the clinical presentation. However, in general, initial therapy is recommended as below:

- *Cold shock* represents a shock state with decreased cardiac output and increased systemic vascular resistance. First-line vasoactive treatment is with epinephrine (IV infusion: 0.1–1.0 μg/kg/min), with dopamine as a second-line agent (IV infusion: 2–20 μg/kg/min).
- *Warm shock* is less commonly in children than in adults, is characterized by increased cardiac output and decreased systemic vascular resistance. First-line vasoactive therapy is with norepinephrine (IV/IO: 0.1–2.0 μg/kg/min), with dopamine as a second-line agent.

Antibiotics

When a shock is suspected to be secondary to sepsis, broad-spectrum antibiotics are recommended (as per local antibiotic guidelines) as soon as possible, preferably within the first hour of presentation. In a large, multicenter study of adult patients with sepsis, every hour of delay in antibiotic administration for patients in shock was associated with an increase in absolute mortality of 1.8%.

Steroids

A shock that persists despite fluid and vasoactive therapy could have underlying adrenal insufficiency. The use of stress-dose corticosteroids may prove beneficial. Use IV hydrocortisone in these scenarios, given at 50–100 mg/m^2/day (2–4 mg/kg/day), maximum 200 mg/day.

Endpoints of Resuscitation

Rapid recognition and early interventions in pediatric shock have been associated with significantly improved outcomes. Resuscitation protocols instituted by the American College of Critical Care Medicine (ACCM) and PALS are associated with a profoundly lower mortality rate (8% vs. 38%). Current consensus recommends resuscitation to target therapeutic endpoints as follows:

- Early resuscitation should target microcirculatory goals—correcting intravascular volume, mean arterial pressure (MAP), and cardiac output. Response to resuscitation can be followed to therapeutic endpoints by evaluating lactate levels (< 2 mmol/L), and central venous oxygen saturation ($ScvO_2$) <70%.
- Return to clinical baseline as an endpoint can be supported by using the following parameters: capillary refill <2 seconds, normal urine output, warm extremities, baseline blood pressure, mental status, and character of pulse.
- Clinicians are reminded that limitations exist when using the guidelines mentioned above and parameters. They are meant to guide resuscitative efforts but should not be regarded with a "one-size-fits-all" mindset. Management of pediatric shock is most effective when patients' individualized response to therapy guides it. Occasionally tachy- or bradyarrhythmias in children can result in significant symptoms including resultant shock. **Flowcharts 3** and **4** depict how to tackle symptomatic tachycardia and bradycardia.

CARDIOPULMONARY ARREST

The original pediatric Utsein guidelines of 1995 defined cardiac arrest as the "cessation of cardiac mechanical activity, determined by the inability to palpate a central pulse, unresponsiveness, and apnea." Pediatric arrest has been primarily described to occur as a consequence of progression from respiratory failure and shock (**Fig. 4**), contrasted to adult etiologies being mostly of a cardiac cause. However, recent literature suggests a rising significance and number of arrests secondary to a cardiac cause. Therefore, management of cardiopulmonary arrest is ideally designed to be comprehensive, emphasizing reversible causes, and incorporating interventions that will most likely improve outcomes.

Recognition of Cardiac Arrest

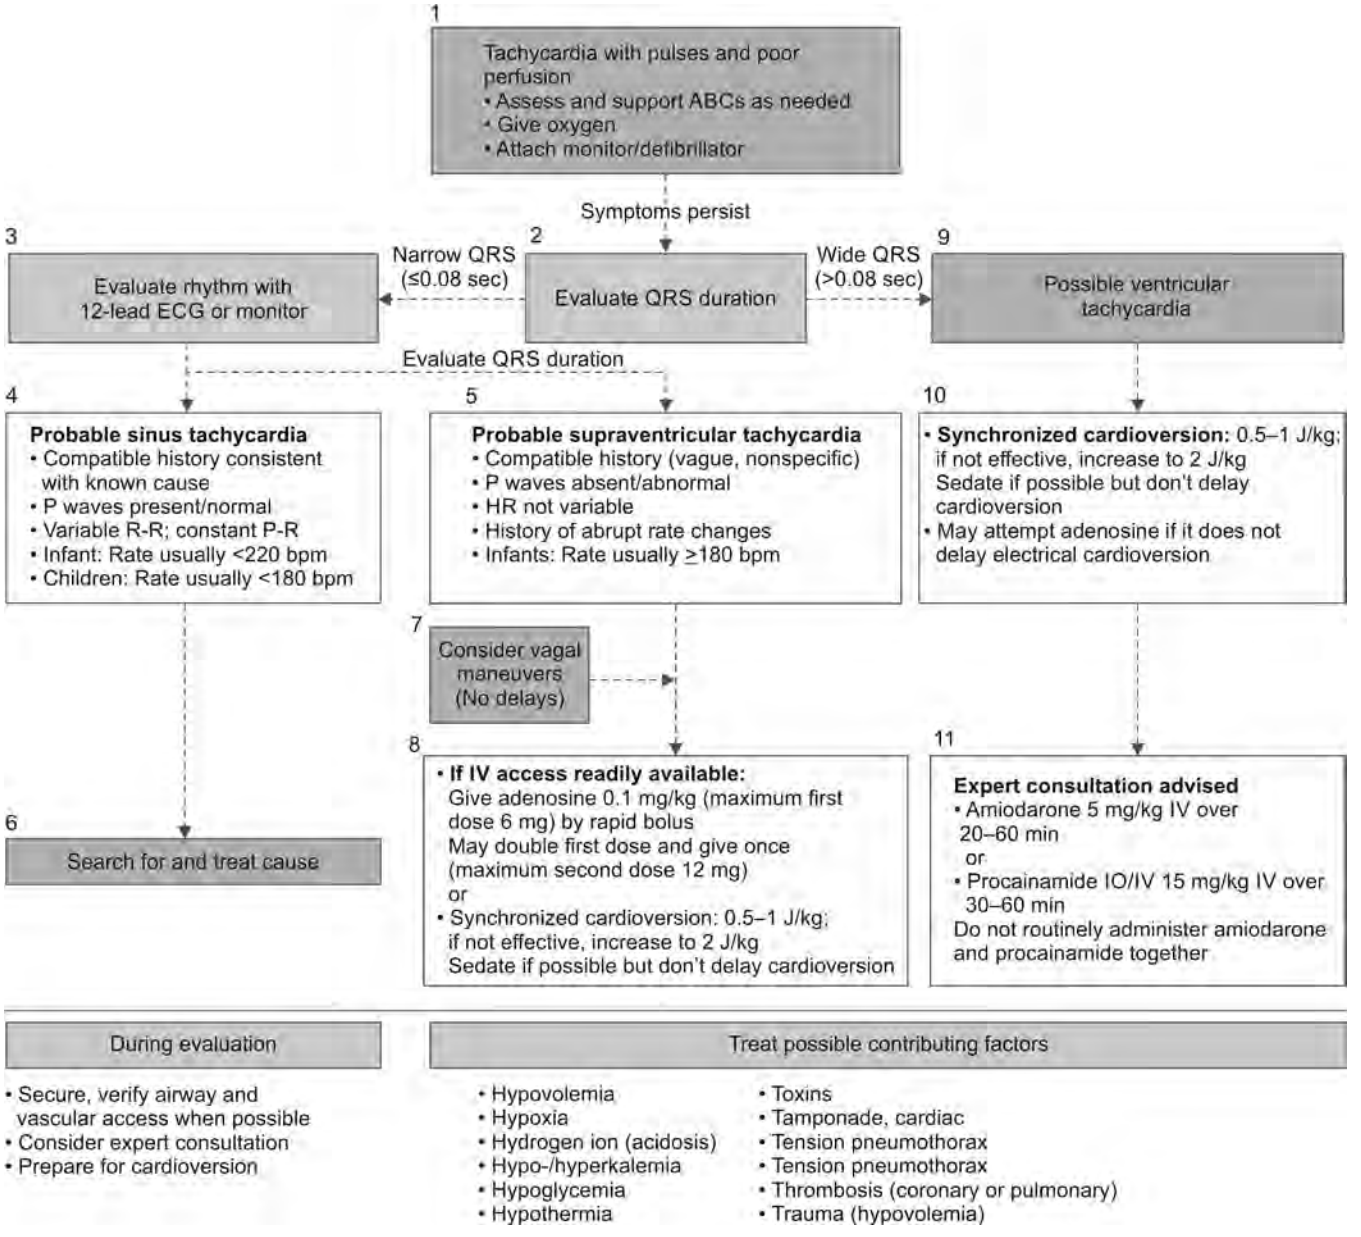
The PALS guidelines recommend assessing the unresponsive pediatric patient by first checking for normal breathing and a pulse. Breathing is ideally assessed by observation for any chest rise for a maximum of 10 seconds while simultaneously palpating for a pulse over the region of the brachial artery for infants and the carotid or femoral artery for children.

- *Respiratory arrest*: If breathing is absent or abnormal (e.g., gasping), but a pulse is present, management consists of providing 12–20 adequate "rescue breaths" per minute (approximately 1 breath every 3–5 sec) over 1 second with visible chest rise. Continue this with a pulse check every 2 minutes to check for progression to cardiac arrest.
- *Cardiac arrest*: Along with absent breathing, if no pulse or a pulse <60 beats/min is palpated, the patient is presumed to be in cardiac arrest, and cardiopulmonary resuscitation (CPR) is initiated after shouting for help and or activating the emergency response system. Start resuscitation using a compressions-airway-breathing (C-A-B) approach, while waiting for the code team to bring the defibrillator.

Compressions

The International Liaison Committee on Resuscitation (ILCOR) and the American Heart Association (AHA) have frequently stipulated the benefits of early, high-quality chest compressions in improving outcomes in cardiopulmonary resuscitation. To ensure compressions result in adequate cardiac output and coronary artery perfusion pressures, most guidelines recommend:

- Minimize interruptions between compressions for ventilation. Give two breaths after 30 compressions (single-rescuer CPR) or 15 compressions (2-person CPR). If possible, do not interrupt CPR for >10 seconds while doing any pulse, rhythm check, or shock delivery (Note: once an advanced airway is in place, chest compressions should be continuous).
- Maintain100–120 compressions per minute



1
Tachycardia with pulses and poor perfusion
• Assess and support ABCs as needed
• Give oxygen
• Attach monitor/defibrillator
Symptoms persist
2
Evaluate QRS duration
Narrow QRS (≤0.08 sec)
Wide QRS (>0.08 sec)
3
Evaluate rhythm with 12-lead ECG or monitor
9
Possible ventricular tachycardia
Evaluate QRS duration
4
Probable sinus tachycardia
• Compatible history consistent with known cause
• P waves present/normal
• Variable R-R; constant P-R
• Infant: Rate usually <220 bpm
• Children: Rate usually <180 bpm
5
Probable supraventricular tachycardia
• Compatible history (vague, nonspecific)
• P waves absent/abnormal
• HR not variable
• History of abrupt rate changes
• Infants: Rate usually ≥180 bpm
10
• Synchronized cardioversion: 0.5–1 J/kg; if not effective, increase to 2 J/kg
Sedate if possible but don't delay cardioversion
• May attempt adenosine if it does not delay electrical cardioversion
7
Consider vagal maneuvers (No delays)
8
• If IV access readily available:
Give adenosine 0.1 mg/kg (maximum first dose 6 mg) by rapid bolus
May double first dose and give once (maximum second dose 12 mg)
or
• Synchronized cardioversion: 0.5–1 J/kg; if not effective, increase to 2 J/kg
Sedate if possible but don't delay cardioversion
11
Expert consultation advised
• Amiodarone 5 mg/kg IV over 20–60 min
or
• Procainamide IO/IV 15 mg/kg IV over 30–60 min
Do not routinely administer amiodarone and procainamide together
6
Search for and treat cause
During evaluation
• Secure, verify airway and vascular access when possible
• Consider expert consultation
• Prepare for cardioversion
Treat possible contributing factors
• Hypovolemia
• Hypoxia
• Hydrogen ion (acidosis)
• Hypo-/hyperkalemia
• Hypoglycemia
• Hypothermia
• Toxins
• Tamponade, cardiac
• Tension pneumothorax
• Tension pneumothorax
• Thrombosis (coronary or pulmonary)
• Trauma (hypovolemia)

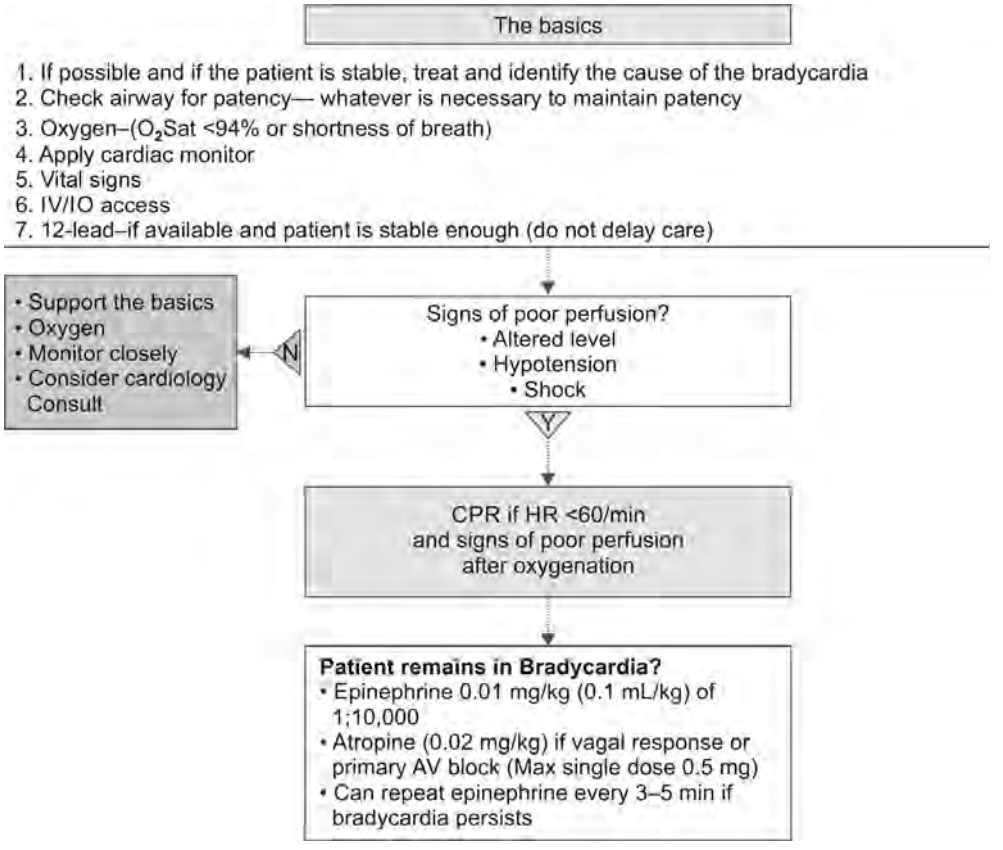
FLOWCHART 3: Pediatric tachycardia.

- Compression force should depress the chest to at least one-third of the anteroposterior diameter (approximately 4 cm deep in infants and 5 cm deep in children)
- Allow complete chest recoil at the end of each compression, allowing the heart to refill with blood
- In infants, if there is only one rescuer use the two-finger technique or the two-thumb-encircling hands technique with thumbs meeting over the lower half of the sternum as shown in **Figure 5A**. In children, the heel of one hand is placed over the lower half of the sternum, with the rescuers' elbows straight and their arm perpendicular to the child's chest. In older children or adolescents, both hands can be used with fingers interlocking **Figure 5B**.

Airway Management

Along with adequate compressions to promote blood flow in patients, an adequate airway is essential to provide sufficient oxygenation and ventilation for the child. Care must be taken to open the airway using the head tilt–chin lift and jaw thrust maneuvers described earlier, as well as ensures adequate seals for bag-valve-mask ventilation (BMV). Consider the following when managing the airway during pediatric resuscitation:

- *Avoid excessive ventilation*: Increased positive pressures from hyperventilation decrease venous return and result in lower cardiac output and reduced coronary perfusion pressures. Give each breath over 1 second and follow guidelines for the number of breaths given during resuscitation.
- Waveform capnography is useful in confirming endotracheal tube placement and predicting the return of spontaneous circulation (ROSC).
- An advanced airway, such as an endotracheal tube, allows for decreased subsequent interruptions during chest compressions. However, a systematic review from 2019 focused on comparing BMV versus endotracheal intubation use for out-of-hospital cardiac arrest (OHCA)



The basics
1. If possible and if the patient is stable, treat and identify the cause of the bradycardia
2. Check airway for patency— whatever is necessary to maintain patency
3. Oxygen–(O_2Sat <94% or shortness of breath)
4. Apply cardiac monitor
5. Vital signs
6. IV/IO access
7. 12-lead–if available and patient is stable enough (do not delay care)
Signs of poor perfusion?
• Altered level
• Hypotension
• Shock
N
• Support the basics
• Oxygen
• Monitor closely
• Consider cardiology Consult
Y
CPR if HR <60/min and signs of poor perfusion after oxygenation
Patient remains in Bradycardia?
• Epinephrine 0.01 mg/kg (0.1 mL/kg) of 1;10,000
• Atropine (0.02 mg/kg) if vagal response or primary AV block (Max single dose 0.5 mg)
• Can repeat epinephrine every 3–5 min if bradycardia persists

FLOWCHART 4: Pediatric bradycardia.

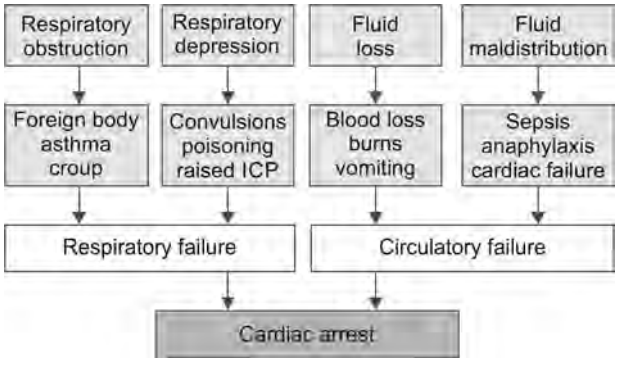


FIG. 4: Etiologies of cardiac arrest in children.

showed no significant difference in good neurological outcome or survival to hospital discharge between both groups. Therefore, it is reasonable to continue with BMV, at least during OHCA, rather than expedite the establishment of an advanced airway.

Defibrillation and Shockable Rhythms

Defibrillation in a pediatric arrest is not associated with improvements in survival outcomes similar to those seen in adults. However, early intervention remains an essential component in the management of shockable rhythms during pediatric resuscitation. Ventricular fibrillation is a chaotic irregular waveform which is never associated with cardiac output. Ventricular tachycardia (broad complex tachycardia) in the absence of a pulse is a shockable rhythm.

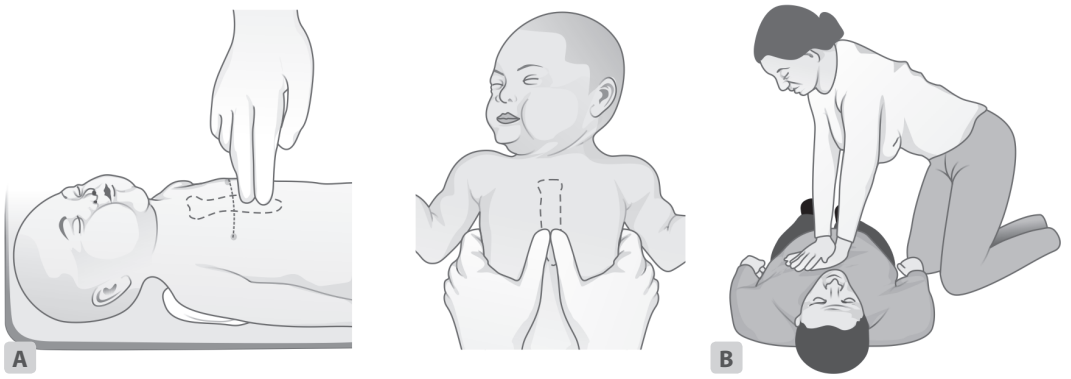
Initiate defibrillation as early as possible when an automated external defibrillator (AED) detects a shockable rhythm during CPR. In an in-hospital setting, attach the patient to a cardiac monitor. It allows the physician to identify a shockable rhythm upon CPR initiation or during pulse and rhythm checks between compressions.

Pulseless Electrical Activity and Asystole

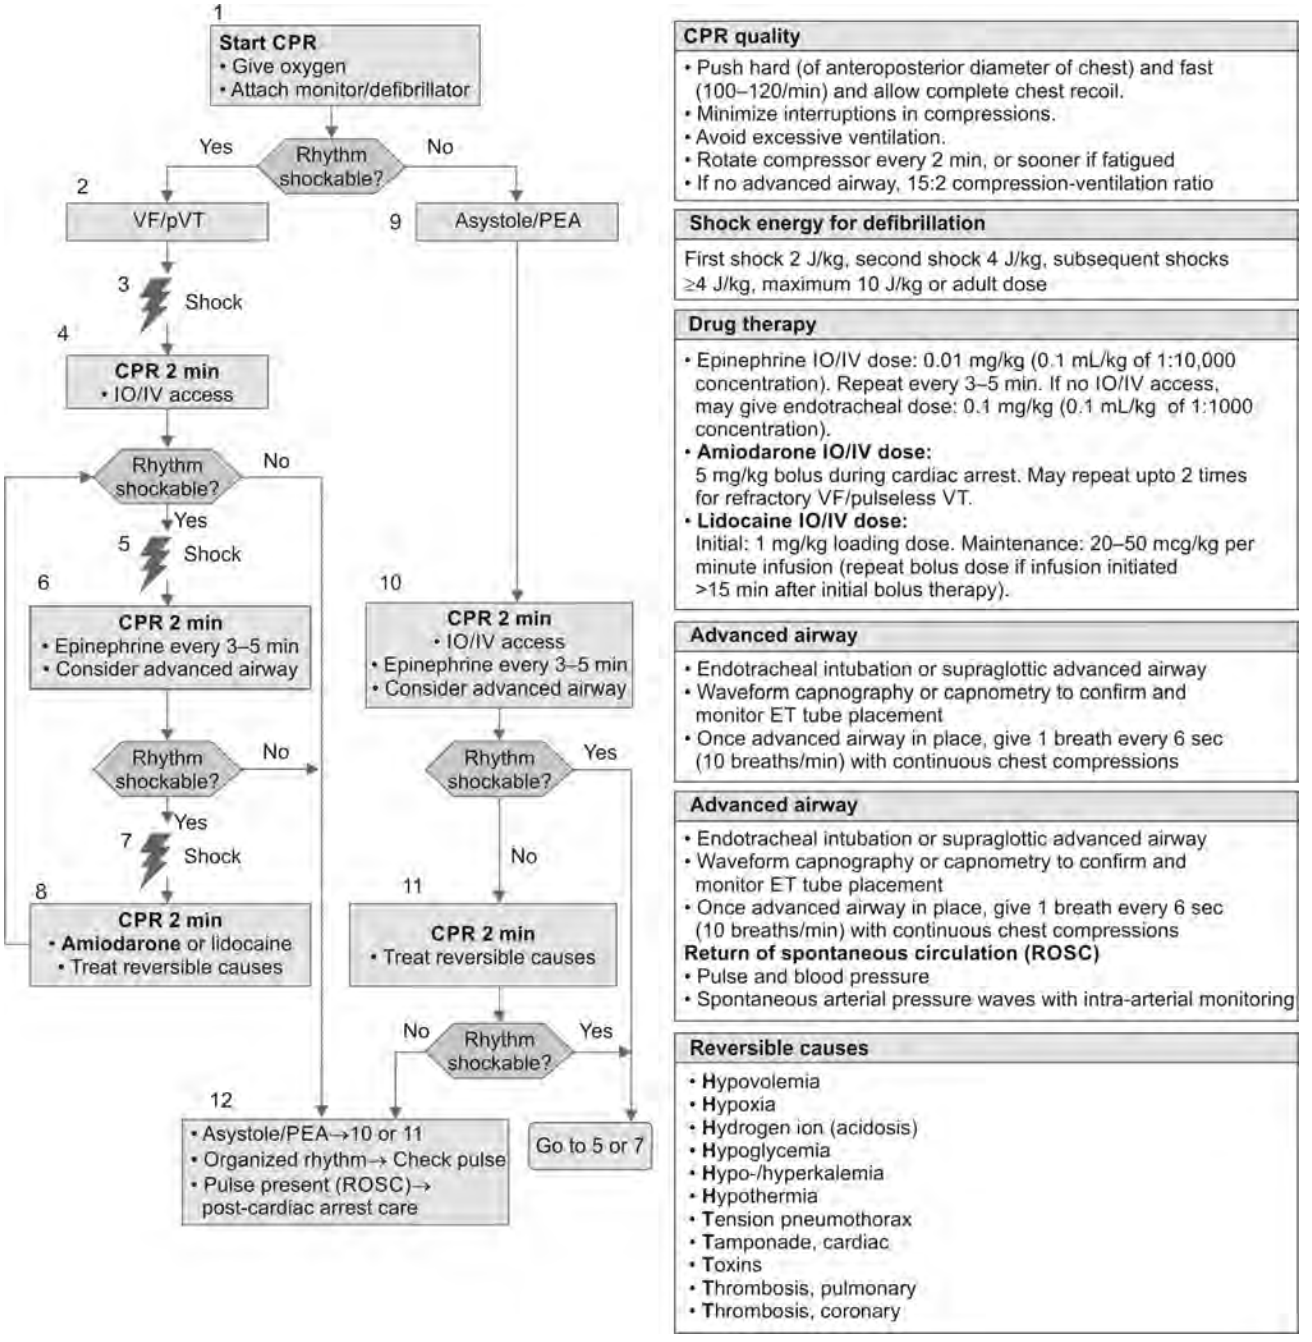
Nonshockable rhythms are managed primarily with compression cycles as described in **Flowchart 5**, with epinephrine administered at regular intervals to promote coronary and cerebral perfusion pressures. During resuscitation, it is important to review and address any potentially reversible causes, denoted by the H's and T's described in the PALS algorithm (**Flowchart 5**). Recognizable complexes in the absence of signs of life and a pulse are known as pulseless electrical activity. Asystole is most commonly seen in children after prolonged period of hypoxia and appears as a wavy line on a cardiac monitor. If a completely flat line appears on the cardiac monitor, check the equipment for any disconnection.

Postarrest Care

Following the successful ROSC, CPR is discontinued but resuscitation continues in the form of postarrest care. It is



FIGS. 5A AND B: (A) Chest compressions in infants; (B) chest compressions in adolescents.



1
Start CPR

• Pulse present (ROSC)→ post-cardiac arrest care
Go to 5 or 7
CPR quality
• Push hard (of anteroposterior diameter of chest) and fast (100–120/min) and allow complete chest recoil.
• Minimize interruptions in compressions.
• Avoid excessive ventilation.
• Rotate compressor every 2 min, or sooner if fatigued
• If no advanced airway, 15:2 compression-ventilation ratio
Shock energy for defibrillation
First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥4 J/kg, maximum 10 J/kg or adult dose
Drug therapy
• Epinephrine IO/IV dose: 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3–5 min. If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1000 concentration).
• Amiodarone IO/IV dose:
5 mg/kg bolus during cardiac arrest. May repeat upto 2 times for refractory VF/pulseless VT.
• Lidocaine IO/IV dose:
Initial: 1 mg/kg loading dose. Maintenance: 20–50 mcg/kg per minute infusion (repeat bolus dose if infusion initiated >15 min after initial bolus therapy).
Advanced airway
• Endotracheal intubation or supraglottic advanced airway
• Waveform capnography or capnometry to confirm and monitor ET tube placement
• Once advanced airway in place, give 1 breath every 6 sec (10 breaths/min) with continuous chest compressions
Advanced airway
• Endotracheal intubation or supraglottic advanced airway
• Waveform capnography or capnometry to confirm and monitor ET tube placement
• Once advanced airway in place, give 1 breath every 6 sec (10 breaths/min) with continuous chest compressions
Return of spontaneous circulation (ROSC)
• Pulse and blood pressure
• Spontaneous arterial pressure waves with intra-arterial monitoring
Reversible causes
• Hypovolemia
• Hypoxia
• Hydrogen ion (acidosis)
• Hypoglycemia
• Hypo-/hyperkalemia
• Hypothermia
• Tension pneumothorax
• Tamponade, cardiac
• Toxins
• Thrombosis, pulmonary
• Thrombosis, coronary

FLOWCHART 5: Pediatric cardiac arrest algorithm—2015 American Heart Association update.

designed to treat the underlying pathologies in the patient, while systematically optimizing the following parameters:

- *Oxygenation*: Supplemental oxygen is titrated to achieve SpO_2 of 94–98% in order to avoid both hypoxemia and hyperoxemia in the resuscitated patient.
- *Ventilation*: $PaCO_2$ is maintained at 35–50 mm Hg to prevent hypo- and hypercapnia.
- *Circulatory support*: Primarily aimed at preventing hypotension. IV fluids are the mainstay along with vasopressor support as needed.
- *Temperature*: Evidence suggests no significant difference in neurologic outcome between therapeutic normothermia versus induced normothermia. However, there is a clear benefit to neurologic recovery in avoidance of hyperthermia. Therefore, guidelines recommend targeting temperatures between 32°C and 36° C with an emphasis on avoiding the emergence of fever during postarrest care.

In addition to the above, it is recommended to monitor blood glucose regularly and maintain modest euglycemia. Extracorporeal membrane oxygenation (ECMO) is feasible, especially in children with congenital heart disease.

OVERVIEW OF NEONATAL RESUSCITATION

Newborn or neonatal mortality contributes to an estimated total of 2.5 million deaths annually, with most of these deaths occurring in low-resource countries. Fortunately, organization, and implementation of standardized neonatal resuscitation protocols can be used to improve neonatal and perinatal outcomes in these settings.

Approximately 1 out of 10 newborns will require some form of resuscitation at birth. Less than 1% requires cardiac compressions and medications. A large number of cases are complicated by the presence of inappropriate oxygenation and or breathing at birth, termed birth asphyxia due to contractions that push the baby through the birth canal. Newborn babies are far more likely to need resuscitation due to respiratory cause rather than a cardiac one as before birth, the baby's lungs are filled with fluid. Therefore, all healthcare providers present during the delivery of infants have to be well-versed in strategies to recognize and manage situations requiring resuscitation of the neonate.

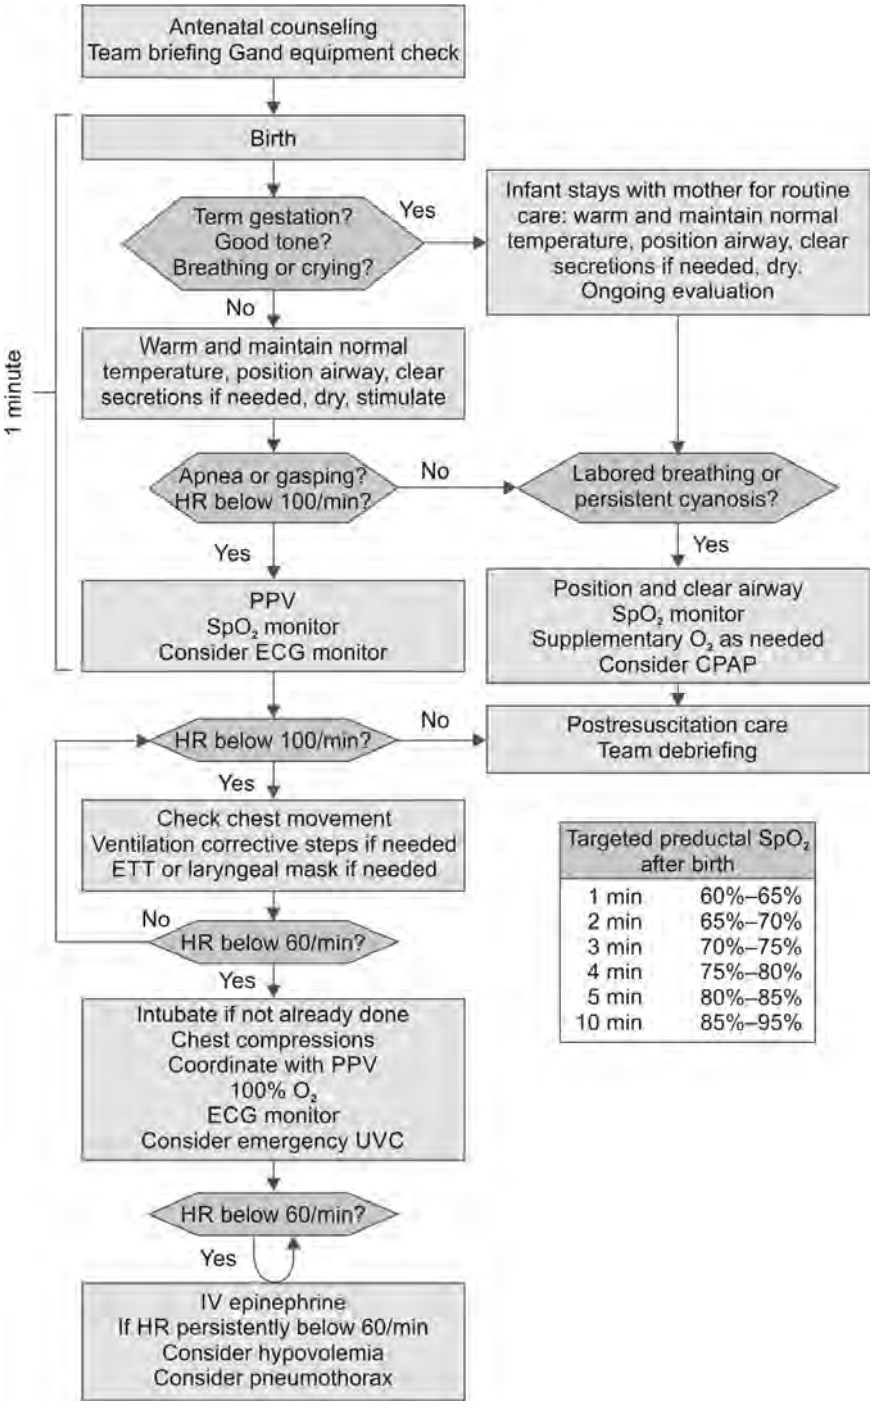
Prepare for delivery by anticipating perinatal risk and organizing the environment. Effective communication with immediate access to essential supplies and at least one person dedicated to the care of the newborn should be present in the delivery room. Care of the term infant upon delivery with good tone and normal breathing and or crying proceeds by drying the baby and placing them skin-to-skin with the mother. Observe breathing, activity, and color. Delayed cord clamping beyond 30 seconds is reasonable in these infants. Delayed cord clamping is associated with less need for transfusion, less necrotizing enterocolitis, and intraventricular hemorrhage (IVH) of any grade.

If, however, the infant is not of a term gestation or does not have an appropriate tone or breathing on delivery, they are placed in a radiant warmer, with interventions listed below in order of execution, alongside the regular assessment of the baby's heart rate (preferably using 3-lead ECG), respirations, and oxygen saturation:

FIG. 6: Optimal airway positioning of the newborn.

- Stabilize initially and prevent hypothermia by warming (wet babies lose heat rapidly), rub the baby dry to stimulate spontaneous breaths or crying, position to open airway [neutral position—place a folded towel under the shoulders (**Fig. 6**)]. Preterm babies may require a plastic wrap, cap, radiant warmer, adjusted room temperature, thermal mattress, and warm humidified gases to prevent hypothermia. Take extreme care not to overextend the neck as this may compromise the baby's soft airway. Clear secretions (blood, meconium, or other fluid) from mouth and nose by gentle suctioning as appropriate. Suctioning offers additional respiratory stimulation. In nonvigorous infants with meconium- stained amniotic fluid, routine intubation for tracheal suction is not recommended.
- If, despite the above, there is abnormal breathing or a heart rate below 100 beats/min (using a stethoscope is the most accurate method of assessing the heart rate), begin rescue breathing within 1 minute of an initial assessment. Use positive pressure ventilation (soft face mask and t-piece or self-inflating bag valve) and oxygenate using room air or supplemental oxygen with SpO_2 monitoring (titrate to achieve a preductal oxygen saturation approximating the interquartile range), possibly including positive end-expiratory pressure (PEEP) of 5 cm H_2O. The chest wall should be seen to rise. Continuous positive airway pressure may be considered in infants with persistent abnormal breathing but has not been shown to affect the need for intubation or mechanical ventilation significantly.
- If heart rate persists below 100, reposition the airway, and optimize ventilation and consider an advanced airway. The most sensitive indicator of a successful response to each step is an increase in heart rate. If low heart rate drops below 60 beats/min, initiate chest compressions using the two-finger or two-thumbs-encircling hands techniques with 3 compressions to every 1 breath. If chest compressions have been started, increase oxygen concentration to 100%. Coordinate compressions and ventilations to avoid simultaneous delivery.
- Seek expert help if not already requested. Persistent deterioration should prompt administration of IV or IO epinephrine at 0.01–0.03 mg/kg (or 0.05–0.1 mg/kg through the endotracheal tube), volume replacement (10 mL/kg of fluid or blood), investigation, and management of other possible causes of arrest, such as pneumothorax.

The neonatal resuscitation program (NRP) algorithm shown in **Flowchart 6** highlights the steps discussed above. Postresuscitative care should be conducted in an environment that allows for close monitoring and observation, emphasizing recognition and prevention of hypoglycemia, and a possible role for therapeutic hypothermia to improve neurologic outcomes in newborns > 36 weeks of gestation. If there is no improvement in the baby's condition after drugs are given, the outcome will be poor. A decision to stop resuscitation is painful, and prolonged attempts are unlikely to be successful. It is acceptable and appropriate for the baby's parents to witness the resuscitation attempts as it helps with the grieving process.



(CPAP: continuous positive airway pressure; ECG: electrocardiography; ETT: endotracheal tube; IV: intravenous; HR: heart rate; PPV: positive pressure ventilation; UVC: umbilical vein catheterization)

162
CHAPTER

Examination of Newborn

Nilu Sunil, Devendra Richhariya

INTRODUCTION

In today's modern world of high technology imaging and sophisticated laboratory examinations, we forget about the power of a thorough physical examination in detecting medical issues. In this chapter, we will discuss normal newborn examination, importance of knowing normal versus abnormal findings and discuss some common and not so common findings on the newborn examination.

Whenever the parent's perception that something is wrong with the newborn infants they may present to the emergency department for a various reason. The role of the emergency physician is important to recognize abnormality and, if no abnormality detected, address the concerns of the parent. It is very important to differentiate conditions that are self-limited or are variants without physiologic consequence from potential to worsen. Illness in the newborn is often subtle and early detection can be lifesaving. Therefore, the emergency physician should be familiar and comfortable with performing a newborn examination. Because of the time constraints in the emergency department, it may not be possible to complete physical examination, a systematic approach can allow a thorough examination in a matter of minutes (**Table 1**). Main focus should be on general wellbeing, heart lung, and abdomen. Complete neurological examination often not required and assessment of two to three of the primitive reflexes (such as the Moro reflex and sucking reflexes) and observing for spontaneous movement of the limbs will give a good sense of the neurological status of the child.

GENERAL EVALUATION

Before the start of a physical examination of a baby by simply watching a newborn and assessing the indicators of the wellness by a clinician is very important. General examination of a baby starts by observing the baby in the bassinet or in a parent's arms. Labored breathing and persistent crying are often the first indicators of signs of distress and impending problem. Generally during examination, newborn infant will often be soundly asleep, moaning or grunting during sleep may have underlying illness and should be evaluated. Baby

TABLE 1: Head-to-toe approach for normal newborn examination.

Head	• Shape • Fontanel • Lesions/swelling
Eyes	• Red reflex • Extraocular movement • Pupillary shape/size
Ears	• Positioning • Tags
Nose	Nasal patency
Mouth	• Palate • Dentition • Oral lesions
Neck	Swelling/cysts
Chest	• Asymmetric chest rise with respirations Retractions • Accessory respiratory muscle use
Lungs	• Symmetric air entry • Breath sounds
Heart	Murmur
Abdomen	• Hepatosplenomegaly • Cord vessels at birth
Genital	• Inguinal masses • Testicular/scrotal asymmetry • Genital hypertrophy/lesions • Rectal patency
Extremities	• Tenderness • Extremity use/range of motion • Additional digits/tags hip click
Neurology	• Tone • Suckling • Palmar/plantar • Moro

should be vigorous and alert and crying should be energetic and strong when awakened. Observe position of newborn, a newborn, full-term child will lie with his or her upper and lower extremities flexed inward thus showing good tone. Extremities observed in extended form from the body showing decreased tone in a premature or impaired child. Observe movement of the extremities and each limb should have spontaneous movement.

VITAL SIGNS

One of the most challenging parts of pediatric examination is recognizing normal versus abnormal vital signs because of variability in the ''normal'' ranges of values. In determination of significant abnormalities, other clinical indicators should be correlated with the vital signs. Temperature should always be included in the vital signs of newborn, temperatures >38°C are associated with increased risk of serious bacterial illness (sepsis, meningitis, urinary tract infection, enterocolitis, and osteomyelitis) in infants <2 months of age. Fever is a red flag for infection and detail work-up is required. Hyperthermia may be a manifestation of drug withdrawal, intracranial hemorrhage, or adrenal hemorrhage. Hypothermia may also be indicators of sepsis; but also associated with hypoglycemia, hypothyroidism, and hypoxia.

For evaluation of the newborn, height, weight, and head circumference (occipital frontal circumference or OFC) are critical very important and provide clues about potential problems or abnormalities. Assessment of weight is very important and the average weight of a term neonate at birth is 3.4 kg. Small or large for gestational age (SGA or LGA, respectively) of the infants can be determined by standardized growth charts, and are considered appropriate for gestational age (AGA) if they are within two standard deviations from the mean.

Physical characteristics of the neonate including skin creases, external genitalia, ears, breasts, and neuromuscular development are also taken in the account for estimation of gestational age. Further detailed evaluation of the child is required on the basis of LGA or SGA status for other possible anomalies. SGA is associated with serious congenital anomalies in infants. LGA infants may be associated with familial inheritance, large parents will often have large infants. Maternal weight gain during pregnancy (diabetes in the mother) is most common may translate into an LGA infant.

Head

The newborn head shows a great degree of variability in the ''normal'' examination, as well as a large number of findings that are due to molding in the vaginal canal and birth trauma. Normal variants and benign birth trauma finding should be differentiated from true pathological lesions. A brief review of anatomy reveals that the newborn skull ''neurocranium'' is composed of eight bones and facial skull is composed of 14 irregular bones, at birth each bone is separated by fibrous webs, known as suture lines. There are total of six fontanels in addition to the anterior and posterior fontanels, there are two pairs of lateral fontanels known as the sphenoidal or anterolateral fontanels and the mastoid or posterolateral fontanels. The four lateral fontanels generally fuse in infancy, posterior fontanel begins to close after the first few months and is generally not appreciable by 1 year of age. The anterior fontanel is generally closed by 18 months of age. Sutures are generally closed by age 12, but complete fusion continues until into the third decade. Head growth is primarily driven by brain growth, the neurocranium expands to allow more room. Brain growth is at a tremendous rate in utero and until during the first 3 years of life. At birth, the infant brain is about 40% of adult volume. By age 3, it has reached nearly 80% and by age 7 it is at 90% of adult size.

Eyes

A pediatrician often examines the red reflexes of the eye (for retinoblastoma), the red reflex can give much more information apart from tumors. A white reflex of eye (leukocoria), associated with many other conditions including cataracts, retinal detachment or dysplasia, papillary membranes, and vitreous opacities and requires referral to an ophthalmologist for further evaluation. In addition to examining for leukocoria, the clinician can look for colobomas, examine the pupillary reflex, and look for strabismus using the ophthalmoscope.

Ears

Cranial molding from birth can move the ears into various positions, so molding should be taken into account when examining the ears. One should examine the ears for their position, noting low-set ears, as this has been associated with several syndromes, and malformation of the auricle. Preauricular pits or skin tags are common, and often are hereditary and need no further work-up unless present with other anomalies. Hereditary preauricular pits can be associated with deafness, ear anomalies can be associated with genitourinary anomalies and this should be followed up with the physician as the infant grows. Additionally, as such a renal ultrasound is generally indicated in these patients.

Mouth

Several normal and benign findings such as natal teeth and Epstein's pearls are present in mouth of a normal child. Natal teeth are any teeth which erupt before 30 days of life (1 in every 3,000 births) and mostly involve mandibular central incisors. They are similar to normal teeth; lack a substantial root system often fall out on their own at some point. There is no need to remove them unless there is risk for aspiration of the tooth (loosen or come out of its own) or if the tooth prevents proper feeding. Epstein's pearls and Bohn nodules (yellowish or white and slightly raised) giving the appearance of a pearl are common findings in neonates. Bohn nodules are located on the alveolar ridges, and Epstein pearls are those located near the midpalate raphe at the junction of the hard and soft palates. They are remnants of embryonic development of the dental lamina and will resolve without treatment. Cleft lip and palate are most common anomaly of the head and neck in newborn. Surgical correction should be considered early in cases of poor nutritional intake and abnormal speech development. Surgery often produces very good cosmetic results also. Most clefts are quite obvious upon examination, can be identified visually, and the clinician is able to palpate the cleft using a finger to examine the upper palate of the infant.

Neck

One of the common (third most common) musculoskeletal anomalies of infants is congenital muscular torticollis. It follows behind clubfoot and dysplasia of the hip and can have an incidence upward of 1 in 250 live births. The exact cause is unknown; but commonly associated with breech and forceps deliveries. In approximately two-thirds of cases, a mass can be felt in the affected sternocleidomastoid muscle. Infants present as head flexed and the chin facing the direction opposite the affected muscle, contracture of the muscle can lead to plagiocephaly with abnormal placement of the eye and ear on the affected side. Physical therapy is generally therapeutic. In rare cases, surgical release of the sternocleidomastoid muscle is needed. If the torticollis is not corrected by age 1, plagiocephaly tends to be persistent. The neck should be examined for any pits or other anomalies such as branchial cleft anomalies, cysts, or sinuses. These branchial arch remnants will be found in the pinna of the ear, the preauricular area, or the lateral neck. When present, these anomalies may be associated with systemic syndromes such as Goldenhar syndrome, Pierre-Robin association, Treacher–Collins syndrome, and Hallermann–Streiff syndrome. A midline neck lesion may represent a thyroglossal duct cyst or cervical cleft.

SYSTEMIC EXAMINATION

Chest

Clavicle fractures are one of the most common chest birth injuries, with an incidence 0.2–3.5%. Clavicle fracture identified by crepitus in the clavicular region on palpation, radiograph confirms the fracture. Clavicular fractures heal well, even in the presence of significant angulation thus no further intervention is required. Assess for symmetry and equal chest excursion as well as adequacy of air exchange while examining the lungs of a newborn. Assess the indicators of respiratory distress while examination of the lungs, e.g., assessment of the respiratory rate, nasal flaring, grunting, or retractions. After cesarean section deliveries (in 0.3–0.5% of newborn) present with tachypnea, increased oxygen requirements, and a lack of hypercapnia on blood gas, the condition is called transient tachypnea of the newborn (TTN). Recovery is the rule, few infants may require ventilatory assistance for a short period of time. Respiratory distress typically will present a few hours after birth and resolves in 24–72 hours.

Cardiovascular

The cardiovascular exam can be difficult in a newborn because of their often rapid heart rate. To briefly review neonatal physiology of the heart, one must have a basic understanding of fetal cardiac physiology. Before birth, lungs are not used for oxygenation, pulmonary pressures are high and blood is returned to the systemic side of blood circulation after shunted through the foramen ovale and the ductus arteriosus. At the time of birth, many changes occur, such as decrease in pulmonary pressures to allow blood to flow through the lungs and closure of the foramen ovale. The ductus arteriosus typically closes 10–15 hours after birth. Full permanent fusion may take 3 weeks. Auscultation of the heart sounds of a neonate typically reveals a single S1 and a single, or very slightly split, S2 because of the continued relatively high pulmonary pressures. Once pulmonary pressures fully drop to their baseline in 4–6 weeks, the S2 becomes more physiologically split. Typically, S1 is louder near the apex of the heart and S2 is louder near the base. An S3 may be heard near the apex and is considered normal. S4 is never normal in a newborn. If a murmur is detected in the emergency department that is concerning for pathology, evaluation is warranted. This should include a chest X-ray and an electrocardiography (ECG) and echocardiography. If abnormalities are found, the neonate should be admitted for further evaluation. If no abnormalities are detected and the child appears well, follow-up with a pediatric cardiologist as an outpatient is reasonable.

Abdomen

In examining the abdomen, the clinician should assess for typical abdominal components, such as palpation for enlarged liver spleen or kidneys. Abdominal palpation is best accomplished using the flats of the fingers rather than the tips, as they are more sensitive to masses and so forth. The liver is often felt approximately 1 cm below the costal margin. This degree of extrusion is considered normal. As a general rule, spleen is only palpable when enlarged. An enlarged spleen with prolonged or severe jaundice should alert the clinician and should evaluate for Rh or ABO incompatibility or other red cell morphological defects such as spherocytosis and other hemolyzing states. While attempting to palpate for an enlarged spleen, one can also palpate for enlarged or cystic-feeling kidneys. The umbilical cord should be inspected to ensure the presence of a single umbilical vein and two umbilical arteries (higher incidence of severe renal anomalies and renal malformation in infants with single uterine artery). A scaphoid abdomen and respiratory distress at birth should raise concern for a congenital diaphragmatic hernia (CDH) (absence of a scaphoid abdomen does not rule out CDH). When the possibility of CDH exists, the infant should be intubated in an effort to prevent the swallowing of air that occurs with spontaneous breathing or with bag-valve mask ventilation. Air in the intestines will lead to worsening respiratory distress as the expanding intestines further compress the lungs and mediastinum. The differential diagnosis for hepatomegaly (a liver edge palpable beyond 3.5 cm below the costal margin is considered enlarged) in a neonate is quite extensive. First, true hepatomegaly is important to recognize. Palpation of the liver edge and percussion of liver span should be performed to ascertain the liver size. Start palpating the liver edges from the lower quadrants to ensure that extreme hepatomegaly is not missed. At 1 week of age, a normal liver span is 4.5–5.0 cm. An enlarged edge below the costal margin in the presence of a normal liver span may be caused by depression of the liver downward due to lung hyperinflation or other anatomical causes. Once hepatomegaly is confirmed, other important finding should be noted to ascertain underlying causes such as presence or absence of jaundice, splenomegaly, and other physical anomalies or systemic symptoms

Genitourinary Tract

Several anomalies can be found when evaluating the genitourinary tract. GU anomalies such as inguinal hernias, hydroceles, varicoceles, undescended testes, or signs of hypospadias and other urethral anomalies are found in both male and female newborns, thus a thorough examination is

important to identify any such findings that may exist. When an inguinal hernia (they can present as a bulge in the inguinal area or may have palpable bowel in the scrotum) is identified, light, constant pressure should be applied to the herniated bowel to reduce the bowel back into the abdomen. Sometime bowel may become nonreducible. This represents an incarcerated hernia and is a surgical emergency. Incarceration of an inguinal hernia may compromise blood flow to the intestines or the scrotal contents resulting in damage to the end organ. Female newborns are also susceptible to inguinal hernias although the male: female ratio is 6:1. Hydroceles are most commonly present at birth, although they rarely can arise later (resolve in 12–28 months duration). Transillumination can be used to aid in the diagnosis of a hydrocele as they tend to easily and uniformly light up, although bowel can occasionally transilluminate as well, making the distinguishing of the two difficult at times. Hydroceles do not extend into the inguinal canal. Varicoceles (almost always on left side) result from dilation of the pampiniform plexus and internal spermatic vein, they can be easily reducible or spontaneously with supine positioning. Any varicocele that does not reduce or is located on the right side should be evaluated by ultrasound, as failure to reduce is an indication of a possible blockage in venous drainage. This may be the result of an abdominal mass. At birth, full-term boys will experience an undescended testis (cryptorchidism) about 3–4% of the time. By age 1, only 0.3% persist. If one fails to locate a testis in the scrotum, examination of the inguinal canal area should be performed. True undescended testes cannot be manually drawn into the scrotum on examination. By 6 months of age, if testes have not descended down into the scrotum, will require intervention by surgical orchiopexy but hormonal treatment with human chorionic gonadotropin (hCG) can also be attempted. Undescended testes should be brought into the scrotum by intervention as this allows for better examination for malignancy (seminomas are most commonly seen) as they have a 4 to 10 times higher risk than descended testes. In girls, congenital adrenal hyperplasia (CAH) is the leading cause of ambiguous genitalia. During examination of the genitalia, the clinician should evaluate for clitoromegaly, micropenis, bifid scrotum, or fusion of the labia resulting in a scrotum-like appearance. Increased pigmentation of the skin can be seen with CAH because of increased adrenocorticotropic hormone (ACTH) concentrations in an attempt to stimulate cortisol production.

Extremities

All four extremities should be examined for any anomalies. Examine for presence/absence of any supernumerary digits in both hands and both feet. Polydactyly is an isolated finding mostly, but may be associated with other malformations. While spontaneous occurrences are frequent, a family history of polydactyly yields up to a 10-fold increase in occurrences. Polydactyly of the fingers is the second most common anomaly of the hand. Simple skin tag that can be removed by tying a suture at the base to a fully formed digit and more complex digits require surgical removal. Single palmar crease is associated with several syndromes, most notably Down syndrome. Talipes equinovarus (clubfoot) is a relatively common deformity (1 in 1,000 live births). Bilateral involvement occurs in 30–50% of cases. Male to female ratios are 2:1 Lknm. Clubfoot is a complex anomaly. It is composed of four main components: (1) The forefoot is inverted and adducted, (2) The heel and hindfoot are inverted, (3) Limitation of extension at the ankle and subtalar joint, and finally (4) Internal rotation of the leg. Inability to bring the foot fully to midline on physical examination. Progressive serial casting is attempted initially for correction, if needed, surgery is generally performed between 6 and 9 months.

Neurological

An extensive neurological examination can be quite time-consuming; however, all infants should receive at least a limited neurological examination including tone, primitive reflexes, and a gross assessment of muscular/sensory status and cranial nerves (CNs). Summary of primitive reflexes can be found in **Table 2**. A systematic neurological approach is helpful in older children, begin with a general assessment, followed by CNs, motor function, sensory function, and reflexes. A good assessment of neurological status can often be obtained simply by careful observation of the infant. Observe movements of the face for symmetry. Arms and legs should be to assessed for active movement. At birth, full-term infants show a flexed posture of the extremities and have the ability to raise their

TABLE 2: Common primitive reflexes.

Rooting reflex	Touch newborn on either side of cheek and baby turns toward stimulus
Walking reflex	Hold baby up in vertical position. As feet touch ground, baby makes walking motion
Tonic neck (fencing) reflex	Rotate baby's head leftward and the left arm stretches into extension and the right arm flexes up above head (opposite reaction if head is rotated rightward)
Moro reflex (startle reflex)	Hold supine infant by arms a few inches above bed and gently release infant back to elicit startle. Baby throws arms out in extension and baby grimaces
Hand-to-mouth (babkin) reflex	Stroke newborn's cheek or put finger in baby's palm and baby will bring his fist to mouth and suck a finger
Swimmer's (gallant) response	Hold baby prone while supporting belly with hand. Stroke along one side of spine and baby flexes entire torso toward the stroked side
Palmar	Stroke inner palm/sole and toes/fingers curl around ("grasp") examiner's finger
Plantar	Stroke outer sole (Babinski) and toes spread with great toe dorsiflexion
Doll's eyes	Give one forefinger to each hand (baby grasps both) and pull baby to sitting with each forefinger. Eyes open on coming to sitting (like a doll's)
Protective reflex	Soft cloth is placed over the baby's eyes and nose. Baby arches head, turns head side to side, and brings both hands to face to swipe cloth away
Crawling reflex	Newborn placed on abdomen and baby flexes legs under as if to crawl

heads in the vertical midline plane, although they may still be quite unsteady. Movements of the extremities should be generally smooth without a significant amount of jerking. The cry should be strong and vigorous. Often neurological problems will produce an altered cry such as a weak cry or a particularly high-pitched cry. CN assessment can begin with the examination of eyes. An infant's neurological system has developed enough by 28 weeks to produce a blink when a bright light is shone in the eyes (CN II and VII). The papillary reflex develops (CN II and III) between 28 and 32 weeks. CN V can be tested via corneal reflex or with light touch/pin prick to the trigeminal branch areas producing a withdrawal from the stimulus. Testing of CN II, III, IV, and VI can be performed by observing fixation and tracking of large objects by full term infants (dysconjugate gaze is not abnormal when a neonate is not fixing on an object). Facial asymmetry may be suggestive of facial nerve lesion. Eye blink on loud noises testing CN VIII. CN IX and X are tested by swallowing reflex. Fasciculations of the sternocleidomastoid muscle or tongue may represent a lesion involving CN XI or XII, respectively. Generally detailed CNs examination is not required unless there is suspicion of any abnormalities. Sensation testing is generally limited to light touch and pinprick testing. During the entire newborn examination, the clinician can be assessing the response of the baby to touch (infants commonly reacts to the stethoscope touching their chest). Motor examination can be assessed by observing spontaneous movement of the head and extremities, as well as muscular tone. Neonatal hypotonia is the most common abnormal neurological sign seen in neonates. It is associated with a wide array of disorders. Hypotonia can be divided into central and peripheral origins. Central hypotonia tends to be associated with other central nervous system (CNS) findings. Down syndrome and Prader-Willi syndromes are associated with hypotonia. Hypoglycemia, hypothyroidism, hypoxic-ischemic encephalopathy, infection, and metabolic disorders are the other important causes should be considered for hypotonia. Often, central causes of hypotonia become more classic of CNS lesions resulting in increased tone, increased reflexes, and so forth. Possible neck hyperextension in utero or during delivery gives rise to transection of the spinal cord should also be considered. Peripheral hypotonia presents without any specific central signs, e.g., spinal muscular atrophy, neonatal myasthenia gravis, and infantile botulism. Infant spinal muscular atrophy, also known as Werdnig-Hoffman syndrome or SMA type 1, can present with hypotonia at birth (in 60% of cases), weakness, poor suck, and absent reflexes. This is due to anterior horn cell degeneration. Neonatal myasthenia gravis occurs in infants born to mothers with myasthenia gravis. The acetylcholine receptor antibodies readily cross the placenta and can attach to the infant's receptors producing a myasthenic phenotype. Signs of bulbar weakness including a weak suck and cry, hypotonia, absence of a Moro reflex, and respiratory insufficiency can develop up to 72 hours after delivery. Treatment is with acetylcholinesterase inhibitors as in adults. Symptoms generally resolve by about 12 weeks of age as the maternal antibodies are cleared. The brachial plexus is formed from the C5-T1 nerve roots. Palsies involving this plexus are divided into three main types. Erb's palsy involves the C5, C6, and occasionally C7. Klumpke palsy involves C8 and T1. The third type involves the complete plexus. Erb's palsies present with the affected upper extremity in the classic ''waiter's tip'' position. Klumpke palsies yield a paralyzed hand with full function of the elbow and shoulder. This palsy is rare, comprising only 0.5% of all brachial plexus injuries. The range of resolution relates to the actual injury to the nerve roots. Mild cases generally are the result of the brachial plexus nerve roots being stretched, termed neurapraxia. In these cases, prognosis is excellent. The most severe cases result when the nerve root is avulsed from the spinal cord, known as axonotmesis. These cases have no chance for spontaneous resolution and surgical correction often does not yield good outcomes. Fortunately, 80–95% of cases (primarily Erb's palsies) will resolve spontaneously over the course of a few weeks to months. If, on physical examination, there is difficulty in determining if the infant does not move the area because of pain (as a result of a clavicular fracture, for example) or a palsy, the Moro reflex can be used. In cases of palsies, the Moro will result in asymmetric movement.

Skin

Newborn babies exhibit a plethora of skin findings. These findings are visible and cause of concern and alarming to parents and result in emergency department visits. Newborns often experience some degree of vasomotor instability that can present in several ways, including cutis marmorata, harlequin color changes, and acrocyanosis. Cutis marmorata is a condition resulting from uneven distribution of capillary blood flow presents as mottled appearance to the skin and often can be induced by cold exposure. Harlequin color changes are precipitated by turning the baby on the side commonly seen in low-birth-weight newborn and resolve during first few weeks. When this is done, the lower half of the baby becomes erythematous or dusky while the upper half becomes pale. Often there is a sharp demarcation between zones. This typically resolves within a few seconds after returning to the supine position but can persist for up to 20 minutes. Acrocyanosis is nonpathological condition (bluish color to the hands, feet sometimes lips) due to pooling of venous blood. This condition is exaggerated with cool temperatures and resolves with warming and resolves as vasomotor stability improves. Erythema toxicum (central flesh-colored papule with surrounding erythema at the base) is extremely common, affecting up to 50% of full-term infants. It typically presents in the first 2–3 days of life and typically resolves in 5–7 days. Biopsy is generally not needed but would show the presence of eosinophils. Its etiology is not well known at this point. Less common is neonatal pustular melanosis, which affects approximately 5% of black infants and <1% of white infants. The pustules are always present at birth or form within the first 24 hours of life. Following pustule formation, the pustules rupture leaving the classic collarettes of scaly skin and hyperpigmentation. 40% of newborn will have milia, most commonly found on the nose. They represent small cysts filled with keratinocytes and sebaceous debris. They may also be seen on other areas of the body.

Nevus simplex is a blanching macule that is typically pink or red in color found commonly on glabella and posterior neck. When located on the glabella, they are commonly referred to as angel kisses, and when located on the posterior neck, they are often termed stork bites but they may be found anywhere along the midline from the eyes to the nape of the neck and they fade with time, but not completely. Nevus simplex should be distinguished from a nevus flammeus or ''portwine stain.'' Port-

wine stains do not tend to resolve much spontaneously. Laser treatment can help reduce their appearance. In particular, a nevus flammeus that involves the ophthalmic and maxillary regions of the trigeminal nerve (unilaterally or bilaterally) may be associated with Sturge-Weber syndrome that can have CNS involvement and lead to seizures. Port-wine stains that involve the face and/or upper extremity with hypertrophy of the affected side may have a condition termed Klippel-Trenaunay. Dermal melanoses (Mongolian spots) are bluish black areas of hyperpigmentation often found on the buttocks, back, and shoulders. They are extremely common in darker skinned babies, fade with age. These spots can be confused with bruising and have resulted in evaluation for abuse in some cases. Hyperpigmented macule cafe´ au lait spot (light brown in color) is another common skin finding on examination of skin. A few cafe´ au lait macules are normal; however, the presence of many macules or a very large macule may indicate the presence of a systemic disease such as neurofibromatosis type 1 or McCune-Albright syndrome, respectively.

SUMMARY

Complete physical examination is highly reliable for screening of illness in infants despite the broad technologic advancements of medicine. It is important for the emergency physician to have a thorough understanding of abnormal findings but also the normal findings and their variants. The vast majority of infants are healthy and findings predictive of future health problems are subtle and infrequent. Yet, outcomes can be devastating. Therefore, it is critical for the physician to remain diligent during screening.

163
CHAPTER

Crying Infant

Prabhat Maheshwari, Upasana Iyer

INTRODUCTION

Crying is a normal response to many stimuli in nonverbal children. It gives a clue to the child's physiological state ranging from normal needs of hunger and sleep to significant pathology. Healthy children cry for about 3 h/day on an average at 6 weeks of age with the peak occurrence between 3 PM and 11 PM. The cry is labeled as abnormal depending on the duration and its inconsolable nature. Excessive crying usually would present in concert with other manifestations of disease or distress such as fever, vomiting, rash, and trauma. However, it can be challenging for evaluation when it is the sole presentation. A systematic and appropriate history and physical examination coupled with a suspicion for a broad range of medical possibilities need to be considered for proper evaluation. Crying is one of the most common indications for seeking medical attention by parents in the first 3 months of life. The studies have reported a range of 0.25–13.6% of all annual emergency department (ED) visits for crying infant. Although most of the times, the etiology is benign and is self-limiting, excessive crying is associated with considerable parental anxiety and stress.

WHAT IS CRY?

A cry is a series of four movements that basically resembles a Valsalva maneuver. Crying has an effect on various organs of the body both immediately as well over the long run.

NORMAL AND EXCESSIVE CRYING

Crying in infant is a part of normal neurodevelopment. It follows a typical curve that peaks during 6th week of age with a mean duration of 110–118 min/day and declines to <1 h/day by 12 weeks of age. In the first week, following birth crying concentrates in late afternoon. Preterm neonates experience their peak at 6th week corrected age, thus have delayed peak. Due to specific age-related pattern, it has been thought to correlate with the development of circadian rhythm. Wessel's *''rule of threes''* states that crying in an otherwise healthy baby aged 2 weeks–4 months that occurs >3 h/day, >3 days in any week for at least 3 weeks may be called excessive crying. Based on above, infants are divided into three groups: (1) Contented, (2) Paroxysmal fussers, and (3) Seriously fussy. Infants meeting the above criteria are grouped as paroxysmal fussers and those not fitting the definition are grouped as contended. Seriously fussy infants are those whose paroxysmal fussing episodes continued for >3 weeks.

ETIOLOGY

An infant cries to shut out painful or disturbing stimuli, communicates hunger, thirst, boredom, fatigue, fussiness, injury, pain, indigestion, and displeasure. Organic diseases account for <5% of infants with excessive crying. The importance of distinguishing crying due to pathologic causes from benign causes needs to be emphasized. As the presentation is so nonspecific, the list of differential diagnosis is exhaustive. It is helpful to use a system-based approach while tacking such an infant. List of various etiologies is enlisted in a systematic approach in **Table 1**.

PATHOPHYSIOLOGY

The cry is one of the most potent distress signals the infant has to offers. It is designed to elicit a maternal response that will change the infant's physiologic condition or provide caregiving. Infant's cry activates the anterior cingulate area of a woman's brain, suggesting the involvement of neuroanatomic control in her response to an infant's cry. There are four phases of crying (**Fig. 1**)—(1) Inspiration (stress phase), (2) Inspiratory gap, (3) Pause, and (4) Expiration. Overall crying gives rise to various immediate and long-term effects (**Table 2**).

FEATURES OF CONCERN (RED FLAG SIGNS)

While evaluating a crying infant, it is important to look out for warning or red flag signs, which indicate toward life-threating condition and warrant urgent management. **Table 3** enlists various such signs.

PREHOSPITAL CARE

Most often the crying infant may present to the ED with their caregivers, but occasionally the ED can be called upon for dispatch of an ambulance. In the latter situation, the

TABLE 1: Etiologies of crying in infant.

System	*Causes*
Nonpathological	Lack of sleep, hunger, discomfort form soiled nappy, nappy rash, extreme temperature, sudden stimulation from light or sound, and parental variables
Head, eyes, ears, nose and throat	Trauma, corneal abrasion, foreign body, glaucoma, otitis media, oral thrush, stomatitis, and panniculitis
Cardiovascular	Congestive cardiac failure, supraventricular tachycardia, endocarditis/myocarditis, and myocardial infarction
Pulmonary	Upper respiratory tract infection, foreign body aspiration, pneumothorax, and pneumonia
Gastrointestinal	Constipation, anal fissure, hemorrhoids, bowel obstruction, intussusception, malrotation/midgut volvulus/ Hirschsprung's disease, milk protein allergy, GERD/esophagitis, celiac disease, appendicitis, and peritonitis
Genitourinary system	Testicular torsion, incarcerated inguinal hernia, balanitis/posthitis/ balanoposthitis, hydrocele, urinary retention, and urinary tract infection
Musculoskeletal	Fracture, osteomyelitis, arthritis, rickets, dactylitis, and vaso-occlusive crisis
Neurological	Raised intracranial pressure (hydrocephalus, mass, hemorrhage, and cerebral edema), meningitis/ encephalitis, and neonatal drug withdrawal
Dermatological	Insect bite, burns, cellulitis, atopic dermatitis, and mastocytosis
Metabolic	Hypoglycemia, electrolyte imbalance, inborn errors of metabolism, hyperthyroidism, toxic ingestion, and carbon monoxide poisoning
Others	Hunger, immunization, and abuses
Etiologic Mnemonic for crying Infant "IT CRIES" I—Infection, T—Trauma, C—Cardiac Disease, R—Reflux, Reaction to medicines, I—Intussusception, E—Eyes (corneal abrasion), S—Surgical emergency (strangulation, torsion, and hernia)	

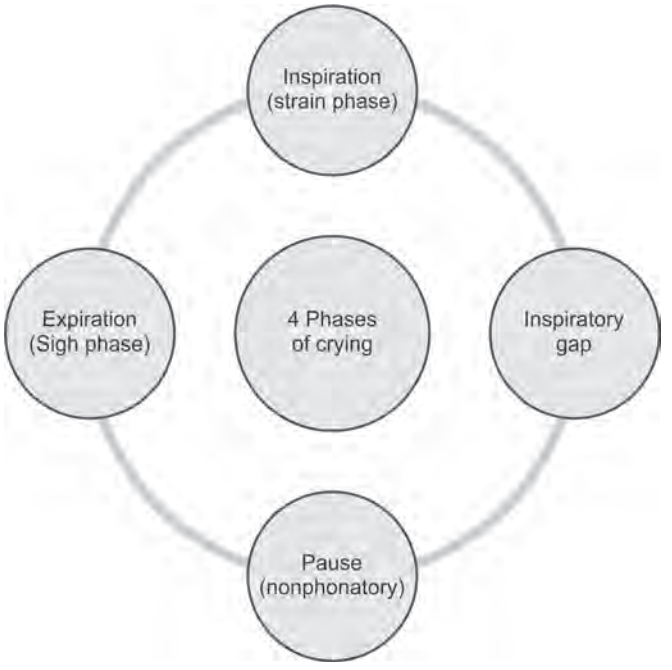

FIG. 1: Phases of crying.

TABLE 2: Sequelae of crying.

Immediate effect	*Long-term effect*
• Increase in heart rate: ○ Slight cry—170 bpm ○ Moderate cry—185 bpm ○ Hard cry—200 bpm ○ Prolonged cry—>200 bpm • Increase in systolic and diastolic blood pressure and fall in pulse pressure • Fall in arterial oxygen level • Fluctuations in cerebral blood flow and intracerebral pressure • Increase in cortisol level • Leukocytosis • Aerophagia and abdominal distension • Disruption of interaction with caregiver	• Hypoxic brain injury and intraventricular hemorrhage • Patent foremen ovale contributing to exertion and focus for stroke • Mother-infant distress syndrome

ED personnel should follow the standardized stabilization protocol while assessing these infants. Considering the heightened parental concern, appropriate assessment of airway, breathing, circulation, and necessary basic interventions such as oxygen administration, intravenous access, fluid administration, and bedside glucose testing should be initiated. The detailed information about the presenting episode from the caregivers and vital sign assessment can be done en route. Desist from providing false reassurances to caregivers and discouraging them from ED visit as there can be a possibility of serious underlying illness in these infants.

TABLE 3: Red flag signs in a crying infant.

Findings	*Possible causes*
Lethargy	Hydrocephalus, meningitis, sepsis, and subdural hematoma
Fever	Acute otitis media, appendicitis, bacteremia, endocarditis, meningitis, osteomyelitis, pneumonia, sepsis, urinary tract infection, and viral respiratory infection
Abdominal distension	Abdominal mass, hepatosplenomegaly, Hirschsprung's disease, intestinal malrotation with volvulus, and necrotizing enterocolitis

EVALUATION OF CRYING INFANTS IN EMERGENCY DEPARTMENT

A detailed history and a through physical examination are of utmost importance while evaluating a crying infant. Infants who continue to cry during the examination should be reevaluated during normal period.

History

Parents are excellent observers and should be asked for subtle signs and symptoms. The following points should be sought after while taking history from parents/caregivers—duration, frequency, intensity and periodicity of crying, aggravating and relieving factors, comorbid medical condition, recent vaccination, feeding and sleep behavior, sibling and family history infant-mother relationship, and maternal fatigue.

Determining the triggers for excessive crying in infants is like solving a puzzle. A comprehensive and detailed history is the key in the assessment of these patients. A good history has been reported as diagnostic in 20–86% of cases, either alone or in concurrence with examination findings.

Nevertheless all resuscitative measures must be performed prior to detailed history taking process. Relevant history to include duration, frequency, and intensity of crying episodes with aggravating and relieving factors and details of any prior evaluations in this respect. Assess for the different crying patterns to get clinical cues:

- High-pitched cry indicates infection of central nervous system.
- Continuous cry with grunting may indicate foreign body or respiratory infection.
- Crying with pulling of ears indicates otitis externa/media.
- Sporadic crying pattern with pallor and undrawn knees over abdomen may indicate intussusception.
- Paroxysmal crying in otherwise healthy infants of <4 months age usually during evening indicates infantile colic.

The points need to be specifically noted are as follows: Birth history, including birth weight, perinatal complications, and maternal substance use during pregnancy. Detailed feeding history, sleep behavior, bowel, and bladder patterns. History of past illnesses, medication use, vaccination. Comorbid medical conditions. Social history. Family history of any congenital or genetic disorders.

Physical Examination

Initial physical examination should aim to assess and identify general condition of the infant to determine if there exists a life-threatening condition associated with incessant crying.

All the vital parameters to be checked and recorded and a thorough whole-body inspection should be done. Studies have proven that physical examination either alone or in addition to history can contribute to diagnosis in >50% cases.

A complete head-to-toe examination to be systematically done. Important considerations while examining the infant are as follows:

- *Head and neck*:
  - Examine the eye for congestion/corneal abrasion; a study by Shope et al., in 2010 found that nearly 50% of infants presenting to primary care center had corneal abrasions.
  - Examine the external ear and perform otoscopic examination to rule out otitis media.
  - Oropharyngeal pathologies are not so common as a cause for crying but presence of trismus should raise a suspicion for peritonsillar abscess or deep neck space infection.
- *Nervous system*:
  - Persistent irritability and high-pitched cry points toward central nervous system cause such as meningitis or encephalitis. Appropriate history, clinical examination, and requisite investigations to be considered for ruling out these serious pathologies.
  - Evaluate for occult head injury especially in infants suspected to have nonaccidental injuries by relevant examination and imaging.
  - A bedside glucose measurement is a minimally invasive test to detect hypoglycemia as the cause for excessive crying.
- *Thorax*:
  - Clavicular fractures may occur during delivery when there is a history of difficult delivery, shoulder dystocia, or when the neonate is large for gestational age.
  - Presence of bony crepitus on palpation should raise a suspicion for rib fractures and also for nonaccidental trauma.
  - Examination of breast tissue for abscess/mastitis
  - Examine for cardiac arrhythmias. Infants with congenital heart diseases may also present with poor feeding, fussiness, irritability, and excessive crying.
- *Abdomen*:
  - Infantile colic affects around 10–30% of infants. It has been defined as episodic paroxysmal crying for >3 h/day for >3 days a week for up to 3 weeks in an otherwise healthy infant aged from 2 weeks to 4 months.
  - Many studies have proven that constipation is one of the common causes of crying infant, history and careful palpation of abdomen to be performed to rule out constipation. Rectal examination may be considered if mandated by clinical suspicion.
  - Paroxysmal crying episodes associated with intermittent flexing of lower extremities with or without bloody stools must raise a suspicion for intussusception.
  - Palpate for an abdominal mass in the right upper quadrant in a poorly feeding infant and history of nonbilious vomiting to rule out pyloric stenosis.
  - Urinary tract infection can also be the reason for excessive crying in an infant and careful evaluation regarding the same to be carried out.
  - Consider evaluation for midgut abnormalities including malrotation/volvulus in an ill looking infant.
  - Examine for inguinal hernia as there is around 60% risk of hernia becoming incarcerated in the first 6 months of life.
- *Extremities*:
  - Examine for joint swelling, tenderness, erythema, and any restriction of range of movement to rule out septic arthritis.
  - In infants of <1-year age have high index of suspicion for nonaccidental injury in cases of suspected or detected fractures.

- *Skin*:
  - Complete exposure of the infant and evaluation for bruises and ecchymosis. The most common sites are anterior tibia, knee, or forehead. However, bruises on face and trunk are rare and their presence should raise a concern for abuse.
  - Burn injuries in the patterned shape of hot objects (like cigarettes), bilateral glove and stocking pattern (suggestive of immersion injuries) should prompt an evaluation for infant abuse. Accidental scald injuries due to spill over of hot liquids tend to usually affect the face, neck, upper limbs, and anterior trunk and are usually asymmetrical and have irregular edge and burn depth.

Interpretation of Findings

Detailed observation of a crying infant gives clues into the underlying condition. For example, a continuous cry associated with grunt points to an underlying respiratory tract infection or foreign body. High-pitched incessant cry indicates a central nervous system etiology, screaming while pulling ears indicates acute otitis media and intermittent bout of crying with knee drawn up over abdomen is suggestive of intussusception.

INVESTIGATIONS

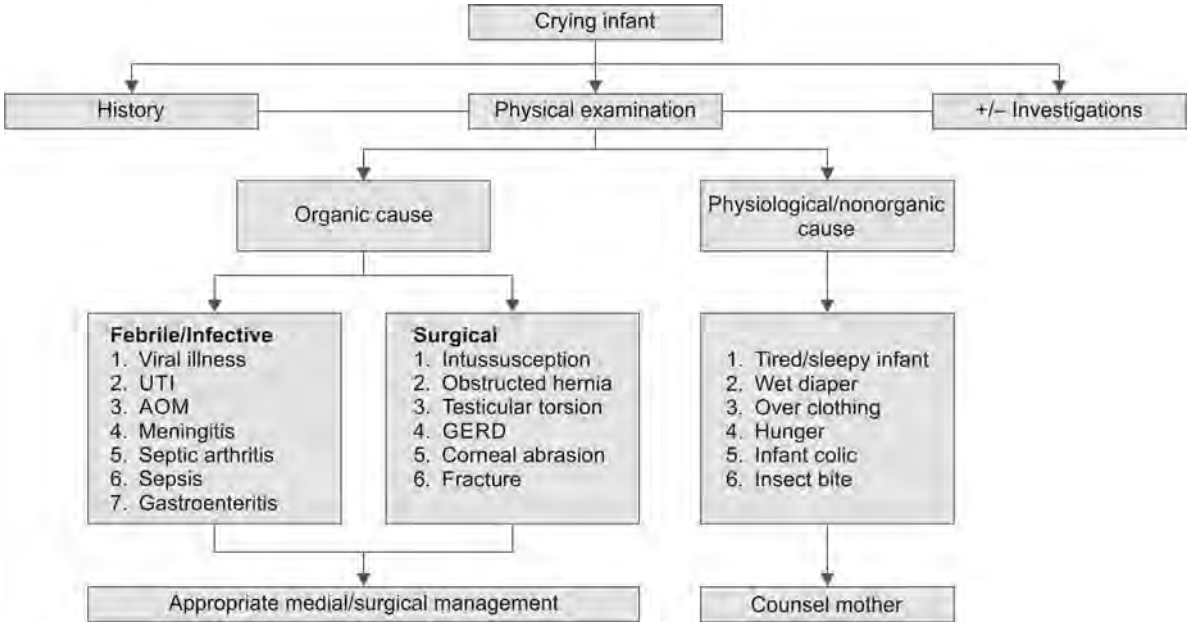
Role of investigations is very limited and may be useful in only about 3–5% cases where history and examinations are inconclusive. History and clinical assessment should guide decision making regarding investigations. A period of observation and follow-up is deemed desirable in cases where diagnosis has not been established. At times, negative results help in ruling out serious illness and can be reassuring before discharge. Investigations that can aid in diagnosis include corneal fluorescein staining for abrasions and USG abdomen for intussusception. Urine microscopic examination and culture, stool occult blood testing, and rectal examination have occasionally been of use in diagnosing an underlying condition in a crying infant. Testing for gastroesophageal reflux is not routinely done.

TREATMENT

Crying is a "common denominator" for a variety of illnesses and physiological disturbances. Management of a crying infant depends on the diagnosis. Ruling out apparent causes of crying such as hunger, sleepiness, and tiredness is the first step in treating an infant with persistent crying. Red flag signs should be sought after and managed accordingly. **Flowchart 1** provides a diagnostic approach.

Managing a crying infant is a two-part procedure, first, comprising of diagnosing and managing the underlying problem and secondly, counseling the mother regarding normal crying and sleep pattern and needs to timely address various clues. Among the benign causes, infant colic poses a challenging situation to both parents as well as to the clinician. Various pharmacological and nonpharmacological strategies have been tried with various successes.

- *Reassurance*—inform the parents the benign nature of the disease and its natural course.
- *Probiotics*—lactobacillus reuteri has been proposed to reduce colics in breastfed infants. Its role in formula fed infants is not well established.
- *Medications*—simethicone, though commonly used, its effectiveness has not been fully established. It is defoaming agent that is proposed to accelerate passage of flatus through intestinal tract. Dicyclomine and dicycloverine are anticholinergic medications thought to act by relieving spasms of intestinal smooth muscles. Owing to the large number of adverse effects these drugs are contraindicated in children <6 months of age. Proton pump inhibitors like omeprazole, act by relieving gastroesophageal reflux, though in various studies their efficacy was no better than that of placebo.



(AOM: acute otitis media; GERD: gastroesophageal reflux disease; UTI: urinary tract infection)

FLOWCHART 1: An approach to a crying infant.

BOX 1: Nonpharmacological interventions in a crying infant.

To prevent or minimize crying:
- Kangaroo care
- Swaddle holding
- Pacifier combined with sugar water
- Sugar water alone
- Sweet-tasting non-sucrose solution
- Heartbeat sounds
- Lullabies or mother's voice
- Rhythmic movement
- Reduction of external stimuli

When responding to a cry:
- Answer the cry as soon as possible
- Answer the cry consistently
- Answer the cry completely: touch, talk, and be in the infant's visual field

- *Diet*—colic prevalence is similar between breastfed and formula fed infants, hence mother should be encouraged to continue to breastfeeding. Maternal dietary modification may be considered in case of family history of atopy. Dietary counseling should be undertaken to ensure adequate nutrition. Formula fed infants might be considered for change of formula. Various nonpharmacological interventions have been studied in the management of a crying infant. **Box 1** enlists various such interventions.
- *REST* for parents includes *R*eassurance, *E*mpathy, *S*upport from the healthcare provider, and *T*ime out for the parents (e.g., rest and renewal). Such comforting measures do not work uniformly for everyone and hence parents should be guided to identify a unique, comforting technique that is suited to their child. Extreme cases may warrant mild sedation and temporary hospitalization. Professional support with reassurance and empathy from healthcare providers is crucial in dealing with these infants and parents.

SUMMARY

A crying infant is a frequent presentation to an emergency department. Each such infant needs to be thoroughly evaluated to look for warning or red flag signs, which might need urgent medical intervention. The role of detailed history from parents and a thorough physical examination cannot be emphasized more. Although infant colics are common, first episode of incessant cry should be dismissed off as colic without detailed evaluation. The general appearance of the baby can give clues to the underlying cause. Child abuse should be kept as a differential diagnosis while evaluating suck infants. Screening and diagnostic tests should be guided by history and examination. When a diagnosis of a benign cause such as colic is made, parents should be offered reassurance as well as insight into various pharmacological and nonpharmacologic methods available to comfort their child. As each child is different, they must be encouraged to seek the best possible intervention suited to their child. Approaching such a problem with an open-minded inquisitive manner is comforting to the parents as well the physician. In cases where history, physical examination, and initial testing do not prove conclusive, a period of observation must be considered in ED and the infant should be closely monitored and reexamined for crying pattern and any new manifestations such as fever and signs of acute abdominal conditions to guide additional testing and decide further disposition. There is no consensus on duration of the observation period in ED.

164 CHAPTER

Immunization in Pregnant Women, Infant and Children

Ashok Mishra

INTRODUCTION AND BACKGROUND

Immunization is one of the most cost-effective public health interventions. Various foreign particles, e.g., proteins, virus, pathogens, parasitic worms, chemicals, and toxins are trying to gain access into the body. Our immune system readily separates them from natural healthy tissues, its cells and proteins. When this immune system is sensitized with the milder infective form of disease, this same immune system helps to protect the body from subsequent attack of disease causing agent. Immunization is the process whereby a person is made immune or resistant to an infectious disease, typically by the administration of a vaccine. Vaccines stimulate the body's own immune system to protect the person against subsequent infection or disease [World Health Organization (WHO)]. The most important elements of immune system are T-cells, B-cells, and the antibodies B-cells, while memory T-cells and memory B-cells are responsible for swift action at the time of second encounter with the disease causing agents. This whole process is known as active immunization. When readymade antibodies are inoculated into the body of a person without it is being produced by body itself, it is known as passive Immunization.

World Health Organization estimates that vaccination averts 2–3 million deaths per year (in all age groups), and up to 1.5 million children die each year due to diseases which could have been prevented by vaccination. During 2016, 116.5 million infants worldwide received three doses of diphtheria-tetanus-pertussis (DPT) vaccine, protecting them against infectious diseases that can cause serious illness and disability. There was 84% drop in measles deaths between 2000 and 2016 worldwide, due to measles vaccination. Polio cases have decreased by over 99% since 1988. Today, only three countries (Afghanistan, Nigeria, and Pakistan) remain polio-endemic, down from >125 in 1988. In 2016, an estimated 19.5 million infants worldwide were not reached with routine immunization services such as DTP3 vaccine. Around 60% of these children live in 10 countries—Angola, Brazil, the Democratic Republic of the Congo, Ethiopia, India, Indonesia, Iraq, Nigeria, Pakistan, and South Africa.

The Global Vaccine Action Plan (GVAP) was launched with a roadmap to prevent millions of deaths through more equitable access to vaccines by 2020. To date, progress toward the GVAP targets is off track. In May 2017, Ministers of Health from 194 countries endorsed a new resolution on strengthening immunization to achieve the goals of the GVAP ·vaccination is a miracle of modern medicine. In the past 50 years, it saved more lives worldwide than any other medical product or procedure. Modern medicine knows Edward Jenner as the father of immunology/vaccination, an English physician and scientist who was the pioneer of smallpox vaccine, the world's first vaccine and also coined the term vaccine and vaccination. But the story of vaccine does not begin here; rather Chinese were pioneer in variolation for smallpox as early as AD 1000.

HISTORICAL ASPECTS OF VACCINATION

Buddhist monks drank snake venom to confer immunity to snake bite and variolation (smearing of a skin tear with cowpox to confer immunity to smallpox) was practiced in 17th century China. The earliest documented examples of vaccination are from India and China in the 17th century, where vaccination with powdered scabs from people infected with smallpox was used to protect against the disease. The mention of inoculation in the *Sact'eya Grantham*, an *Ayurvedic text*, was noted by the French scholar Henri-Marie Husson in the journal Dictionnaire des sciences médicales. However, the fascinating story of vaccination goes back all the way to Ancient Greece.

Brief History of Vaccination

Prior to 1974 and Expanded Program on Immunization (EPI), child vaccination coverage for tuberculosis, diphtheria, pertussis, tetanus, polio, and measles was estimated to be <5%.

The WHO initiated the EPI in May 1974 with the objective to vaccinate children throughout the world. But the vaccination schedule for EPI was formulated by WHO in 1984 and included Bacillus Calmette–Guérin (BCG), DPT, oral polio vaccine (OPV), and measles. With the advent of newer vaccines, EPI was expanded and included HepB, *Haemophilus influenzae type B* (Hib), and Yellow Fever vaccine in endemic areas. Subsequently in 1999 Global Alliance for Vaccines and Immunization (GAVI) was created to increase the access of

EPI in the farthest and poorest countries. Inspired from WHO, India launched the EPI in 1978 which was expanded in 1985 as Universal Immunization Program (UPI) which became part of Child Survival and Safe Motherhood in 1992. UIP then became important component of National Reproductive and Child Health Program in 1997, currently UIP is part of NHM since 2005. At present, 12 vaccine preventable diseases are covered under UIP, i.e., TB, diphtheria, pertussis, tetanus, polio, measles, hepatitis B, diarrhea, Japanese encephalitis, rubella, pneumonia (Hib), and pneumococcal diseases (pneumococcal pneumonia and meningitis). Hepatitis B and pneumococcal diseases were added to the UIP in 2007 and 2017, respectively. Inactivated poliovirus vaccine (IPV), rotavirus vaccine (RVV), Measles-Rubella (MR), and JE were the addition in the UIP program recently. To strengthen routine immunization planning and delivery mechanism, the Ministry of Health and Family Welfare (MoHFW), Government of India (GOI) launched its flagship program "Mission Indradhanush" in December 2014 to achieve >90% full immunization coverage in the country.

VACCINATION IN PREGNANCY

Fetal development and its fate depend on mother's health and wellbeing. Her contracting the disease affects the fetus in womb. Hence, proper immunization of "to be mother" plays a significant role in preventing untoward incidents during pregnancy and at term. Vaccinated mother passes disease protecting antibodies to fetus having immature adaptive immune system, which then protects both mother and fetus from vaccine preventable diseases during pregnancy and later life as "to be born baby" is highly susceptible for various disease-causing agents.

Live virus poses a threat to developing fetus in womb hence it is generally contraindicated for giving live vaccines to women planning conception within 4 weeks (in preconception phase) and already pregnant women. Toxoids, killed/inactivated bacteria, or virus vaccines have not shown any untoward incidents to both mother and fetus hence it is very important to vaccinate a mother if she is at high risk of being exposed to vaccine preventable disease or if infection poses a great threat to the lives of fetus or mother or both.

It is very imperative to assess the risk versus the protective benefits provided by the vaccination in each situation, regardless of its being live or inactivated vaccine. UIP by government of India recommends two doses of tetanus toxoid (TT) to all pregnant women at an interval of 4 weeks as soon as pregnancy is detected.

All live attenuated vaccines are not routinely recommended for immunization schedule. Vaccines which are contraindicated in pregnant women are human papillomavirus (HPV), measles, mumps, rubella, varicella, oral typhoid vaccine, live attenuated JE vaccine, and zoster vaccine. Others not recommended in routine immunization schedule can be given in exceptional circumstances where benefits of vaccination surpass the associated risk.

BC 429	• The Greek historian *Thucydides* observed that those who survived the smallpox plague in Athens did not become reinfected with the disease.
AD1554	• Some 8,000 children died in Goa, India, from a smallpox epidemic most likely introduced by the Portuguese.
1718	• Variolation in Turkey–Lady Mary Wortley Montagu (1689–1762) had her son variolated in Constantinople by Dr Charles Maitland, April 1718.
1721	• Lady Mary Montagu brought the practice of variolation to England, where she had Dr Charles Maitland variolate her 2-year-old daughter.
1796	• On May 14, 1796, Edward Jenner inoculated 8-year-old James Phipps with matter from a cowpox sore on the hand of milkmaid Sarah Nelmes and form the basis of vaccination.
1813	• US Vaccine Agency established signed by James Madison.
1853	• The United Kingdom Vaccination Act of 1853 made smallpox vaccination mandatory in the first three months of an infant's life.
1881-85	• Louis Pasteur presented the success of rabies vaccine and successfully used them on 350 people later, only one died as vaccination was started late. Anthrax vaccine was developed by Louis Pasteur in 1881.
1923	• Diphtheria toxoid vaccine developed.
1926-27	• Pertussis, BCG vaccination.
1936	• Oral polio vaccine.

Vaccination for Pregnant Women as per National Immunization Schedule

Tetanus Toxoid Vaccine

Exotoxin produced by *Clostridium tetani* causes tetanus which is an acute, often fatal disease. This is due to low levels of antitetanus antibody in neonates transferred passively from mother.

Tetanus toxoid vaccine was first produced in 1924 and used extensively for the first time among soldiers during World War II. Since then, immunization program using TTs has been highly successful in preventing maternal and neonatal tetanus (MNT) as well as injury-associated tetanus.

World Health Organization estimates that there were 59,000 neonatal tetanus deaths in 2008, a 92% reduction from the late 1980s and an indicator of how widely maternal TT immunization is being used. It is estimated that at least 100 million doses of TT vaccine were given to pregnant women in 2011 (compared with 64 million women between 1995 and 2004).

A WHO position paper on tetanus, published in 2006, suggested that three doses of DTP vaccine should be given in infancy, with boosters in childhood and adolescence and a sixth dose at first pregnancy as tetanus diphtheria and acellular pertussis (TdaP). If a good immunization history is not available, pregnant women should receive two doses of vaccine 4 weeks apart and at least 2 weeks (preferably 4 weeks) before delivery.

Optimal timing for TdaP/TT administration is between 27 and 36 weeks of gestation although TdaP/TT may be given at any time during pregnancy.

A search of the vaccine adverse event reporting system (VAERS) database for 2005–2010 did not identify any concerns about maternal, infant, and fetal outcomes following vaccination with a reduced amount of diphtheria toxoid, tetanus toxoid, and acellular pertussis vaccine (DTaP).

Recently, vaccination with TdaP combined with IPV has been recommended for pregnant women in the United Kingdom.

The American Congress of Obstetricians and Gynecologists also recommends giving diphtheria toxoid, TT, and acellular pertussis vaccine to pregnant women.

Vaccination for Pregnant Women under Special Circumstances

Influenza Vaccine

Pregnant women are at increased risk of influenza disease. Its severe complications included small for gestational age and preterm birth for fetus, both are at increased risk of mortality. Pregnant women with underlying medical conditions develop increased incidence of seasonal influenza disease with severity. Benefits associated with influenza vaccination particularly in second and third trimester with transplacental transfer of protective antibodies providing indirect protection against illness in mothers and their infants have outnumbered the risk factors. These benefits have made many countries all over the world to incorporate influenza vaccines in their national immunization schedule and policies. A single dose of 0.5mL IM is to be given.

Though live attenuated influenza vaccine (LAIV) is not recommended for use during pregnancy.

Japanese Encephalitis Vaccine

Japanese encephalitis vaccine should not be routinely administered during pregnancy. Pregnant women who must travel to an endemic area during the transmission season where risk of JE is high and if staying for >30 days should be vaccinated. Vaccination should be considered, if she is visiting a rural area with extensive outdoor activities and even if staying for <30 days, as the theoretical risks of immunization are outweighed by the risk of infection to the mother and developing fetus. Dose is 1 mL SC on 0, 7, and 30 days. Booster doses of 1.0 mL may be administered after 2 years.

Hepatitis A Vaccine

Not routinely recommended for immunization in pregnant lady. Hepatitis A vaccine (HAV) is produced from inactivated HAV; the theoretical risk to the developing fetus is expected to be low. The risk associated with vaccination should be weighed against the risk for hepatitis A in pregnant women who might be at high risk for exposure to HAV. Live vaccine is contraindicated in pregnancy.

Hepatitis B Vaccine

Pregnant women who are identified as being at risk for hepatitis B vaccine (HBV) infection during pregnancy [e.g., having more than one sex partner during the previous 6 months, been evaluated or treated for an sexually transmitted disease (STD), recent or current injection drug use, or having had a HBsAg-positive sex partner] should be vaccinated. Dose of vaccination is 1 mL IM at 0, 1, and 6 months interval.

Meningococcal Vaccines

Meningococcal conjugate vaccines may be given to pregnant women who are at increased risk, e.g., complement component deficiency, e.g., C5-C9, properdin, factor H, factor D, etc., or functional or anatomic asplenia (including sickle cell anemia), HIV, etc. Two primary doses of meningococcal conjugate vaccines are required with booster doses every 5 years.

Serogroup B meningococcal vaccines should only be given to pregnant or breastfeeding women who are at increased risk for serogroup B meningococcal disease, if the benefits of receiving the vaccine outweigh the risk. Dose is 0.5 mL IM.

Haemophilus Influenzae Type B

Pregnant women with certain high-risk conditions, for example, lack of a functioning spleen, need vaccination with Hib. It is safe to receive this at any time during pregnancy though not routinely recommended in immunization schedule.

Pneumococcal Polysaccharide Vaccine-23

Pneumococcal polysaccharide vaccine (PPSV) can be given in pregnant women if she is having high risk of getting pneumococcal infection/disease, i.e., DM, chronic lung disease, chronic cardiovascular diseases, cochlear implants, immunocompromising conditions, and functional or anatomic asplenia (e.g., sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia, splenic dysfunction, or splenectomy).

Rabies Vaccine

If a pregnant lady gets exposed to category two or three bites by a wild animal/rabid dog or untraceable dog/cat, she should get five doses of ARV IM on 0, 3, 7, 14, and 28 days with or without rabies immunoglobulin as per schedule without delay. If the risk of exposure to rabies is substantial, pre-exposure prophylaxis also might be indicated during pregnancy on 0, 3, and 21 days or 0, 7, and 21 days.

As an alternative to intramuscular (IM) regimen intradermal (ID) route can be used. Dose is 0.1 mL ID on both shoulders on 0, 3, 7, and 28 days.

Yellow Fever Vaccine

Vaccines are live attenuated viral vaccines from the 17D lineage. As far as possible, it should be avoided in pregnant women. Pregnant women should be advised against going to the rural areas of yellow fever endemic areas (and to urban areas of West African countries as well). However, where travel to an at-risk country is unavoidable, such women should be vaccinated. Yellow fever vaccines are given as a single dose (0.5 mL) injected either subcutaneously or intramuscularly.

VACCINATION IN CHILDREN

Every year vaccination prevents 2.5 million deaths globally. All the children immunized against vaccine preventable diseases can thrive and have better chances of survival with full potential. Hence immunization is, and should be recognized as, a core component of the human right to health. As part of a comprehensive package of interventions for disease prevention and control, vaccines, and immunization is an essential investment in a country's—indeed, in the world's—future. Now is the time for showing commitment to achieving the full potential of immunization. The vision for the decade of vaccines (2011–2020) is of a world in which all individuals and communities enjoy lives free from vaccine-preventable diseases. The mission of the decade of vaccines is to extend, by 2020 and beyond, the full benefit of immunization to all people, regardless of where they are born, who they are or where they live. Vaccines routinely recommended for children as per National Immunization Schedule from birth onward are summarized in **Table 1**. Some vaccines are recommended in special situation which are also summarized in **Table 2**.

TABLE 1: National Immunization Schedule for children and pregnant women endorsed by IAPSM.

Vaccine	*Dose /site*	*Schedule for children*	*Schedule for pregnant women*
TT	0.5 mL, IM	At 10 years and 16 years as boosters	First dose as soon as pregnancy is diagnosed. Second dose, 4 weeks later. Only one booster if present pregnancy is within 3 years of the previous pregnancy with full immunization
BCG	0.05 mL or 0.1 mL, ID	As soon as possible after birth till 1 month of age. If missed can be given till 1 year of age	
Hepatitis B	0.5 mL, IM	Birth dose within 24 h. Then as pentavalent vaccine at 6, 10, and 14 weeks	
bOPV	Two drops orally	• At birth as zero dose, then 6, 10, and 14 weeks.16–24 months as booster • Also, as a part of pulse polio campaign	
Pentavalent vaccine	0.5 mL, IM	At 6, 10, and 14 weeks	
Fractional IPV	0.1 mL, ID	At 6 and 14 weeks	
Rotavirus	Five drops orally	At 6, 10, and 14 weeks	
Measles	0.5 mL, SC	First dose at 9–12 months and second dose at 16–24 months	
Vitamin A	1 lakh IU (1 mL) 2 lakh IU (2 mL)	• First dose At 9–12 months • Second dose at 16–24 months then repeated every 6 months till 5 years of age	
DPT	0.5 mL, IM	At 16–24 months, and at 5 years of age, can be given up to 7 years	
Pneumococcal conjugate vaccine	0.5 mL, IM	6 and 14 weeks then booster at 9 months	
JE live attenuated vaccine	0.5 mL, SC	2 doses at 9–12 months then 16–24 months of age (in selected endemic states)	

Pentavalent vaccine contains diphtheria toxoid, pertussis, tetanus toxoid, hepatitis B, and H. influenzae type B

(BCG: Bacillus Calmette–Guérin; bOPV: bivalent oral polio vaccine; ID: intradermal; IAPSM: Indian Association of Preventive and Social Medicine; IM: intramuscular; IPV: inactivated poliovirus vaccine; JE: Japanese encephalitis; SC: subcutaneous; TT: tetanus toxoid)

TABLE 2: Other vaccines recommended under special circumstances.

Vaccine	*Dose*	*Recommended in children in special situation*	*Recommended in pregnant women in special situation*
TdaP	0.5 mL, IM		Ideally at 27 and 36 weeks of pregnancy. But can be given at any time in pregnancy
HepB	0.5 mL, IM	0, 1, and 6 months if not received earlier	Pregnant women with increased risk can get 1 mL IM at 0, 1, and 6 months
Mumps	0.5 mL, IM	12–18 months then 2nd at 2–6 years of age	
Rubella	0.5 mL, IM, SC	12–15 months as single dose	
Pneumococcal polysaccharide vaccine	0.5 mL, IM, SC		Can be given as single dose
Japanese encephalitis (JE) (inactivated Vero cell)	0.5 mL, SC	2 doses 4 weeks apart	All should be vaccinated if travelling to high risk areas. 1.0 mL SC, on 0, 7, and 30 days
Inactivated influenza vaccine	0.5 mL, IM		Single dose in pregnant women. 0.5 mL, IM
Hepatitis A—Inactivated	0.5 mL, IM	>1 year age children then 2nd at an interval of 6/12 months	Single dose 0.5 mL, IM
Hepatitis A—live	0.5 mL, SC	Single dose	
Meningococcal conjugate vaccine (quadrivalent)	0.5 mL, IM	High-risk children • >2 years as 0.5 mL, single IM dose • 9–23 months should get two doses 3 months apart	High-risk pregnant women should get two primary doses with booster every 5 years depending on the conditions
Meningococcal polysaccharide	• 0.5 mL, IM • Not recommended in <2 years children	High risk >2 years old, booster after 3–5 years later	High-risk pregnant women should get a dose with booster every 5 years
Haemophilus influenzae type b (Hib)	0.5 mL, IM	>1 year of age, only single dose	High-risk pregnant women should get single dose
Typhoid vaccine (live attenuated Ty21a) Ty21a also as an oral capsule	• 0.5 mL, IM • Enteric-coated capsule	• >6 months as a single dose • Two doses on alternate days (oral capsule)	
Typhoid vaccine unconjugated Vi polysaccharide (ViPS)	0.5 mL, IM, SC	>2 years as a single dose	
Cholera vaccine	Oral vaccine	2–5 years, three doses, 1–6 weeks apart. >5 years, two doses, 1–6 weeks apart recommended	High-risk pregnant women. Two doses, 1–6 weeks apart to help prevent spread
Varicella vaccine	0.5 mL, SC	Preferably starting at 12–18 months of age. Two doses 4–12 weeks apart	
Rabies vaccine	0.5/1 mL, IM	Depending on exposure/risk 0, 3, 7, 14, and 28 days of schedule	Depending on exposure/risk 0, 3, 7, 14, and 28 days of schedule
Human papillomavirus vaccine	0.5 mL, IM	• 9–14 years age—0, 6 month or 0, 1–2, 6 months • 15–26 years age should get 0, 2, and 6 months	
Yellow fever vaccine	0.5 mL IM, SC	9–12 months of age	

*All vaccines which are recommended in special circumstances must be given after consultation with qualified doctor.

(IM: intramuscular; SC: subcutaneous)

Vaccination for Children as per National Immunization Schedule

Bacillus Calmette–Guérin Vaccine

Bacillus Calmette–Guérin vaccine is a suspension of a live attenuated strain of mycobacterium. Reconstituted vaccine contains 8–32 × 10^6 colony forming units per mL and monosodium glutamate 1.5% w/v. BCG vaccination probably has little effect on preventing infection per se, or reactivation among those already infected with TB. However, there is strong evidence that BCG vaccination in infancy provides >70% protection against severe disseminated forms of TB disease in young children, including military TB and tubercular meningitis. BCG vaccine should be stored at +2 to +8°C, not to be frozen and should be protected from light. Reconstituted vaccine is very unstable and must be stored at +2 to +8°C and used within one working session preferably of 4 hours. Diluent of BCG vaccine is normal saline. Dose is 0.05 mL for infants <1 month, 0.1 mL for >1 month till 1 year by intradermal route, using 26–27-gauge needle as a single dose on left deltoid region only. Generally, within 2–3 weeks of vaccination a small red papule forms and eventually ulcerates, it heals subsequently. Moderate-to-late preterm infants (gestational age >31 weeks) and low birth weight infants (<2,500 g) who are healthy and clinically stable can receive BCG vaccination at birth, or at the latest, upon discharge. Infants born to mothers treated with disease modifying anti-rheumatic drugs (DMARDs) [e.g., tumor necrosis factor-alpha (TNF-α) blocking monoclonal antibodies] in the third trimester of pregnancy frequently have detectable antibodies for several months and they should not be vaccinated. Infants exposed to immunosuppressive treatment in utero or via breastfeeding should not receive BCG.

Precaution can be taken for neonates who are medically unstable or born to mothers who are HIV positive and HIV status of infant is not ascertained yet, till then it should be avoided.

Hepatitis B Vaccine

About 0.5 mL monodose vial or prefilled syringe of HBV contains 10 μg HBsAg protein, adsorbed onto 0.25 mg aluminum as aluminum hydroxide and it may contain yeast proteins also. Hepatitis B is given at birth along with OPV and BCG, as birth dose of hepatitis B, followed by three doses of a hepatitis B containing combination vaccine (e.g., pentavalent) at 6th, 10th, and 14th week of life. As per UIP, birth dose is to be given within 24 hours of birth only, if missed need not be given later, only three doses at 6th, 10th, and 14th week can be given. For older children <20 years, if hepatitis B is missed earlier, a three-dose schedule of pediatric formulation can be given at 0, 1st, and 6th month interval. For those >20 years, 1 mL IM dose can be given at 0, 1st, and 6th month.

Oral Polio Vaccine

Two drops of zero dose bivalent OPV (bOPV) is to be given to infant at birth or as soon as possible within 15 days followed by bOPV at 6th, 10th, and 14th week along with other vaccines. To ensure early protection, a schedule of two fractional intradermal doses of IPV administered at 6 and 14 weeks is added in the National Immunization Schedule. Site is right upper arm. There was a planned global switch from trivalent OPV (tOPV) to bOPV in April 2016. A booster dose is given at 16–24 months of age.

Government of India launched the Pulse Polio Abhiyan in 1995 as an immunization campaign by vaccinating all children under 5 years of age till poliomyelitis is eliminated from India. Since almost all the cases of polio come under 5 years, the upper age limit for vaccination in the campaign is 5 years for bOPV. The age range of polio might go up in well-immunized communities, due to the retardation of circulation of the causative wild polioviruses. The WHO recommends to monitor all cases of acute flaccid paralysis in children up to 15 years and to investigate them for poliovirus etiology.

Pneumococcal Vaccine

The vaccine contains 0.02% polysorbate 80 (P80), 0.125 mg of aluminum as aluminum phosphate (AlPO4) adjuvant, 5 mL of succinate buffer, and no thiomersal preservative. Except for the addition of six serotypes, P80, and succinate buffer, the formulation of PCV13 is the same as that of PCV7. Dose is 0.5 mL IM on anterolateral aspect of mid-thigh at 6th and 14th week followed by booster dose at 9 months of age or alternately as three primary doses 4/8 weeks apart.

Pentavalent Vaccine

It contains combination of five vaccines, i.e., diphtheria toxoid, pertussis, TT, Hib, and HepB vaccine. In 2000, before widespread introduction of Hib vaccine in resource-poor countries, Hib caused 8.13 million cases of serious disease in children aged 1–59 months with 371,000 deaths.

When Hib is given to a child >12 months of age for the first time (who has not received pentavalent vaccine), only one dose is recommended. Hib vaccine is not required for healthy children after 5 years of age.

Pentavalent vaccine is given in a dose of 0.5 mL IM on anterolateral aspect of mid-thigh at 6th, 10th, and 14th week of age. The need for early infant vaccination with DTP-containing vaccine, i.e., pentavalent vaccine is principally to ensure rapid protection against pertussis, because severe disease and death from pertussis are almost entirely limited to the first weeks and months of life. Despite high vaccination coverage (in 2014, 86% coverage with three doses of a pertussis containing vaccine), pertussis remains endemic in all countries and continues to be a public health concern. Pertussis containing vaccine (DPT, pentavalent vaccine, etc.) should be started as soon as 6 weeks of age and WHO recommends that primary series of immunization should ideally be completed by 6 months. It provides protection for at least 6 years. Only acellular pertussis containing vaccines should be used for vaccination of persons aged ≥7 years.

Pentavalent vaccine is a freeze sensitive vaccine, and should be stored and transported at +2 to +8°C in ice-lined refrigerators and vaccine carriers with conditioned ice packs.

From 2011–2015, India had the largest number of reported cases of diphtheria (18,350 cases) followed by Indonesia and Madagascar (3,203 and 1,633 cases, respectively). The first dose of vaccine should be given as early as 6 weeks of age, and the third dose should be completed by 6 months of age, i.e., 4 week interval between doses. DPT is given at 16–24 months of age as first booster and at 5–7 years as second booster dose.

Tetanus can be protected for life if at least six doses (three primary plus three booster doses) are provided to all people through routine childhood immunization schedules. WHO recommends three TT booster doses, ideally with at least 4 years between booster doses. These should be given at: 12–23 months of age; 4–7 years of age; and 9–15 years of age.

In National Immunization Schedule, TT is given as pentavalent vaccine at 6, 10, and 14 weeks, then as DPT vaccine at 16–24 months and at 5–7 years of age. Then TT is given at 10 and 16 years of age. Pentavalent vaccine is not given beyond 1 year of age.

Rotavirus Vaccine

Rotaviruses (RVs) are globally the leading cause of severe, dehydrating diarrhea in young children. Two RVVs are available. RV1 originates from a human strain, whereas RV5 contains five reassortants developed from RVs of human and bovine origin. It is a live, oral, and attenuated RVV. National Immunization Program recommends three doses at 6th, 10th, 14th week. Five drops are given orally along with pentavalent vaccine and OPV. Healthy children aged over 2 years are not considered necessary. Precautions for use of rotavirus vaccination include a history of intussusceptions or intestinal malformations, chronic gastrointestinal disease, and severe acute illness. Vaccination should be postponed when the child has ongoing acute gastroenteritis or fever with moderate-to-severe illness.

Measles Vaccine

Measles is one of the most contagious diseases of humans, and in the absence of vaccination, about 95% of individuals would be infected with measles virus by 15 years of age. In 2000, measles was the fifth leading cause of childhood morbidity and mortality worldwide. There were estimated 770,000 deaths, with more than half of these occurring in Africa. In 2015, there were estimated 134,200 measles deaths globally, representing a 79% decline since 2000. All six WHO regions have measles elimination goals before or by 2020, and the GVAP, endorsed by the WHO, has a goal to eliminate measles in five of the six WHO Regions by 2020.

Measles vaccination is a cost-effective measure in preventing morbidity and mortality with measles. Dose recommended is 0.5 mL SC at 9–12 months of age and booster to be given at 16–24 months of age. Vaccinating infants before or at the age of 6 months often fails to induce seroconversion due to the immaturity of the immune system as well as the presence of neutralizing maternal antibodies. WHO recommends vaccination of infants from 6 months during a measles outbreak/epidemic, here the risk of measles among infants <9 months is high; infants travelling to countries experiencing measles outbreaks; infants known to be HIV infected or exposed. Measles administered before 9 months of age should be considered a supplementary dose and recorded as "measles 0 (Zero) dose, these infants should be immunized at recommended age as per schedule. Diluent for measles vaccine is double distilled water and reconstituted vaccine should be used within 2 hours to prevent toxic shock syndrome due to contamination with *Staphylococcus aureus*.

Vaccination for Children under Special Circumstances (Table 2)

Mumps Vaccine

The initial dose is recommended between the age of 12 and 18 months of age. The second dose is then typically given between 2 and 6 years of age. Usage after exposure in those not already immune may be useful. Combined vaccine in the form of MR, MMR, and MMRV can be given with minimum 4 weeks interval between two doses.

Rubella Vaccine

Usually a mild self-limited illness, rubella during early pregnancy may result in miscarriage, fetal death, or congenital defects known as congenital rubella syndrome (CRS). Before introduction of rubella vaccine, the incidence of CRS varied from 0.1 to 0.2 per 1000 live births during endemic periods and from 0.8 to 4 per 1,000 live births during rubella epidemics.

Most rubella vaccines are based on the live, attenuated RA 27/3 strain. Up to 95–100% of susceptible persons aged ≥12 months develop rubella antibodies after a single dose of the vaccine. Dose schedule is 0.5 mL, SC or IM at 12–15 months of age.

Japanese Encephalitis Vaccine

Japanese encephalitis virus is the leading cause of viral encephalitis in Asia, currently and estimated three billion people live in the 24 countries mainly in the WHO South East Asia and Western Pacific Regions, considered at risk of JE. It is estimated that 67,900 severe clinical cases of JE occur annually despite widespread availability of vaccine with approximately 13,600-20,400 deaths.

Japanese encephalitis vaccines fall into four classes:

1. Inactivated mouse brain derived vaccines
2. Inactivated Vero cell-derived alum-adjuvanted vaccine (SA14-14-2 strain) requires two intramuscular doses at 4-week intervals, starting at ≥6 months of age in endemic settings. The dose is 0.5 mL, IM.
3. Live attenuated vaccines with single dose of 0.5 mL SC at ≥8 months of age
4. Live recombinant (Chimeric) vaccines single dose at ≥9 months of age, a single booster dose can be given 12–24 months later for those <18 years of age as booster for adults are not recommended as of now.

In our national immunization schedule, two doses of live attenuated JE vaccine (SA-14-14-2) are given at 9–12 months and at 16–24 months of age in high endemic areas, e.g., in selected endemic districts of UP, Bihar, Assam, Karnataka, and West Bengal. Diluent used for JE vaccine is phosphate buffer.

Yellow Fever Vaccine

Vaccines are live attenuated viral vaccines from the 17D lineage. Yellow fever vaccines are given as a single dose (0.5 mL) injected either subcutaneously or intramuscularly at age 9–12 months at the same time as the measles vaccine. All unvaccinated travelers aged >9 months and asymptomatic HIV infected persons with CD4 T-cell counts ≥ 200 cells/mm should

get yellow fever vaccine. Yellow fever vaccine is contraindicated in children aged <6 months. It is not recommended for those aged 6–8 months, except during epidemics.

Typhoid Vaccine

Typhoid fever is an acute generalized infection, caused by a highly virulent and invasive enteric bacterium, *Salmonella typhi*. Global estimates of typhoid fever burden range between 11 and 21 million cases and approximately 128,000 to 161,000 deaths annually. The majority of cases occurs in South/South-East Asia and sub-Saharan Africa.

Currently three types of typhoid vaccines are licensed for use: (1) Typhoid conjugate vaccine (TCV); (2) Unconjugated Vi polysaccharide (ViPS); and (3) Live attenuated Ty21a vaccines. The second and third types have been recommended by WHO since 2008 for the control of typhoid in endemic and epidemic settings. Typbar-TCV was first licensed in India in 2013 for intramuscular administration of a single dose (0.5 mL) in children aged 6 months and older. Each vaccine dose comprises 25 μg of purified Vi-capsular polysaccharide conjugated to TT. ViPS is licensed for use in individuals aged 2 years and older, to be administered subcutaneously or intramuscularly as a single dose of 0.5 mL. But booster dose may be given after 3 years.

The Ty21a vaccine is currently only available as enteric-coated capsules for oral administration on alternate days in a three-dose regimen (or a four-dose regimen in Canada and the USA).

Cholera Vaccine

Cholera is a rapidly dehydrating diarrheal disease caused by ingestion of toxin producing strains of serogroup O1, or less commonly, serogroup O139, of the bacterium *Vibrio cholera*. Approximately 1.3 billion people are at risk of cholera in endemic countries. An estimated 2.86 million cholera cases (uncertainty range 1.3–4.0 m) occur annually in endemic countries. Among these cases, there are an estimated 95,000 deaths. About half of the cholera cases and deaths are estimated to occur in children ≤5 years of age. WC vaccines (Shanchol, Euvichol, and mORCVAX) [killed modified whole cell bivalent (O1 and O139) vaccine without the B subunit], two doses should be given 14 days apart to individuals ≥1 year of age.

For WC-rBS vaccine (Dukoral) [killed whole cell monovalent (O1) vaccines], three doses should be given to children 2–5 years of age, and two doses to children aged ≥6 years and adults, with an interval of 1–6 weeks between doses in both groups.

Rabies Vaccine

If a child gets exposed to category two or three bites by a wild animal/rabid dog or untraceable dog/cat, he/she should get five doses of ARV IM on 0, 3, 7, 14, and 28 days with or without rabies immunoglobulin as per schedule without delay. If the risk of exposure to rabies is substantial, preexposure prophylaxis also might be indicated on 0, 3, and 21 days or 0, 7, and 21 days

As an alternative to IM regimen ID route can be used. Dose is 0.1 mL ID on both shoulders on 0, 3, 7, and 28 days.

Human Papillomavirus Vaccine

Persistent infection by oncogenic HPV types is a prerequisite for the development of cervical cancer, which each year hits about 528,000 women and causes 266,000 deaths worldwide. The viral types 16 and 18 HPV are the most common types in invasive cervical cancer, accounting for about 70% of all cervical cancers. In total, 85% of cervical cancer cases occur in the less developed regions and mortality rates vary as much as 18-fold between industrialized and developing countries. Other manifestations of HPV infection include vaginal, vulvar, penile, Oropharyngeal, and anal cancers. In addition, HPV types 6 and 11 cause anogenital warts and recurrent respiratory papillomatosis. HPV is mainly transmitted sexually. Recommended target population for the prevention of cervical cancer is females aged 9–14 years, prior to becoming sexually active.

Three prophylactic HPV vaccines are in use directed against high-risk HPV types. The quadrivalent vaccine (e.g., Gardasil) was first licensed in 2006. It contains noninfectious protein antigens for HPV 6, 11, 16, and 18. The bivalent vaccine was licensed in 2007 and contains noninfectious protein antigens for HPV 16 and 18. The monovalent vaccine (e.g., Gardasil 9) licensed in 2014 contains noninfectious protein antigens for HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58.

Dose is 0.5 mL, IM. Two-dose schedule for 9–14 years old children are 0 and 6–12 months. Three-dose schedules for 9–14 years are 0, 2, and 6 months. For >15 years old, three-dose schedule is recommended at 0, 2, and 6 months interval.

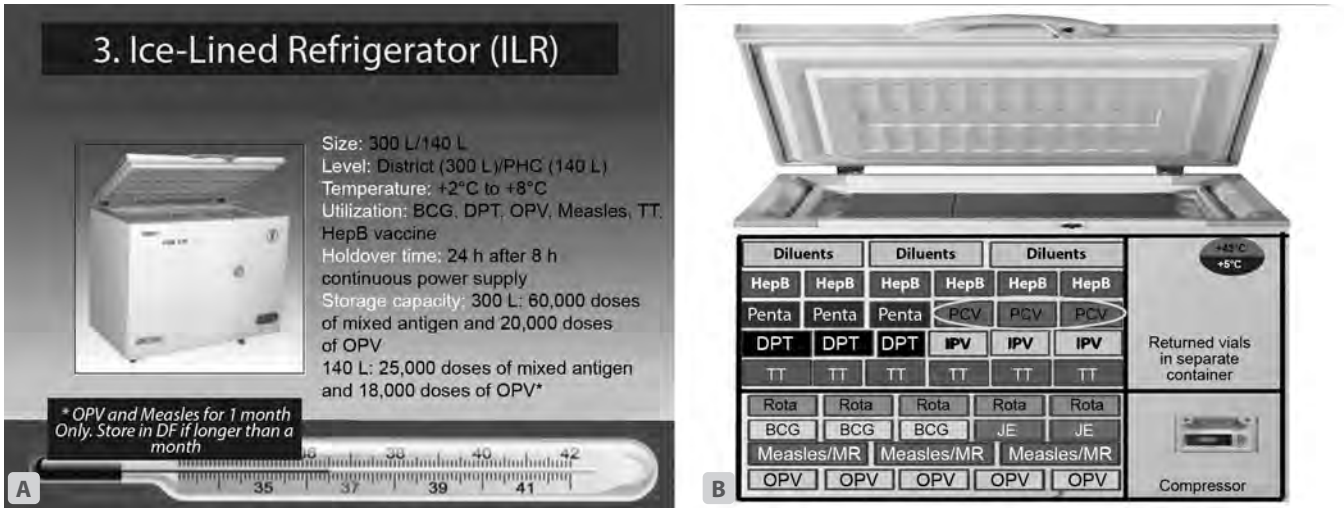
Varicella Vaccine

Varicella (chickenpox) is an acute, highly contagious disease with worldwide distribution caused by the varicella zoster virus (VZV). In temperate climates, most cases occur before the age of 10 years. Based on conservative estimates, the global annual varicella disease burden would include 4.2 million severe complications leading to hospitalization and 4,200 deaths. In the prevaccine era in high-income developed countries, case fatality rates for varicella were approximately 3 per 100,000 cases.

Two doses of varicella vaccine are recommended and should be administered at 12–18 months of age as 0.5 mL SC dose 3 months apart till 12 years of age. For >12 years, two doses of 0.5 mL each can be given as subcutaneous (SC) injection 4 weeks apart.

COLD CHAIN

Vaccines are sensitive biological products. Some vaccines are sensitive to freezing, some to heat, and others to light. Vaccine potency, meaning its ability to adequately protect the vaccinated patient, can diminish when the vaccine is exposed to inappropriate temperatures. Once lost, vaccine potency cannot be regained if it is lost anytime between manufacturing site and administration site. The storage and transportation of vaccine from the site of manufacturing to the site of utilization under optimum temperature (+2 to +8°C) are known as cold chain and equipment used is ice-lined refrigerator (**Figs. 1A** and **B**).



3. Ice-Lined Refrigerator (ILR)
Size: 300 L/140 L

(BCG: bacillus Calmette–Guérin; DPT: diphtheria-tetanus-pertussis; IPV: inactivated poliovirus vaccine; TT: tetanus toxoid; OPV: oral polio vaccine)

FIGS. 1A and B: (A) Ice-lined refrigerator specifications; (B) arrangement of vaccine in ice-lined refrigerator.

Freeze sensitive vaccines are—cholera DTP, hepatitis B, Hib, IPV (hexavalent), pentavalent, HPV, IPV, influenza, pneumococcal, rotavirus (liquid and Freeze-dried), Tetanus, DT, and Td.

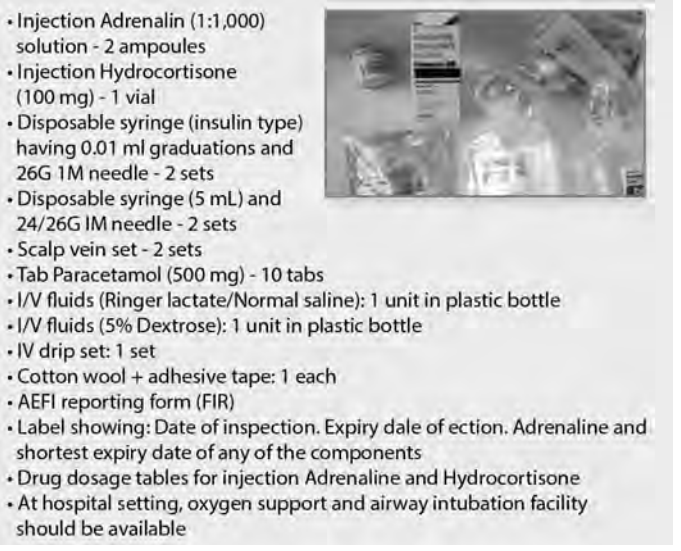
Vaccines that are as sensitive to light as they are to heat include BCG, measles, measles-rubella, measles-mumps-rubella, and rubella. These vaccines are often supplied in dark glass vials.

A vaccine vial monitor (VVM) is a label containing a heat sensitive material which is placed on a vaccine vial to register cumulative heat exposure over time.

ADVERSE EVENT FOLLOWING IMMUNIZATION

Immunization is among the most cost-effective public health interventions. It has led to the global eradication of smallpox as well as the elimination of poliomyelitis in regions of the world. Immunization currently averts an estimated 2–3 million deaths from diphtheria, tetanus, pertussis (whooping cough), and measles every year in all age groups. Unlike drugs, the expectations from vaccinations are much higher and problems arising from the vaccine or vaccination are less acceptable to the general public. Allegations that vaccines/vaccination cause adverse events must be dealt with rapidly and effectively as it can undermine confidence in a vaccine and ultimately have dramatic consequences for immunization coverage and disease incidence long after proof is generated that the adverse event was not caused by vaccine (e.g., autism and MMR, encephalopathy, and pertussis).

Adverse event following immunization (AEFI)—this is defined as any untoward medical occurrence which follows immunization and which does not necessarily have a causal relationship with the use of the vaccine. The adverse event may be any unfavorable or unintended sign, an abnormal laboratory finding, a symptom, or a disease. All vaccines should be given under medical supervision after consultation with a qualified medical practitioner. Before starting any immunization session, kindly ensure the availability of emergency tray (**Fig. 2**) with all necessary drugs and equipment.



• Injection Adrenalin (1:1,000) solution - 2 ampoules
• Injection Hydrocortisone (100 mg) - 1 vial
• Disposable syringe (insulin type) having 0.01 ml graduations and 26G 1M needle - 2 sets
• Disposable syringe (5 mL) and 24/26G IM needle - 2 sets
• Scalp vein set - 2 sets
• Tab Paracetamol (500 mg) - 10 tabs
• I/V fluids (Ringer lactate/Normal saline): 1 unit in plastic bottle
• I/V fluids (5% Dextrose): 1 unit in plastic bottle
• IV drip set: 1 set
• Cotton wool + adhesive tape: 1 each
• AEFI reporting form (FIR)
• Label showing: Date of inspection. Expiry dale of ection. Adrenaline and shortest expiry date of any of the components
• Drug dosage tables for injection Adrenaline and Hydrocortisone
• At hospital setting, oxygen support and airway intubation facility should be available

FIG. 2: Contents of AEFI treatment kit.

SUMMARY

Immunization is a proven, time tested, and effective tool for controlling and eradicating disease. A successful immunization program is very much important for India because country contributes to one-fifth of global under-five mortality and most number of deaths due to vaccine preventable diseases. There is a significant progress which has been achieved in India with wider use of vaccines, resulting in prevention of several diseases. Successful immunization strategy for the country goes beyond vaccine coverage in that self-reliance in vaccine production, creating epidemiological database for infectious diseases and developing surveillance system are also integral parts of the system. National Immunization schedule for pregnant women, infants, and children are summarized in **Table 3**.

TABLE 3: National Immunization Schedule for pregnant women, infants, and children.

Vaccine	*When to give*	*Dose*	*Route*	*Site*
For pregnant women				
TT-1	Early in pregnancy	0.5 mL	Intramuscular	Upper arm
TT-2	4 weeks after TT-1*	0.5 mL	Intramuscular	Upper arm
TT-Booster	If received 2 TT doses in a pregnancy within the last 3 years*	0.5 mL	Intramuscular	Upper arm
For infants				
BCG	At birth or as early as possible till 1 year of age	0.1 mL (0.05 mL until 1 month age)	Intradermal	Left upper arm
Hepatitis B—Birth dose	At birth or as early as possible within 24 hours	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
OPV-0	At birth or as early as possible within the first 15 days	2 drops	Oral	Oral
OPV-1, 2, and 3	At 6 weeks, 10 weeks, and 14 weeks (OPV can be given till 5 years of age)	2 drops	Oral	Oral
Pentavalent 1, 2, and 3	At 6 weeks, 10 weeks, and 14 weeks (can be given till 1 year of age)	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
Rotavirus#	At 6 weeks, 10 weeks, and 14 weeks (can be given till 1 year of age)	5 drops	Oral	Oral
IPV	Two fractional dose at 6 and 14 weeks of age	0.1 mL	Intradermal two fractional doses	Intradermal: Right upper arm
Measles/MR 1st Dose$	9 completed months–12 months, (can be given till 5 years of age)	0.5 mL	Subcutaneous	Right upper arm
JE-1**	9 completed months–12 months	0.5 mL	Subcutaneous	Left upper arm
Vitamin A (1st dose)	At 9 completed months with measles-Rubella	1 mL (1 lakh IU)	Oral	Oral
For children				
DPT booster 1	16–24 months	0.5 mL	Intramuscular	Anterolateral side of mid-thigh
Measles/MR 2nd dose$	16–24 months	0.5 mL	Subcutaneous	Right upper arm
OPV Booster	16–24 months	2 drops	Oral	Oral
JE-2	16–24 months	0.5 mL	Subcutaneous	Left upper arm
Vitamin A*** (2nd to 9th dose)	16–18 months. Then one dose every 6 months up to the age of 5 years	2 mL (2 lakh IU)	Oral	Oral
DPT Booster-2	5–6 years	0.5 mL	Intramuscular	Upper arm
TT	10 years and 16 years	0.5 mL	Intramuscular	Upper arm

* Give TT-2 or booster doses before 36 weeks of pregnancy. However, give these even if >36 weeks have passed. Give TT to a woman in labor, if she has not previously received TT.

** JE vaccine is introduced in select endemic districts after the campaign.

*** The 2nd to 9th doses of vitamin A can be administered to children 1–5 years old during biannual rounds in collaboration with ICDS.

Phased introduction, at present in Andhra Pradesh, Haryana, Himachal Pradesh, and Orissa from 2016 and expanded in Madhya Pradesh, Assam, Rajasthan, and Tripura in February 2017, and planned in Tamil Nadu and Uttar Pradesh in 2017.

$ Phased introduction, at present in five states namely Karnataka, Tamil Nadu, Goa, Lakshadweep, and Puducherry (As of February 2017).

(BCG: Bacillus Calmette–Guérin; DPT: diphtheria, pertussis, and tetanus; IPV: inactivated poliovirus vaccine; JE: Japanese encephalitis; MR: Measles–Rubella; OPV: oral polio vaccine; TT: tetanus toxoids)

165 CHAPTER

Pediatric Fever and Other Life-threatening Infections

Faiz Ahmad, Devendra Richhariya

INTRODUCTION

Fever is one of the most common presenting complaints in children brought to the emergency department. It is defined as a rectal temperature > 38°C (100.4°F). Rectal temperature most closely represents the core temperature in ambulatory setting and is more accurate than oral, axillary, tympanic, and temporal artery thermometry. A patient with a fever measured rectally at home should undergo the same evaluation as if this measurement were obtained in ED. In most children it's due to viral infection but in some it may be due to serious bacterial infection (SBI) such as urinary tract infection (UTI), pneumonia, bacteremia, meningitis, bacterial gastroenteritis, osteomyelitis, septic arthritis, retropharyngeal/parapharyngeal abscess, or intra-abdominal abscess. On rare occasion, a child may have sepsis without fever or even with hypothermia, especially in noticeably young children. Other than infection, fever could also be due to poisoning (aspirin, phenothiazines), collagen vascular disease, vasculitis (Kawasaki disease), familial Mediterranean fever, or malignancy to name a few.

Traditionally, febrile young children are divided into three general groups—(1) neonates (birth to 28 days old), (2) young infants (1 month to 2–3 months of age), and (3) older infants or toddlers (2–3 months of age and older).

ETIOLOGY

One of the most common presenting complaints in pediatric age-group is fever, which is associated with several illnesses. All types of fever can be divided into four main groups based on the etiology, i.e., (1) infectious, (2) inflammatory, (3) neoplastic, and (4) miscellaneous. Common causes of fever in pediatric age-group are shown in **Figure 1**. Each of them shows certain characteristics, which can provide us clue about the underlying etiology. Such as fever related to viral infections is typically associated with a slow declining fever with relatively shorter duration, which may be up to 1 week. Whereas in a bacterial infection, fever gets subsided promptly after administration of proper antibiotics. Usually the pathogens are eliminated once the antimicrobial therapy is employed, but still fever may persist for few more days as a result of tissue injury and related inflammatory changes. Cause of very high-grade fever, i.e., higher than 105.8 is usually associated with noninfectious cause, and most importantly due to central nervous system dysfunction. Types of fever are summarized below:

- *Intermittent fever*: Fever with exaggerated circadian rhythm, period of normal temperature
- *Septic or hectic fever*: Fever with wide fluctuations throughout
- *Sustained fever*: There is a persistent temperature with variations not > 0.9°F per day.
- *Remittent fever*: Persistence of fever and variations of > 0.9°F per day
- *Relapsing fever*: Febrile period is separated by interval of normal temperature
- *Biphasic fever* indicates a single illness with two distinct periods, characteristically seen in poliomyelitis, enteroviral infection, leptospirosis, and dengue fever.

Causes of prolonged fever, lasting for > 14 days has different etiology, however, infectious cause still remains the most common, below are the other etiologies of prolonged fever:

- Infectious—tuberculosis, human immunodeficiency virus (HIV), chronic fungal infection, and liver abscess
- Inflammatory diseases—rheumatoid arthritis, systemic lupus erythematous, Kawasaki disease, Behçet disease, and polyarteritis nodosa
- Malignancies—lymphomas, leukemia, neuroblastoma, and Wilms tumor
- Hematological and immune deficiency—spherocytosis, hemolytic anemia, Langerhans cell histiocytosis, disorders of phagocytosis, and T or B cell
- Other causes—drug fever, anhidrotic ectodermal dysplasia

PATHOPHYSIOLOGY OF FEVER

Body temperature is regulated by thermosensitive neurons which are located in the anterior hypothalamus, which responds to any change in temperature of blood and also through the warm and cold receptor located at skin and muscle. To maintain the temperature either the blood flow is redirected to or from the cutaneous vascular bed, regulating the extracellular fluid volume and also by increasing or decreasing the sweating. There are *three main mechanisms* for producing fever—(1) in response to the pyrogens, (2) production of heat is in excess to the loss, and (3) defective mechanism of heat loss.

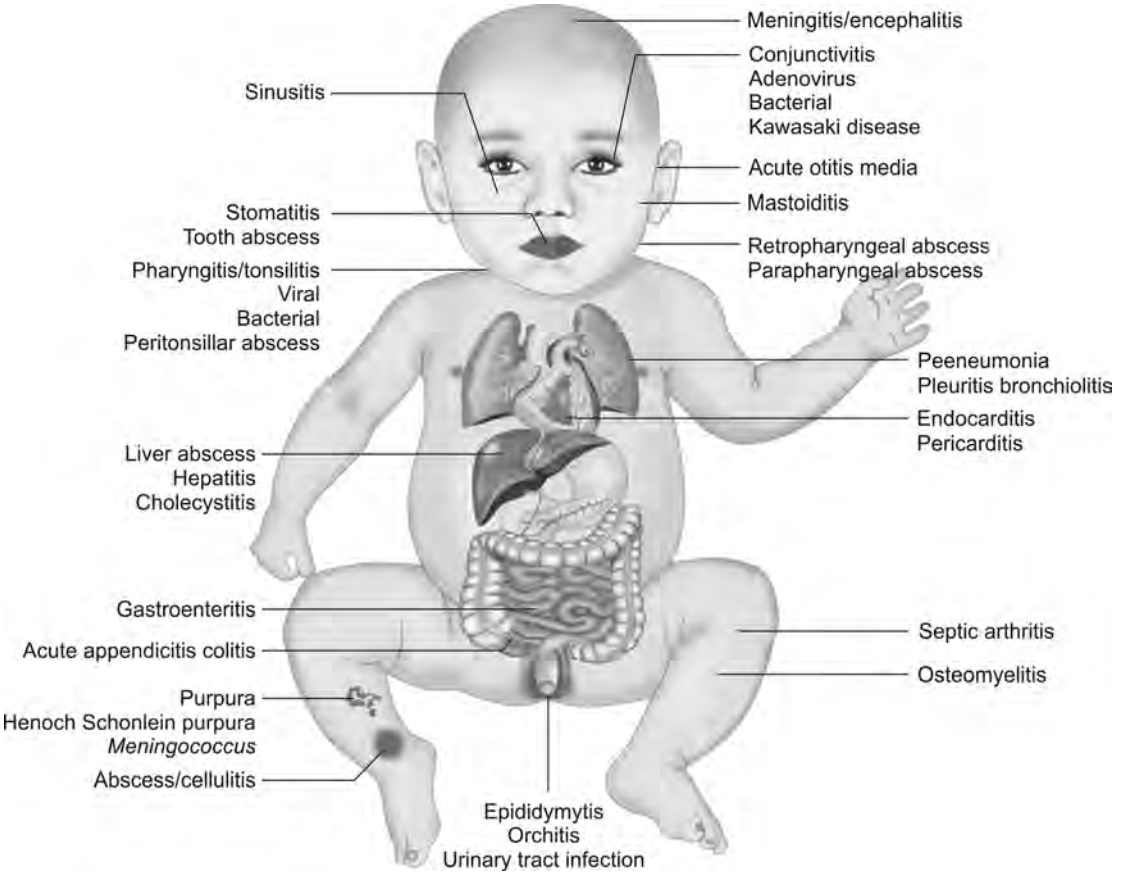

FIG. 1: Causes of fever in pediatric age-group.

The pyrogens play a big role in inducing fever, by raising the hypothalamus temperature set point. These pyrogens may be endogenous and exogenous. Endogenous pyrogens are mainly cytokines such as interleukins 1 and 6 (IL-1 and IL-6), tumor necrosis factor-α (TNF-α), and interferons β and γ. Other endogenous pyrogen includes leukemia inhibitory factor-M (LIF), ciliary neurotrophic factor (CNTF) and oncostatin-M. In cases of febrile illnesses, higher levels of IL-6 have been seen, and also the IL 6 with TNF contributes in clinical pyrexia. Prostaglandin E2 is the ultimate pyrogen in the whole cascade, which in turn attaches to the prostaglandin receptor site located on the hypothalamus and produces a net temperature set point.

Many exotoxins such as drugs, malignancies, and inflammatory diseases can also produce fever by production of endogenous pyrogens. Among all exogenous pyrogens, endotoxins are one of substances which can directly alter the thermoregulation center in hypothalamus, and stimulate endogenous pyrogens as well.

Another mechanism in which the heat production is in excess to the release, for example in case of salicylate poisoning and, malignant hyperthermia. The third mechanism, where the loss of heat is defective, is seen in cases of ectodermal dysplasia and victims of severe heat exposure.

CLINICAL PRESENTATION

Unlike in adults, adolescent and elder children, young infants and younger children have certain differences in clinical presentations, as they may become irritable and show fatigue, without any other apparent symptoms. Fever in children makes them very much uncomfortable. Fever can present in wide range of symptoms in children from no symptoms at all to extreme malaise. They may be having facial flushing appearance, experience shivering, and complain of feeling hot or even cold. Various other symptoms may be manifested such as loss of appetite, and some clinical features may be typical for specific diseases and can be used to point out the etiology, for example any sick child with fever and petechial rashes, raise suspicion toward meningococcemia or acute bacterial endocarditis.

Changes in the heart rate from baseline, is the most prominent clinical finding, and most of the patients have fever associated with tachycardia (increase in heart rate by 10, for each raise in temperature of 1.8°F). Disproportionately increase in heart rate is commonly seen in noninfectious conditions, or in infections in which toxins play role in clinical manifestation. In children of age-group 6–60 months (5 years), children may present with episodes of febrile convulsions.

FEATURES OF CONCERN—RED FLAGS

Parent concerns or physician instincts to evaluate further

- Inconsolable cry, change in crying pattern
- Rapid breathing or shortening of breaths with any duration of onset
- Findings such as decreased breath sounds, or crackles on respiratory examinations
- Poor peripheral circulation, hypotension, and appearing cyanosed on examination

- Fever associated with rash
- Seizures during the febrile illness
- Fever with meningeal irritation signs, neck stiffness, or photophobia
- Child presenting with cyanosis, breathlessness
- Poor hydration status and decreased skin turgor
- Drowsiness or lethargic or in altered consciousness
- Fever with chills and rigor, or bleeding manifestations

HISTORY AND PHYSICAL EXAMINATION

Fever could be from infectious or noninfectious causes. Fever in young children is accepted as a rectal temperature of 38.0°C (100.4°F) or higher. In younger children, hyperpyrexia (temperature 40°C) may be associated with increased rates of SBI. The duration of fever does not predict whether a child has occult bacteremia. Similarly, response to antipyretics does not distinguish between bacterial and viral infections. Although bundling a young child may increase the skin temperature, this does not increase the core temperature. Teething does not cause fever. It is important to look for additional signs and symptoms, underlying medical conditions, sick contacts, recent immunizations, and immunization status.

Yale Observation Score (YOS) is an objective scoring system based on child's alertness, playfulness, interaction with the environment, color, state of hydration, quality of cry, and whether the child is consolable or not. In young infant (<8 weeks), YOS cannot be relied upon to determine the risk of SBI. In this age-group, a history of poor feeding, lethargy, irritability, moaning, increased sleepiness or difficulty in breathing, seizure, or cyanotic episode is overly concerning for SBI. An infant with UTI may only have a low-grade fever with vomiting or diarrhea.

In young infant, physical examination may reveal mottled skin, pallor, bulging fontanel, weak cry, grunting, tachypnea, tachycardia, and lethargy. Meningeal signs may not be present even in meningitis.

In children above 8 weeks of age, clinical impression is more reliable. A child with sepsis is usually not interested in surrounding and does not smile. Parents often report a change in child's behavior. Localizing signs are more reliable in older children (toddlers), like in case of meningitis the presence of nuchal rigidity and positive Kernig's or Brudzinski's signs.

There are three common criteria (Boston criteria, Rochester criteria, and Philadelphia criteria) commonly used to determine if the patient is at low risk or high risk for SBI. These risk stratification rules are derived for febrile young infants and are not helpful in neonates. They all have following components in common for a patient to be in low-risk category:

- Patient must appear well
- No signs of focal infection on examination
- Peripheral white blood cell (WBC) count within a specific range
- No evidence of UTI on rapid urine testing

Boston Criteria

It is designed for febrile children from 1 to 3 months of age with a temperature of 38.0°C or more. Patients meet the low-risk criteria if they appear well, and had no ear, soft tissue, bone, or joint infection on examination. Laboratory evaluation must have a peripheral WBC count of ≤20,000/mm^3, microscopic UA showing ≤10 WBC/hpf or urine dipstick negative for leukocyte esterase, and cerebrospinal fluid (CSF) with ≤10 WBC/hpf and a normal chest X-ray (CXR) if that is performed. 5.4% children (27 out of 503) in the original study were later found to have SBI (UTI, bacterial gastroenteritis, and occult bacteremia).

Rochester Criteria

It is designed for febrile children < 60 days old. Patients are at low risk for SBI if they appear well, have been previously healthy, have no evidence of ear infection, skin, soft tissue, bone, or joint infection. Additionally, these patients must have normal peripheral WBC count (5,000–15,000/mm^3), normal absolute band counts (≤1500/mm^3), UA ≤10 WBC/hpf of centrifuged urine and patients with diarrhea should have ≤5 WBC/hpf on stool smear. Lumbar puncture is not a required component of the Rochester criteria. The Rochester criteria, in the original study, had a negative predictive value of 98.9%.

Philadelphia Criteria

It is designed for patients between 29 and 56 days of age with temperature ≥38.2°C. Patients are at low risk of SBI, if they appear well (defined by an infant observation score of ≤10), have a peripheral WBC count ≤15,000/mm^3, a band to neutrophil ratio ≤0.2, UA with <10 WBC/hpf, few or no bacteria on a centrifuged urine sample, CSF with <8 WBC/mm^3, a gram-negative stain, negative result on CXR (obtained on all patients), and stool negative for blood and few or no WBC on microscopy (ordered on patients with diarrhea). The low-risk patients were not treated with antibiotics. Of the 747 enrolled patients, in the original study, 65 (8.7%) had SBI and all of them were identified using these screening criteria. In another follow-up study of 422 febrile children (temp ≥38°C rectally), 43 (10%) had SBI and all of them were identified as high risk for SBI using the Philadelphia criteria.

Even though there is an imperfect correlation between physical examination findings and serious bacterial illness, ill-appearing children are more likely than well-appearing children to have SBI. Similarly, patients with septic shock presenting with abnormal mental status, weak peripheral pulses, cool extremities, delayed capillary refill with or without hypotension need aggressive resuscitation, and empiric antibiotic therapy. Children with clinically recognizable viral conditions (e.g., croup, chickenpox, and stomatitis) have lower rates of bacteremia than children with no obvious source of infection.

DIAGNOSIS AND MANAGEMENT

Birth to 8 Weeks of Age

Full sepsis evaluation including complete blood count (CBC) with differential count, blood culture, urine culture, urinalysis (catheterized or suprapubic aspiration), and lumbar puncture (cell count, glucose, protein, Gram's stain, and culture) should be performed. CXR is indicated if there are respiratory signs and symptoms. Stool study is indicated if there is diarrhea. All cultures, including lumbar puncture, should be obtained before starting antibiotics unless the infant is in respiratory distress or shock. Any patient who appears ill or toxic (inconsolable, lethargic, or tachypneic has poor perfusion or grunting) should be admitted and treated for sepsis while entertaining other diagnosis such as congenital heart disease or metabolic conditions.

Febrile young infants (age 0–90 days) have a 12.5–12.6% prevalence of SBI if they were tested negative for RSV, whereas the prevalence is 1.15–7.0% in those positive for RSV. And most of these SBIs are UTIs. Similarly in febrile young infants (age 0–90 days) have a 13.3–17.5% prevalence of SBI if they tested negative for influenza, whereas the prevalence is 2.5–2.65% in those positive for influenza. And similar to patients with RSV, most of these SBIs are UTIs.

The incidence of neonatal herpes simplex virus (HSV) infections is approximately 1 per 3,200 deliveries in the United States. These neonates with HSV infections usually present within the first 2 weeks of life, and only a small number of infected children have fever. Risk factors for neonatal HSV infection include primary maternal HSV infection (especially in those neonates delivered vaginally); prolonged rupture of membranes at delivery; use of fetal scalp monitoring electrodes; eye, skin, or oral lesions; and seizures.

Both the C-reactive protein and procalcitonin performed better than the peripheral WBC count in detecting SBIs, with procalcitonin having a higher sensitivity [83%, 95% confidence interval (CI) 70–91%] than the C-reactive protein (74%, 95% CI 49–67%) and peripheral WBC count (58%, 95% CI 49–67%).
Infants with following criteria are at low risk for sepsis:

- Well appearing
- No focal signs of infection on examination
- No known immunodeficiency/VP shunt or other comorbidity
- White blood cell 5,000–15,000/mm^3
- Erythrocyte sedimentation rate (ESR) < 30 mm/H, CRP <1 or a band to neutrophil ratio <0.2
- Urinalysis with ≤10 WBC per high-power field and no bacteria
- Cerebrospinal fluid shows <8 WBC/mm^3 and no bacteria on Gram stain
- Stool is heme negative and ≤5 WBC per high-power field.
- Normal CXR

Under 4 weeks (28 days) of age:

- Admit all patients
- IV ampicillin (<1 week: 100 mg/kg/day, div q 12 h; >1 week: 200 mg/kg/day, div q 6 h)
- IV cefotaxime (< 1 week: 100 mg/kg/day, div q 12 h; 1–4 weeks: 150 mg/kg/day, div q 8 h)
- Gentamicin 2.5 mg/kg IV can be used instead of cefotaxime
- In case of suspected meningitis increase the dose of cefotaxime to 200 mg/kg/day div q 6 h
- Ceftriaxone is not recommended for this age-group because of the concern of inducing unconjugated hyperbilirubinemia.
- IV acyclovir if HSV infection is suspected; high-dose acyclovir (20 mg/kg IV) improves outcomes in patients.

4–8 weeks of age:

- Infants who meet the low-risk criteria for sepsis may be managed as outpatients with close follow-up without antibiotics.
- Additional antibiotics should be considered in some circumstances (e.g., ampicillin or vancomycin for suspected infection by *Listeria*, gram-positive cocci, or *Enterococcus*).
- Empiric antibiotic therapy before discharge of low-risk patients should be considered if a lumbar puncture is performed. Ceftriaxone, 50 mg/kg IV or IM can be given before discharge.
- Infants who appear ill or do not meet low-risk criteria for sepsis should be admitted to the hospital and treated with IV ceftriaxone (100 mg/kg/day div q 12 h); can be given IM if IV access is difficult

8 Weeks–6 Months of Age

Clinical impression is more reliable in this age-group. If there is no definite source of fever, partial sepsis work-up with blood and urine studies should suffice. CXR should be done if patient has respiratory symptoms or there is focal finding on physical examination. Treat focal infections such as UTI, pneumonia, and otitis media with appropriate antibiotic. Infants under 3 months of age with UTI or suspected bacterial pneumonia should be admitted to the hospital for antibiotic therapy.

ANTIPYRETICS

Antipyresis includes use of both pharmacological and nonpharmacological approach. However, use of antipyretics may help to manage the child overall, but it does not appear to play any role in occurrence of febrile seizures.

Nonpharmacological Antipyresis

- *Environmental modification*: Keeping the room temperature cooler (21–22°C) in order to enhance the heat loss by convection and minimal clothing can be helpful in bring the body temperature lower.
- *Hydration*: Due to raised body temperature there is an increase in metabolism and increase in insensible water losses, i.e., for each 1°C of increase in temperature above 37.2°C, insensible water loss increases by 7 mL/kg. Hence increasing fluid intake is recommended in febrile patients.
- *Hydrotherapy or sponging*: Tepid water sponging helps to lower the temperature by evaporation, conduction, and convection. It lowers the temperature gradually, but it doesn't lower the thermoregulatory set point, and also soon it limits the further body cooling by inducing vasoconstriction and shivering. Hence the hydrotherapy should always be accompanied by pharmacological therapy.

Pharmacological Antipyresis

Antipyretic agents act upon the arachidonic acid pathway. The main action is to competitively bind on COX enzymes catalytic site competing with arachidonic acid, hence inhibiting production on prostaglandin 2.

- *Paracetamol*: It is recommended in dose of 10–15 mg/kg, at 4–6 hourly intervals (maximum 60 mg/kg/day). Antipyretic effect takes 30–60 min to initiate. Paracetamol helps in reduction of body temperature by 1–2°F within 2 hours of administration. Greater the initial temperature, greater the fall of temperature after the drug intake.
- *Ibuprofen*: This drug can be used at dose of 10 mg/kg, as a first-line antipyretic. No great differences have been shown in safety and efficacy as compared to paracetamol. Although combination of these two can be more effective, but not recommended routinely in children because of associated improper drug dosages.
- *Mefenamic acid*: This is an effective antipyretic, mainly in controlling the high-grade fever at the dose of 6–7 mg/kg/dose (20 mg/kg/day is maximum). Commonly practiced as

to give 1 dose of mefenamic acid for high temperature and then subsequently to follow with paracetamol.

Care to be taken in prescribing antipyretics, regarding the need of pharmacological agents, personal experience, clinical data on safety and efficacy, ~duration of effect, cost, adverse effects and patient's clinical condition. Paracetamol is safest antipyretic in children in therapeutic dosage, but also is associated with most serious cause of hepatotoxicity in children. Ibuprofen is also known for overdose and is relatively difficult to manage as compared to paracetamol. Aspirin should be avoided in children, due to its adverse effects, like Reye syndrome, other side effects like blunting of immune response, increased risk of gastritis, and gastrointestinal bleeding.

URINARY TRACT INFECTION

Urinary tract infection is a common source of fever in young children and, if untreated, can lead to renal damage. Despite the high disease prevalence, this diagnosis is often missed. In young children, symptoms are often nonspecific, and fever may be the only symptom of UTI.

Risk factors for UTI include uncircumcised status, young age, female sex (girls are at higher risk for UTIs than boys in all age categories except for young uncircumcised boys), and nonblack race. Urine testing is generally indicated in girls younger than 2 years with at least 1 risk factor for UTI (history of UTI, temperature >39°C, fever without other apparent source, ill appearance, suprapubic tenderness, fever >24 hours, or nonblack race). Circumcised boys between 3 months and 2 years of age without suprapubic tenderness or with no >1 risk factor for UTI (temperature 39°C, fever without other apparent source, fever >24 hours, or nonblack race) have a probability of UTI of ≤2%. Increased risk of UTI in uncircumcised males persists until at least 12 months of age.

Urine dipstick (positive for either leukocyte esterase or nitrites) has a sensitivity of 88%. It is important to remember that no rapid screening test detects all UTIs, therefore, urine cultures should be ordered for all of these patients.

OCCULT BACTEREMIA

Haemophilus influenzae type b (Hib) and *Streptococcus (diplococcus) pneumoniae* used to be two most common organisms responsible for bacteremia in young children. But since the introduction of Hib and pneumococcal conjugate vaccine covering 13 serotypes (PCV 13), the incidence of bacteremia from these two organisms has significantly decreased after administration of at least 2 doses (2 months and 4 months).

The third most common cause of bacteremia is *E. coli*. *E. coli* bacteremia is the most common in children 3–6 months of age but also seen in children up to 12 months of age. And most of these children have concomitant *E. coli* UTI.

Salmonella bacteremia is seen in about 0.1% of all children 3–36 months old who have temperatures ≥39.0°C. Most patients with *Salmonella* bacteremia have diarrhea but about 5% have primary bacteremia.

Neisseria meningitidis is an infrequent cause of bacteremia and risk factors include sick contact with patients with meningococcal disease, periods of meningococcal outbreaks, and presence of fever and petechiae.

PNEUMONIA

Occult pneumonia in most young children is viral and does not require antibiotic treatment. In case of bacterial pneumonia, high-dose amoxicillin is the first-line agent (90 mg/kg divided into 2 daily doses), because this agent is effective against *Streptococcus pneumoniae*. Mycoplasma pneumonia is uncommon in this age-group but if suspected, azithromycin or other macrolide antibiotics can be used. Oseltamivir should be started if influenza is thought to be either the primary infectious cause or if there is concern for influenza coinfection in someone with suspected bacterial pneumonia.

Children with community-acquired pneumonia require admission if they have respiratory distress with or without hypoxia, poor feeding or an inability to take oral medications, infants 3–6 months of age, documented or suspected infection by a pathogen with increased virulence (e.g., methicillin-resistant *Staphylococcus aureus*), and in cases where follow-up or close home observation cannot be ensured. Vancomycin or clindamycin should be also given to those patients with suspected methicillin-resistant *S. aureus* pneumonia.

6–36 months of age:

- Due to widespread use of pneumococcal vaccine, the risk of occult bacteremia is <1–2% in a child with a temperature of ≥39.5°C (103°F)
- If the blood culture is positive of *Streptococcus pneumoniae* and the patient is still febrile or afebrile <24 hours—repeat the blood culture.
- If the patient is ill-appearing or still febrile, complete the sepsis work-up and admit and treat with IV penicillin G (100,000 units/kg/day div q6h).
- If there is a concern for resistant strain of *S. pneumoniae* based on local antibiogram administer third-generation cephalosporin (ceftriaxone or cefotaxime) and vancomycin (10–15 mg/kg q8h).
- If the patient with *S. pneumoniae* bacteremia has been afebrile for >24 hours and is well appearing, treat as outpatient with oral penicillin (50 mg/kg/day div QID) for 7 days.
- In children treated as outpatient, parents should be given specific instructions to control the temperature (acetaminophen 15 mg/kg orally/rectally q4h) and bring the child back to the hospital for irritability, decreased oral intake or lethargy.
- Ensure follow-up within 24–48 hours.

SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2 INFECTION IN CHILDREN

Coronavirus disease 2019 (COVID-19) is a global health crisis and caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). The clinical characteristics, disease progression, and outcome in children and young adults appear significantly milder compared to older individuals. Coronaviruses are a family of enveloped, single-stranded, zoonotic RNA viruses which can rapidly mutate and recombine, leading to novel viruses that can spread from animals to humans. SARS-CoV-2 is transmitted via inhalation of respiratory droplets of an infected person and touching surfaces contaminated with the virus.

Pathogenesis

The SARS-CoV-2 virus utilizes angiotensin converting enzyme-2 (ACE-2) receptors as its cell surface receptor. ACE2 is expressed highly by ciliated epithelial cells in the human lungs and this receptor allows the virus to attach to the cell. The ACE2 receptor is also expressed in the intestines, potentially accounting for the gastrointestinal symptoms that commonly occur in the early stage of the illness. Severe COVID-19 disease is characterized by three phases: (1) The first being the viral phase; (2) The second being the cytokine storm; and (3) The third encompassing acute respiratory distress syndrome (ARDS), impaired cardiac function and death.

The cytokine storm associated with severe COVID-19 disease is similar to that of secondary hemophagocytic lymphohistiocytosis (HLH), which is a rare complication of other viral infections and characterized by fulminant and fatal hypercytokinemia with multiorgan failure. In severe infection, lower peripheral lymphocyte counts (CD4 and CD8 T cells), higher interleukin (IL) levels (IL-6 and IL-10), decreased interferon-gamma expression in CD4+ T cells and higher D-dimer and fibrin degradation products (FDP) levels, leading to increased thrombosis and multiorgan injury have been observed. Patients with severe infection may also have abnormal coagulation parameters, perhaps related to high expression of ACE2 receptors in vascular endothelial cells.

Transmission

Most likely children are secondary cases and acquire the infection after exposure to a COVID-19 positive adult, although there are no large studies at present to confirm this. Intra-family transmission may be important. An as yet unquantified proportion of children with COVID-19 is asymptomatic and may contribute to transmission. Multiple reports have demonstrated that children and young adults have a milder form of the disease compared to adults. The possible reasons for lower number and milder infections in children and young adults include healthier respiratory tracts, home isolation, lower exposure to virions, and minimal exposure to pollution and cigarette smoke.

Clinical Features

Children of all ages can be infected with SARS-CoV-2 (COVID-19) with more cases reported in younger children and infants. There is no age or sex preponderance and the median age of infection is 6.7 years (range: newborn to 15 years). The incubation period of COVID-19 in children has been reported as 2 days (range: 2–10 days). The most common symptoms described at onset in children are fever (50%) and mild cough (38%). Fever is present in about 40% of children. Other clinical features include sore throat, rhinorrhea, sneezing, myalgia, fatigue, diarrhea, and vomiting. Children may have more upper respiratory symptoms than lower respiratory symptoms, and appear to recover in 1–2 weeks. The Ministry of Health and Family Welfare (MOHFW) in their updated guidelines (as of 18 June, 2021) has categorized patients into three groups—those with mild, moderate, and severe illness.

Diagnosis and Investigations

Reverse transcription polymerase chain reaction (RT-PCR) testing of nose and throat swab for detection of SARS-CoV-2 nucleic acid has been recommended as the confirmatory test for COVID-19. On the basis of confirmatory RT-PCR and the antibody test, clinical assessment, hospital treatment or home isolation measures are provided to the patient. Contact tracing measures are also instituted per protocol. If signs for severe infection are present, recommendation to monitor the lymphocyte count and CRP, and procalcitonin levels to detect potential bacterial co-infection. Chest X-ray findings in children are usually nonspecific. In view of the high-radiation exposure, children with mild disease should not routinely need computed tomography (CT) chest. When CT is performed, ground glass opacities are seen in one-third of patients. Peripheral distribution of lung lesions has been noted, with multilobar involvement. Consolidation and surrounding halo sign are considered typical of pediatric patients. However, chest CT alone cannot accurately diagnose COVID-19 due to similar radiological presentations with other infections. Patients admitted with severe infection are known to have elevated plasma levels of elevated ferritin and IL-2, IL-7, IL-10, granulocyte colony stimulating factor (GCSF), interferon-gamma-inducible protein 10 (IP10), monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein 1-alpha (MIP-1α), and tumor necrosis factor (TNF) alpha. These cytokines are produced by inflammatory macrophages which have been implicated in the cytokine storm.

Management of Pediatric Severe Acute Respiratory Syndrome Coronavirus 2 (Coronavirus Disease 2019)

Immediate infection prevention control (IPC) measures must be instituted upon suspicion of COVID-19 infection. Standard precautions such as hand hygiene, use of personal protective equipment (PPE), safe waste management, and cleaning and disinfection of equipment must be followed as per the guidelines issued by the MOHFW. For the few children who will require admission to a healthcare facility, the cornerstone of management is supportive therapy including adequate nutrition and calorie intake, fluid and electrolyte management, and oxygen supplementation. Emergency physician must communicate with parents regularly and alleviating anxiety is an important part of management. Classification of severity, investigations, and management of SARS-CoV-2 infection in children are summarized in **Table 1**.

MULTISYSTEM INFLAMMATORY SYNDROME IN CHILDREN RELATED TO COVID-19

Multisystem inflammatory syndrome in children (MIS-C) is a new entity in children characterized by unremitting fever >38°C and epidemiological linkage with SARS-CoV-2.

WHO Diagnostic criteria of MIS-C:Children and adolescents 0–18 years of age with fever ≥3 days and any two of the following features:

- Rash or bilateral nonpurulent conjunctivitis or muco-cutaneous inflammation signs (oral, hands, or feet)
- Hypotension or shock
- Features of myocardial dysfunction, pericarditis, valvulitis, or coronary abnormalities (including ECHO findings or elevated Troponin/NT-pro BNP)

- Evidence of coagulopathy (PT, PTT, and elevated D-dimers)
- Acute gastrointestinal problems (diarrhea, vomiting, or abdominal pain)
- And raised inflammatory markers such as ESR (>40 mm), C-reactive protein (>5 mg/L), or procalcitonin
- And no other possible microbial cause of inflammation, e.g., bacterial sepsis, staphylococcal or streptococcal shock syndromes.
- And evidence of recent COVID-19 infection (RT-PCR, antigen test, or serology positive), or likely contact with COVID-19 infected patient.

Following conditions must be excluded before making a diagnosis of MIS-C:

- Tropical infections (malaria, dengue, scrub typhus, and enteric fever)
- Toxic shock syndrome (staphylococcal or streptococcal)
- Bacterial sepsis

Multisystem inflammatory syndrome in children with Kawasaki disease (KD) phenotype is presented with fever, conjunctival redness, oropharyngeal findings (red and/or cracked lips, strawberry tongue), rash, swollen and/or erythematous hands and feet and cervical lymphadenopathy.

Investigations

Group 1 tests: May be done at COVID Care Center: CBC, complete metabolic profile (LFT/KFT/blood gas/glucose), CRP and/or ESR, SARS-CoV-2 serology and/or RT-PCR, blood culture. If: 1. CRP > 5 mg/L and/or ESR > 40 mm/h; 2. At least one of these: Absolute leukocyte count < 1,000 µL, Na < 135 mEq/L, neutrophilia, hypoalbuminemia follow group 2 tests.

Group 2 tests: Cardiac (ECG, echocardiogram, BNP, troponin T); inflammatory markers (procalcitonin, ferritin, PT, PTT, D-dimer, fibrinogen, LDH, triglyceride, cytokine panel); blood smear; SARS-CoV-2 serology.

TABLE 1: Clinical features of SARS-CoV-2 (COVID-19) in children.

Common symptoms: Fever, sore throat/throat irritation, diarrhea, cough, body ache/headache, anorexia/nausea/vomiting, rhinorrhea, malaise/weakness, loss of sense of smell and/or taste

Differentiating features	***Asymptomatic***	***Mild***	***Moderate***	***Severe***
Respiratory rate/min	Normal with age	Normal with age	Rapid respiration (age based): • <2 months: ≥60 breaths/min • 2–12 months: ≥50 breaths/min • 1–5 years: ≥40 breaths/min • >5 years: ≥30 breaths/min	Rapid respiration (age based): • <2 months: ≥60 breaths/min • 2–12 months: ≥50 breaths/min • 1–5 years: ≥40 breaths/min • >5 years: ≥30 breaths/min
SpO_2 on room air	≥94%	≥94%	≥90%	<90%
Grunting/severe chest retraction	–	–	–	±
Lethargy somnolence	–	–	–	±
Seizures	–	–	–	±
Where to treat	Home isolation (teleconsultation SOS)	Home isolation (tele consultation SOS) or COVID Care Centre	Admit COVID-19 hospital	Admit in HDU/ICU of COVID-19 hospital
Investigations	No investigation needed	No investigation needed	• *Baseline*: CBC including ESR, blood glucose chest X-ray • CT chest is not indicated in diagnosis or management of COVID-19 infection in children. Consider CT chest only if no improvement in respiratory status	• *Baseline*: CBC including ESR, blood glucose, CRP, LFT, KFT, serum ferritin, D-Dimer • Chest X-ray • CT chest is not indicated in diagnosis or management of COVID-19 infection in children. Consider CT chest only, if no improvement in respiratory status

Continued

Differentiating features	***Asymptomatic***	***Mild***	***Moderate***	***Severe***
Mainstay of treatment	Infants and younger children to stay under immediate care of parents/guardians: • No specific medication required for COVID-19 infection • Continue medications for other conditions, if any • Promote COVID appropriate behavior (mask, strict hand hygiene, physical distancing); please see guide for using mask • Fluids and feeds: ensure oral fluids to maintain hydration and give a nutritious diet • Advise older children and family to stay connected and engage in positive talks through phone, videocalls, etc. • Parent/caregivers to contact the doctor in case of appearance of symptoms	• For fever, give paracetamol 10–15 mg/kg/dose; may repeat every 4–6 h • For cough, give throat soothing agents and warm saline gargles in older children and adolescents • Fluids and feeds: ensure oral fluids to maintain hydration and give a nutritious diet • No other COVID-19 specific medication needed • Antimicrobials are not indicated • Maintain monitoring chart including counting of respiratory rate 2–3 times a day, look for chest indrawing, cold extremities, urine output, oxygen saturation, fluid intake, activity level, especially for young children • Promote COVID appropriate behavior (mask, strict hand hygiene, physical distancing); please see guide for using mask • Advise older children and family to stay connected and engage in positive talks through phone, videocalls, etc. • Parents/caregivers to contact the doctor in case of deterioration of symptoms	*Initiate oxygen if SpO_2 is 38°C (or 100.4°F)*: Paracetamol 10–15 mg/kg/dose; may repeat every 4–6 h • Antimicrobials to be administered if there is evidence/strong suspicion of superadded bacterial infection; please see antimicrobial use guide • Supportive care for comorbid conditions, if any Remdesivir (an emergency use authorization drug) is NOT recommended in children. There is lack of sufficient evidence on safety and efficacy with respect to remdesivir in children below 18 years of age	• Initiate immediate oxygen therapy and maintain target SpO_2 94–96% • Maintain fluid and electrolyte balance • Corticosteroid therapy to be initiated • Anticoagulants may also be indicated • In case of (ARDS) or shock develops, initiate necessary management; see ARDS and shock guide • Antimicrobials to be administered if there is evidence/strong suspicion of superadded bacterial infection; see antimicrobial use guide • May need organ support in case of organ dysfunction, e.g., renal replacement therapy Remdesivir (an emergency use authorization drug) is NOT recommended in children. There is lack of sufficient evidence on safety and efficacy with respect to remdesivir in children below 18 years of age
Management of ARDS	ARDS may be classified based on Pediatric Acute Lung Injury Consensus Conference (PALICC) definition into mild, moderate, and severe. • Mild ARDS: High flow nasal oxygen (start with 0.5 L/kg/min to begin with and increase to 2 L/kg/min with monitoring) or noninvasive ventilation (BiPAP or CPAP) may be given • Moderate–Severe ARDS: Lung protective mechanical ventilation may be initiated; low tidal volume (4–8 mL/kg); plateau pressure <28–30 cmH_2O; MAP <18–20 cmH_2O; driving pressure <15 cmH_2O; PEEP: 6–10 cmH_2O (or higher if severe ARDS); FiO_2 < 60%; Sedation + analgesia ± neuromuscular blockers; cuffed ETT, inline suction, and heat and moisture exchange filters (HMEF) • Avoid frequent disconnection of ventilator circuit, nebulization, or metered dose inhaler • Restrict fluids; calculate fluid overload percentage, keeping it <10% • Prone position may be considered in hypoxemic children, if they are able to tolerate it • Daily assessment for weaning and early extubation; enteral nutrition within 24 h, achieve full feeds by 48 hours • Transfusion trigger Hb <7 g, if stable oxygenation and hemodynamic and <10 g/dL if refractory hypoxemia or shock			
Management of shock	• Consider crystalloid fluid bolus 10–20 mL/kg cautiously over 30–60 min with early vasoactive support (epinephrine) • Start antimicrobials within the first hour, after taking blood cultures, according to hospital antibiogram or treatment guidelines • Consider inotropes (milrinone or dobutamine) if poor perfusion and myocardial dysfunction persists despite fluid boluses, vasoactive drugs, and achievement of target mean arterial pressure • Hydrocortisone may be added if there is fluid refractory catecholamine resistant shock (avoid if already on dexamethasone or methylprednisolone) • Once stabilized, restrict IV fluids to avoid fluid overload • Initiate enteral nutrition—sooner the better • Transfusion trigger Hb <7 g/dL if stable oxygenation and hemodynamic, and <10 g/dL if refractory hypoxemia or shock			

Continued

Continued

Antimicrobial use	COVID-19 is a viral infection, and antimicrobials have no role in the management of uncomplicated. • Asymptomatic and mild cases: antimicrobials are not recommended for therapy or prophylaxis. • Moderate and severe cases: antimicrobials should not be prescribed unless there is clinical suspicion of a superadded infection. • Septic shock: empirical antimicrobials (according to body weight) are frequently added to cover all likely pathogens based on clinical judgment, patient host factors, local epidemiology, and antimicrobial policy of the hospital.
Use of steroid and anticoagulation	*Steroids*: • Steroids are not indicated and are harmful in asymptomatic and mild cases of COVID-19 • Indicated only in hospitalized severe and critically ill COVID-19 cases • Steroids should be used at the right time, in right dose, and for the right duration • Indications and recommended dose of corticosteroids—may be used in rapidly progressive moderate and all severe cases: ○ Dexamethasone 0.15 mg/kg, maximum dose 6 mg once a day, or ○ Methylprednisolone 0.75 mg/kg, maximum dose 30 mg once a day • Continue for 5–7 days and taper, up to 14 days, depending on clinical assessment on daily basis • Avoid steroids in first 3–5 days since onset of symptoms as it prolongs viral shedding *Anticoagulants*: • Not indicated routinely • All hospitalized children should be monitored for thrombosis; on suspicion, confirm by appropriate investigations and start on low molecular weight heparin in therapeutic doses for period of 12 weeks with monitoring • Predisposing risk factors for development of thrombosis—personal history of venous thrombotic events (VTE), family history of first-degree relative with VTE, presence of central venous line, decreased mobility from baseline, burns, active malignancy, estrogen therapy, flare of inflammatory disease, morbid obesity, severe dehydration, recent surgery or trauma • Prophylactic anticoagulant is indicated in following circumstances: (a) Strong personal or family history of VTE, or (b) An indwelling central venous line and two or more additional risk factors, or (c) Four or more risk factors • The decision to administer prophylactic anticoagulation must be balanced with the child's bleeding risk • Children already on anticoagulation therapy may continue same unless they develop active bleeding • Dose of low molecular weight heparin (enoxaparin), if indicated in severe cases: ○ Prophylactic dose 0.5 mg/kg twice daily, till child is discharged from hospital ○ Therapeutic dose 1 mg/kg twice daily
Guideline for using mask in children	• Masks are not recommended for children aged 5 years and under • Children aged 6–11 years may wear a mask depending on the ability of child to use a mask safely and appropriately under direct supervision of parents/guardians • Children aged 12 years and over should wear a mask under the same conditions as adults • Ensure hands are kept clean with soap and water, or an alcohol-based hand rub, while handling masks
Infection prevention and control	Every COVID care facility should have a multidisciplinary hospital infection control committee; key components of infection control strategy are: • Standard precautions • Droplet precautions • Airborne precautions • Contact precautions and hand hygiene • Physical distancing • Cough etiquette/respiratory hygiene • Well-ventilated rooms • Monitor healthcare associated infections • Train all healthcare workers to develop IPC skills • Environment cleaning, disinfection, and sanitation • Cleaning/disinfection of frequently touched surfaces/equipment • Cleaning and disinfection of linen • Safe management of biomedical waste • Triple layer mask to be worn by patient, as per guidance below • Masks for caregivers (home/hospital)

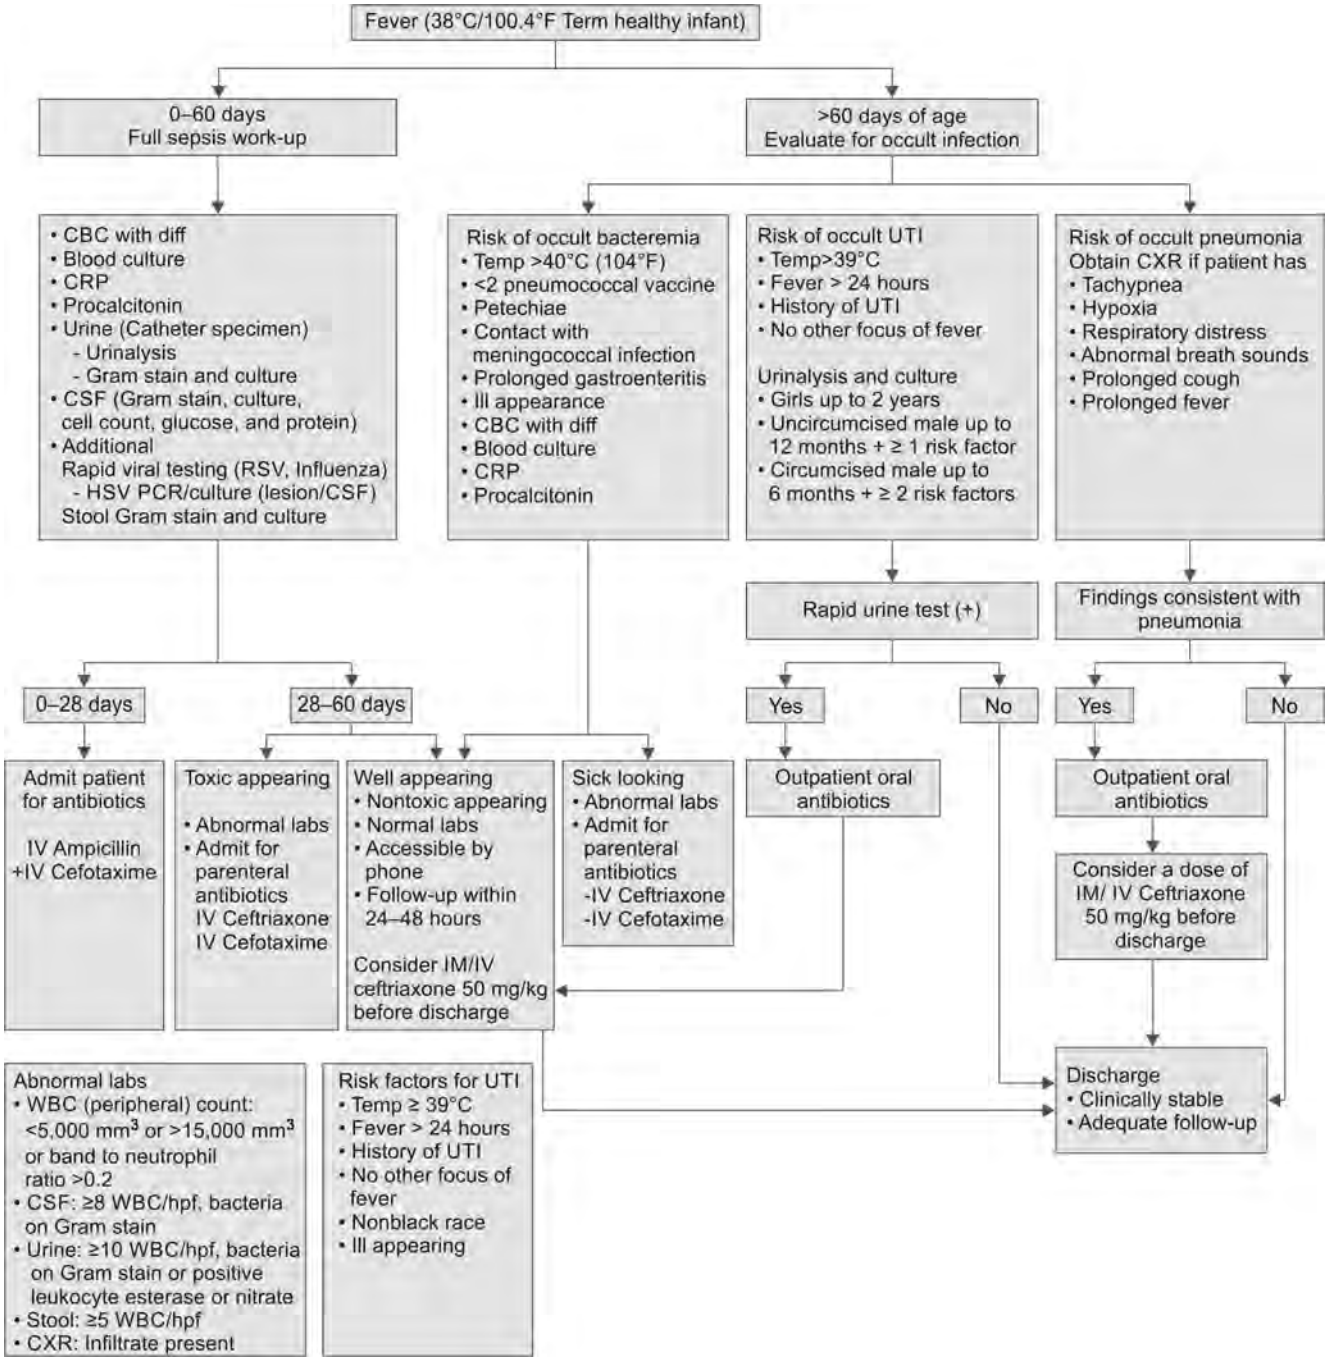
(ARDS: acute respiratory distress syndrome; BiPAP: bi-level positive airway pressure; CBC: complete blood count; COVID-19: coronavirus disease 2019; CPAP: continuous positive airway pressure; CRP: C-reactive protein; ESR: erythrocyte sedimentation rate; KFT: kidney function test; LFT: liver function test; SARS-CoV-2: severe acute respiratory syndrome coronavirus 2; SpO_2: oxygen saturation)

Carry out investigations to rule out common tropical infections include malaria, dengue, enteric fever, rickettsial illness (scrub typhus), etc.

Guidelines for Management of Multisystem Inflammatory Syndrome in Children Related to Coronavirus Disease 2019

Appropriate supportive care is needed preferably in ICU for treatment of cardiac dysfunction, coronary involvement, shock, or multiorgan failure. Methyl prednisolone (MPS), intravenous immunoglobulin (IVIG) antiplatelet, and heparin are the mainstay of treatment.

- Intravenous immunoglobulin to be given slower (over up to 48 hours) in children with cardiac failure/fluid overload
- Taper steroids over 2–3 weeks with clinical and CRP monitoring
- Aspirin 3–5 mg/kg/day, maximum 75 mg/day in all children for 4–6 weeks (with platelet count >80,000/μL) for at least 4–6 weeks or longer for those with coronary aneurysms
- Low molecular weight heparin (enoxaparin) 1 mg/kg/dose twice daily subcutaneously in >2 months (0.75 mg/kg/dose in <2 months) if patient has thrombosis or giant aneurysm



(CXR: chest radiography; CRP: C-reactive protein)

FLOWCHART 1: Fever without apparent source in children 0–24 months of age.

with absolute coronary diameter ≥8 mm or Z score ≥ 10 or LVEF < 30%

- For children with cardiac involvement, repeat ECG 48 hourly and repeat ECHO at 7–14 days and between 4 and 6 weeks, and after 1 year if initial ECHO was abnormal. Therapy for MIS-C with or without shock is discussed as below.

MIS-C without shock: IV methylprednisolone 1–2 mg/kg/day, if symptoms persist for 48–72 hours of treatment, or if early worsening, treat as per the phenotype to which evolution occurs.

MIS-C with shock or multiorgan failure: IVIG 2 g/kg over 12–16 hours (maximum 100 g), and IV methylprednisolone 2 mg/kg/day, and empirical antimicrobials as per hospital antibiogram. If symptoms persist for 48–72 hours of treatment, or if early worsening, increase IV MPS to 10 mg/kg/day (maximum 1 g) consult specialist/expert for biological.

MIS-C with Kawasaki phenotype: IVIG 2 g/kg over 12–16 hours (maximum 100 g), and IV methylprednisolone 1–2 mg/kg/day. If symptoms persist for 48–72 hours of treatment, or if early worsening, consult specialist/expert for biologicals. Use biologicals only after expert consultation and at tertiary care only.

SUMMARY

Fever is one of the most common presenting complaints in children brought to the emergency department. Serious bacterial infection such as UTI, pneumonia, bacteremia, meningitis, bacterial gastroenteritis, osteomyelitis, septic arthritis, retropharyngeal/parapharyngeal abscess, or intra-abdominal abscess are required to diagnose and manage in early stage. Unlike in adults, adolescent and elder children, young infants and younger children have certain differences in clinical presentations, as they may become irritable and show fatigue, without any other apparent symptoms. Fever in children makes them very much uncomfortable. Observation score is used for evaluation and assessment of child with fever. Various risk stratification scores are helpful in SBI. Child should be admitted if indicated for antibacterial therapy. Evaluation and management of SBIs in children are summarized in **Flowchart 1**.

CHAPTER

Pediatric Abdominal Pain

Thiagrajan Jaiganesh, Faiz Ahmad

INTRODUCTION

Abdominal pain in pediatric age group continues to be a frustrating presenting symptom. Diagnosis and treatment of a child with abdominal pain is time consuming—time for listening, counseling, and education. A majority of pediatric patients who evaluated for abdominal pain do not have features of classic organic disease and fall into a functional category. Abdominal pain may develop due to disorders in multiple organ systems, including the pulmonary, gastrointestinal, urologic, and gynecologic systems. Infectious, neoplastic, metabolic, and anatomic mechanisms may give rise to the presenting symptom of abdominal pain (**Box 1**).

BOX 1: Potential causes of abdominal pain in the pediatric patient.

- ***Functional*:** IBS, functional abdominal pain, functional constipation, cyclic vomiting syndrome
- ***Gynecological*:** Ovarian cyst, ovarian torsion, and testicular torsion
- **Pulmonology:** Pneumonia
- **Infectious:** *Viral*: Enterovirus, adenovirus; *Bacterial*: ***Salmonella, Shigella, Campylobacter, Yersinia, E. coli;*** *Parasites*: ***Giardia, Entamoeba histolytica***
- ***Intestinal*:** Gastroesophageal reflux (esophagitis), gastritis ulcer (duodenal/peptic), cholelithiasis, cholecystitis, choledochal cyst, pancreatitis (acute and chronic), pancreatic pseudocyst, hepatitis, inflammatory bowel disease (Crohn/ulcerative colitis), eosinophilic disease (esophagitis and gastroenteritis), and carbohydrate malabsorption (lactose intolerance)
- ***Metabolic*:** Diabetes mellitus
- ***Neoplastic*:** Porphyria tumors
- ***Structural/Surgical*:** Malrotation, intussusception, polyp, foreign body, Meckel's diverticulum volvulus, and trauma
- ***Urologic*:** Urinary tract infection, nephrolithiasis, urinary pelvic junction obstruction

(IBS: irritable bowel syndrome)

Acute abdominal pain is one of the most common pediatric complaints, and it is a diagnostic challenge for emergency physician due to the variety of underlying causes. Acute abdominal pain is mostly a self-limiting, benign condition, such as in gastroenteritis, constipation, or viral illness. However, the challenge for the emergency physician is to identify potentially life-threatening conditions that require urgent evaluation and treatment, such as appendicitis, intussusception, volvulus, or adhesion. Around 1% of pediatric population presenting with acute abdominal pain require surgical intervention. But major concern for emergency physician is not to miss serious organic etiology and accurate and timely diagnosis is the key for preventing significant morbidity and mortality.

Chronic abdominal pain remains one of the most common problems seen by pediatrician and pediatric gastroenterologists. Abdominal pain is best understood with biopsychosocial model of disease, i.e., multifactorial nature of abdominal pain, including genetic, environmental, social, and psychological components. History and physical examination remain the most important steps for evaluation of alarming symptoms, which may guide emergency physician for more specific testing (**Box 2**). Treatment plans can be individualized on the basis of history, physical examination, and investigations.

EVALUATION OF ACUTE ABDOMINAL PAIN IN CHILDREN

In children, acute abdominal pain can be the harbinger of acute appendicitis or a presentation of Hirschsprung's disease or can be presentation of a child with pneumonia or a life-threatening illness requiring urgent surgical intervention. Therefore, it is very important to differentiate the cause of the acute abdominal pain in children. This chapter addresses the common causes, red flags, evaluation, and treatment guidelines for a pediatric acute abdomen in the emergency room.

Etiology

A wide spectrum of medical and surgical causes of acute abdomen in children. Out of which, only 6% require surgical intervention. In the emergency room, it is a diagnostic challenge

BOX 2: Red flags signs suggestive of higher risk in children with chronic abdominal pain.

- Involuntary weight loss
- Deceleration of linear growth
- Gastrointestinal blood loss
- Significant vomiting (bilious emesis and protracted vomiting)
- Dysphagia
- Odynophagia
- Chronic severe diarrhea
- Night-time stooling
- Pain awakening the child at night
- Persistent right upper or right lower quadrant pain
- Unexplained fever
- Abnormal physical findings (clubbing, localized tenderness, mass, hepatomegaly, splenomegaly, perianal abnormalities, and erythema nodosum)
- Abnormal laboratory testing (elevated C-reactive protein/erythrocyte sedimentation rate, and occult blood in stool)
- Family history of inflammatory bowel disease

to accurately gather all the key signs in a child with severe pain. The most common causes of acute abdominal pain in children are gastroenteritis, mesenteric adenitis, acute appendicitis, colic, obstructed inguinal hernia, ovarian/testicular torsions, intestinal obstruction, and constipation. Various causes of acute abdominal pain are listed in **Table 1**.

TABLE 1: Causes of acute abdominal pain in children.

Hemodynamically stable (medical causes)	• Gastroenteritis • Constipation • Early stage of acute appendicitis • Hemolytic uremic syndrome • Acute pneumonia
• *Hemodynamically unstable (surgical causes)* • *Sick looking, severe pain, and signs of shock*	• Perforated bowel or appendicitis • Intestinal obstruction (volvulus, bands) • Intussusception >24 hours • Ovarian/testicular torsion • Obstructed and strangulated hernia • Trauma

Pathophysiology

Essentially, abdominal pain can have three origins. It is more commonly visceral pain or parietal pain and rarely it is referred pain. Visceral pain occurs when noxious stimuli affect bowel. Tension, stretching, and ischemia stimulate visceral pain fibers. Tissue congestion and inflammation tend to sensitize nerve endings and lower the threshold for stimuli. Visceral pain fibers are bilateral and unmyelinated and enter the spinal cord at multiple levels, visceral pain usually is dull, poorly localized, and felt in the midline. Pain from foregut structures (e.g., lower esophagus and stomach) generally is felt in the epigastrium. Midgut structures (e.g., small intestine) cause periumbilical pain, and hindgut structures (e.g., large intestine) cause lower abdominal pain (**Fig. 1**).

Parietal pain originates from noxious stimulation of the parietal peritoneum. Pain due to ischemia, inflammation, or stretching of the peritoneum is transmitted through myelinated afferent fibers to specific dorsal root ganglia on the same side and at the same dermatomal level as the origin of the pain. Parietal pain usually is sharp, intense, discrete, and localized, and coughing or movement can aggravate it. Referred pain has many of the characteristics of parietal pain but is felt in remote areas supplied by the same dermatome as the diseased organ. It results from shared central pathways for afferent neurons from different sites. A classic example is a patient with pneumonia who presents with abdominal pain because the T9 dermatome distribution is shared by the lung and the abdomen. Pain due to laparoscopic surgeries can be felt in the left shoulder.

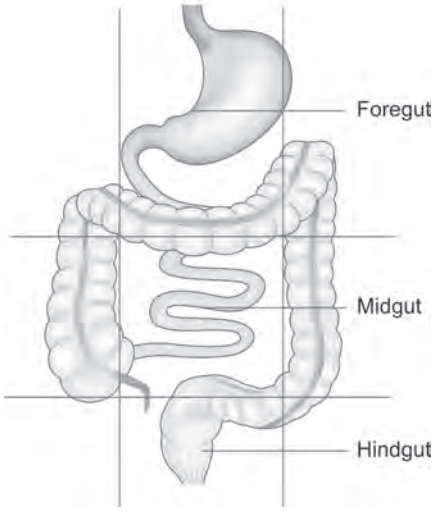

FIG. 1: *Pathophysiology*: Possible site of origin of acute abdominal pain in children.

Clinical Presentation

The challenge for the clinician is to identify patients with abdominal pain who may have the following: serious, potentially life-threatening conditions, such as an acute abdomen from appendicitis or bowel obstruction (as can occur from volvulus, intussusception, or adhesions); acute manifestations of inflammatory bowel disease (IBD), pancreatitis, hepatitis, myocarditis, or intra-abdominal mass. Extra-abdominal infections that require specific treatment (such as streptococcal pharyngitis, urinary tract infection, or pneumonia), this is very important to note serious life-threatening signs (red flags) in the early stage (**Table 2**). If these red flag signs are noted, urgent surgical consult should be obtained and rapid radiological confirmation of the diagnosis is needed before surgical intervention.

Evaluation

Assess general condition, vitals, and hydration status:

- *History taking*: It is extremely vital to get an accurate history, although it can sometimes be hearsay in children. The clues we can obtain by simple questioning are, length of current illness, similar episodes in the past, periodicity,

colicky nature of pain, and aggravating factors. Which came first, pain or vomiting? For example, in surgical causes of acute abdomen, the pain comes before the vomiting, but vice versa in medical causes. Nature of vomiting, whether bilious, also carries significance, as it indicates intestinal obstruction.

TABLE 2: Red flags: Acute onset abdominal pain.

Red flags	*Interpretation*
Acute abdomen with septic shock (hypotension, lethargy, and tachycardia)	In generalized abdominal sepsis
Bilious vomiting with scaphoid abdomen	Malrotation with volvulus
"Red currant jelly" stools	Classical in intussusception
Generalized guarding/ peritonism	Bowel perforation
Irreducible groin swelling	Obstructed inguinal hernia's
Testis pulled up into upper scrotum/inguinal region, firm, and tender	Testicular torsion
Abdominal distension, tenderness with shock (H/o blunt trauma abdomen)	Internal hemorrhage due to solid organ/bowel injury secondary to trauma
Feculent vomitus/ obstipation	Intestinal obstruction
Palpable tender abdominal mass	Appendicular mass/abscess
Inability to walk due to abdominal pain	Appendicular/psoas abscess
Hematemesis	Bowel gangrene/portal hypertension
Incessant cry	Bowel strangulation/ischemia/ obstruction

- *Physical examination:* The examiner's technique should be gentle and patient, with both the parent and the child. The examination should end in the area of interest while trying to engage the child in conversation or distraction. A per rectal examination is a must, as it adds diagnostically relevant information regarding the stool, melena, hematochezia, and sphincter tone. Evaluation should be completed by examining the genitalia, testes, and spine of the child. **Table 3** describes the differential diagnosis of acute abdominal pain in children.

Investigations

X-ray abdomen is a good diagnostic tool in children with abdominal pain, signs such as football sign or Rigler's sign (pneumoperitoneum), multiple air fluid levels indicating bowel obstruction, or the pneumatosis intestinalis [intramural air in necrotizing enterocolitis (NEC)], paucity of bowel gas in volvulus, paucity of rectal gas in Hirschsprung's disease, all are good diagnostic markers of specific disease. X-ray can be used in adjunction with oral contrast also when feasible to confirm certain diagnosis. Ultrasound abdomen is the standard investigation for the common appendicitis, mesenteric adenitis and intussusception seen in the pediatric emergency room every day. A finding of a nonperistaltic blind ending dilated >6 mm in the region of the right iliac fossa is diagnostic of appendicitis. In intussusception, the pseudo kidney sign or target sign is the classical finding. When Doppler is added to the USG, malrotation and volvulus can also be picked up, if we see the whirlpool sign. Important modalities of investigation are listed in **Table 4**.

Treatment

Treatment should be aimed at the underlying cause of the acute abdomen once the diagnosis is made, till the resuscitative measure should be carried out, e.g., intravenous fluids should be started for dehydrated children according to the metabolic

TABLE 3: Differential diagnosis of acute abdomen with regards to the age.

	0–1 years	*2–5 years*	*6–10 years*	*11–15 years*
Medical causes	Infantile colic	Gastroenteritis	Gastroenteritis	Gastroenteritis
	Gastroenteritis	Lower lobe pneumonia	Constipation	Pancreatitis
	Constipation	Urinary tract infection	Mesenteric lymphadenitis	Constipation
	Urinary tract infection	Henoch–Schönlein purpura	Urinary tract infection	Mittelschmerz
		Constipation	Pneumonia	Pelvic inflammatory disease
		Mesenteric adenitis	Inflammatory bowel disease	Inflammatory bowel disease
		Sickle cell crisis		
Surgical causes	Intussusception	Intussusception	Appendicitis	Appendicitis
	Obstructed inguinal hernia	Appendicitis	Trauma	Ovarian/testicular torsion
	Midgut volvulus	Trauma	Testicular torsion	Trauma
	Hirschsprung's disease	Volvulus	Cholecystitis	Hollow viscus perforation
		Ovarian/testicular torsion	Ovarian/testicular torsion	Intestinal obstruction
		Obstructed inguinal hernia	Intestinal obstruction	
		Intestinal obstruction	Hollow viscus perforation	

TABLE 4: Important investigations helpful in acute abdominal pain in children.

Modality	*Radiological sign*	*Interpretation*
X-ray abdomen	Football sign/Rigler's sign	Pneumoperitoneum/bowel perforation
	Multiple air fluid levels	Intestinal obstruction
	Paucity of bowel gas	Midgut volvulus
	Paucity of rectal gas	Hirschsprung's disease
	Pneumatosis intestinalis	Necrotizing enterocolitis
USG abdomen	Nonperistaltic blind ending dilated bowel loop >6 mm in the RIF	Appendicitis

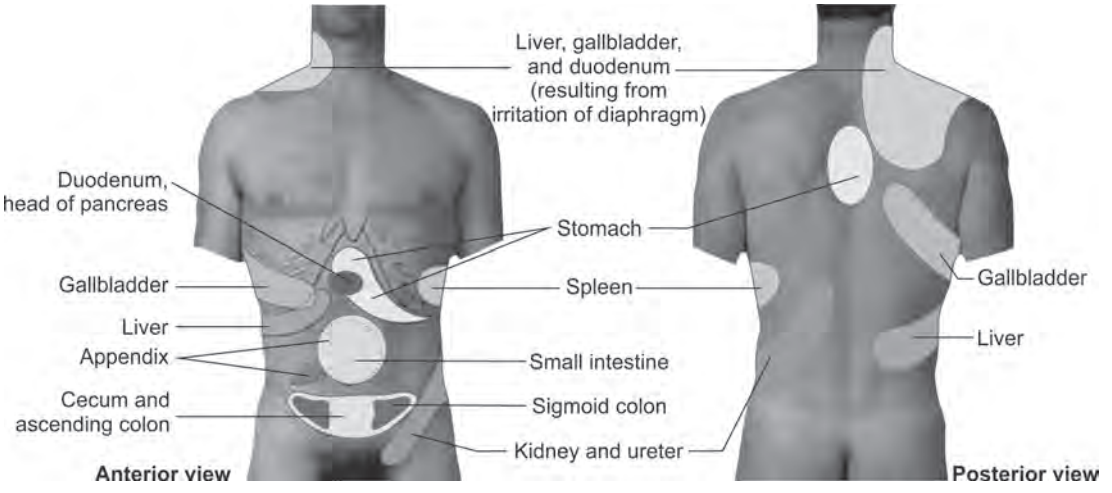

FIG. 2: Possible site of origin of chronic abdominal pain in children.

deficit. Urine output assessment can be done by catheterizing the bladder. Nasogastric decompression is advisable in children with bilious or feculent vomiting to prevent aspiration of vomitus. Analgesics can be avoided in some situations till the diagnosis is clear, as nature of tenderness can guide the physician. Occasionally, an irritable infant may not allow optimal examination unless sedated with oral/nasal/IV sedatives.

EVALUATION OF CHRONIC OR RECURRENT ABDOMINAL PAIN IN CHILDREN

Chronic abdominal pain is defined as at least three episodes of pain over at least 3 months interfering with a child's normal function. In clinical practice, abdominal pain that is >2 months in duration is considered chronic abdominal pain. The term "chronic abdominal pain" encompasses "recurrent abdominal pain" classically defined by four criteria: (1) ≥3 episodes of abdominal pain; (2) pain sufficiently severe to affect activities; (3) episodes occur over a period of ≥3 months, and (4) no known organic cause. The prevalence of recurrent abdominal pain in children ranges from 9 to 15%. Chronic abdominal pain in children could result in poor social and education development while placing a significant burden on local healthcare resources. Therefore, our aim is summarizing a variety of childhood disorders that could lead to chronic abdominal pain and provide some diagnostic and treatment strategies (**Fig. 2**). The two main categories of causes of chronic abdominal pain in children are organic and functional disorder (**Table 5**).

Pathophysiology

The pathophysiology of functional abdominal pain is likely due to the involvement of the enteric nervous system (ENS), also known as "gut brain". Pain receptors in the abdomen respond to mechanical or chemical stimuli. Stretch is the major mechanical stimulus involved in visceral pain which is induced by distension, contraction, traction, compression, and torsion.

Clinical Presentation

The clinical presentation could be varied, but one should pay attention to the "*red flags*" as they may indicate an organic cause. Organic pathology is identified in approximately 1 in 10 children who present with chronic and or recurrent abdominal pain. The signs and symptoms that can suggest underlying organic pathology are—nocturnal or chronic diarrhea, deceleration of linear growth, delayed puberty, dysphagia, family history of inflammatory bowel, celiac or peptic ulcer disease, gastrointestinal blood loss, genitourinary tract symptoms, involuntary weight loss, pain that wakes the

TABLE 5: Chronic causes of abdominal pain in pediatric age.		
Organic disorders	Gastrointestinal	Celiac disease, chemical gastritis, constipation, eosinophilic esophagitis, erosive esophagitis, gallbladder disease, gastroenteritis/colitis, GERD, *Helicobacter pylori* infection, hiatal hernia, inflammatory bowel disease irritable bowel syndrome, pancreatitis, and peptic ulcer
	Genitourinary	Imperforate hymen, menstrual cramps, mittelschmerz, ovarian cyst, endometriosis, pelvic inflammatory disease, recurrent UTI, testicular pain, ureteropelvic junction obstruction, and urolithiasis
	Metabolic	Adrenal crisis, diabetic ketoacidosis, porphyria
	Musculoskeletal	Anterior cutaneous nerve entrapment
	Neurologic	Spinal tumor and transverse myelitis
	Other	Familial mediterranean fever, lead poisoning, lymphoma, peritoneal, abscess/tumor, pneumonia, sickle cell disease, polyarteritis nodosa/vasculitis, IgE-mediated food allergy
Functional disorders	Functional dyspepsia	Dyspepsia is pain or discomfort in the epigastric region. Children with dyspepsia and alarm findings should be evaluated for an organic disorder (e.g., peptic ulcer disease)
	Irritable bowel syndrome (IBS)	It is characterized by chronic abdominal pain and altered bowel habits (diarrhea or constipation) in the absence of any alarm findings
	Abdominal migraine	It is characterized by recurrent episodes of abdominal pain for at least 6 months, usually in the midline or poorly localized, moderate to severe in intensity and is associated with at least two more features including anorexia, nausea, vomiting, headache, photophobia, and pallor. A family history of a migraine headache is common

child from sleep, persistent right upper or lower quadrant pain, significant vomiting, and recurrent unexplained fevers.

Evaluation

The initial evaluation of chronic abdominal pain includes history, physical examination, and stool guaiac for occult blood to determine, if the child has any "*red flags*" that can help in distinguishing organic from functional abdominal pain and direct the need for additional evaluation:

- *History*: It is important to ask specifically about the alarm findings: unexplained fever or weight loss, painful swallowing or difficulty swallowing, vomiting—bilious, protracted, projectile, or worrisome, diarrhea—severe and chronic (lasting >2 weeks and >20 mL/kg/day), bloody or nocturnal, back pain, urinary symptoms, family history of IBD, celiac disease, or peptic ulcer disease, and skin changes (e.g., hives, eczema, and rash).
- Asking the patient/family to keep the pain diary regarding the time of the day the pain started, pain location and severity, pain duration, triggering factors, and interventions if any and if they were helpful.
- *Physical examination*: A thorough physical examination may help in the diagnosis of chronic abdominal pain. General appearance and level of discomfort may indicate the severity of abdominal pain. Alarm findings on examination include—deceleration in linear growth, anemia, oral ulcers or perianal skin tag, fissure or fistula, localized abdominal pain, suprapubic tenderness, or costovertebral angle tenderness, delayed puberty, hepatosplenomegaly, guaiac-positive stool, joint swelling or tenderness, and hypertension.
- *Carnett sign:* It helps to differentiate visceral from abdominal wall pain. With the child in a supine position, ask him or her to cross the arms and sit halfway forward. A focal tenderness that increases and or remains the same during abdominal wall contraction (i.e., positive Carnett sign) suggests pain originating in the abdominal wall (e.g., hematoma, hernia, muscular pain, and anterior cutaneous nerve entrapment syndrome).
- *Psoas sign*: Pain on hyperextension of the hip is suggestive of inflammation of psoas muscle (e.g., psoas abscess). Delayed puberty may be a clue to organic disease (e.g., IBD); absence of menarche despite sexual maturity may be a clue to hematocolpos.

Investigations

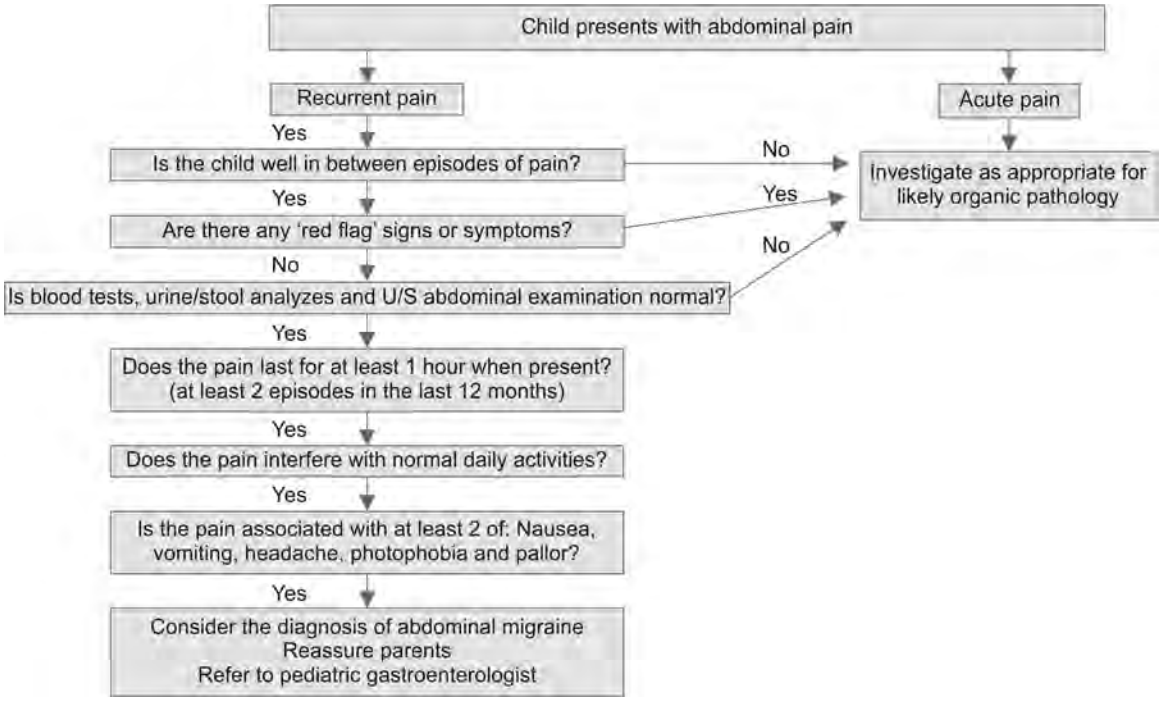
Careful and detailed history and physical examination in combination with judicious and selective use of diagnostic studies are required to delineate the underlying cause of chronic abdominal pain in children. Routine testing in patients with chronic abdominal pain without any "*red flag or alarm findings*" is not useful, though it may be reassuring for the parents. A 2005 systematic review found little or no evidence to suggest that laboratory, ultrasonography, endoscopy, or esophageal pH monitoring increases the yield of organic disease in the absence of "red flags"/"alarm findings". Laboratory tests to consider in patients with alarm findings are complete blood count with differential for anemia or infection, C-reactive protein or erythrocyte sedimentation rate for inflammation or infection, metabolic panel, liver function test, lipase, pregnancy test, tissue transglutaminase antibody for screening celiac disease, thyroid stimulating hormone and free thyroxine (T4) to evaluate for hypothyroidism as a cause of chronic constipation, urinalysis and culture for urinary tract infection, stool guaiac test for gastrointestinal bleeding, stool ova, and parasite. *Helicobacter pylori* stool antigen or urea breath test, the fecal calprotectin test had a pooled sensitivity of 92% and a pooled specificity of 76% for IBD. A child with weight loss, anemia, and blood in the stool should be evaluated for Crohn's disease because these conditions have a cumulative sensitivity of 94% for Crohn's disease in children. Abdominal radiography may be helpful in the diagnosis of obstruction,

foreign body, or constipation. Abdominal ultrasound abnormalities are found in about 10% of children who have jaundice, persistent fever, urinary symptoms, significant weight loss, back or flank pain, vomiting, abnormal abdominal examination findings, abdominal pain away from midline, and gastrointestinal bleeding, compared with <1% of those without these findings. Pelvic ultrasonography—is done to evaluate ovarian masses or pregnancy. Upper gastrointestinal series is done to assess bowel obstruction. Computed tomography of the abdomen with contrast is done to evaluate retroperitoneal or intraperitoneal abscess; usually reserved for urgent evaluation because of the risk of exposure to radiation in young children. Magnetic resonance enterography will be done, if IBD is suspected. Esophagogastroduodenoscopy and colonoscopy with ileoscopy can be done if Crohn's disease is suspected. Diagnosis of functional abdominal pain can be made without additional diagnostic testing in children with chronic abdominal pain who meet the following criteria: no alarm findings, normal physical examination, and stool sample negative for occult blood. A simplified diagnostic algorithm for the assessment of children presenting with recurrent abdominal pain is shown in **Flowchart 1**. Diagnostic imaging pathways for children presenting with chronic abdominal pain is depicted in **Flowchart 2**.

Treatment

Treatment depends on the cause of pain and whether the abdominal pain is organic or functional. The primary goal of therapy is improving quality-of-life, reducing parent and child concern about the seriousness of the condition, and reducing disability associated with pain rather than complete resolution of pain. In children with functional abdominal pain, use of probiotics, such as lactobacillus, reduces the intensity and frequency of abdominal pain and is safe for children. Cognitive behavior therapy is an evidence-based psychosocial method that focuses on changing the patterns of thinking that causes unwanted behaviors. Hypnotherapy is another promising psychological therapy in which a hypnotized child visualizes relaxing images to ease symptoms such as pain and anxiety. Gut-directed hypnotherapy demonstrates sustained long-term effects, with continued pain relief 5 years after treatment in 68% of the patients. Following interventions may be beneficial in conjunction with supportive management:

- *Acid reflux*: Antacid and H2 receptor antagonists.
- *Dyspepsia*: Proton-pump inhibitors, including lansoprazole and pantoprazole, are safe and effective for the treatment of dyspepsia in children, with the improvement of pain in more than 70% of patients.
- *Celiac disease*: A gluten-free diet should be initiated.
- *Inflammatory bowel disease*: Children should be referred to a pediatric gastroenterologist for anti-inflammatory medications and biologics.
- *Chronic constipation*: Treatment includes dietary interventions, such as increased fluids, fiber, and prune, pear, and apple juices; behavioral interventions, including regular toilet time for 5 or 10 minutes after meals and use of stool diaries; reward system; and parental education. Polyethylene glycol is the first-line therapy for children. Magnesium hydroxide is another option. Severe constipation may require manual disimpaction, enemas (e.g., saline, mineral oil, and polyethylene glycol), suppositories (e.g., bisacodyl and glycerine) or other laxatives (e.g., magnesium citrate, lactulose, sorbitol, docusate, and mineral oil).



Child presents with abdominal pain
Recurrent pain
Acute pain
Yes
Is the child well in between episodes of pain?
No
Investigate as appropriate for likely organic pathology
Yes
Are there any 'red flag' signs or symptoms?
Yes
No
No
Is blood tests, urine/stool analyzes and U/S abdominal examination normal?
Yes
Does the pain last for at least 1 hour when present? (at least 2 episodes in the last 12 months)
Yes
Does the pain interfere with normal daily activities?
Yes
Is the pain associated with at least 2 of: Nausea, vomiting, headache, photophobia and pallor?
Yes
Consider the diagnosis of abdominal migraine
Reassure parents
Refer to pediatric gastroenterologist

US +/- TVUS

FLOWCHART 2: Diagnostic imaging pathways in children presenting with chronic abdominal pain.

SUMMARY

Evaluation of pediatric abdominal pain is challenge, it is very important to differentiate the cause of the acute abdominal pain in children because this may be life-threatening. Chronic abdominal pain is defined, if present for at least 2 months. Two major causes of chronic abdominal pain are organic disorders and functional disorders. The initial evaluation of chronic abdominal pain includes history, physical examination, and stool guaiac test. If there are no "alarm findings", no further evaluation is necessary in most cases. Patients with alarm findings require additional laboratory and imaging studies to look for organic causes.

167 CHAPTER

Vomiting, Diarrhea, Dehydration in Children

Deepak Goyal

INTRODUCTION

Diarrhea is defined as the passage of *three or more loose or liquid stools per day*. Acute diarrhea is defined as diarrhea, which lasts <14 days. Frequent passing of formed stools is not diarrhea, nor is the passing of loose and pasty stools by breastfed infants. *Childhood diarrhea* is one of the leading causes of morbidity and mortality throughout the world. Dysentery is diarrhea with presence of visible blood in stools with presence of cramps and or fever. Dysentery does not include blood streaks on surface of formed stool or blood detected by microscopy/biochemical examination. *Nausea* is the sensation of impending emesis and is frequently accompanied by autonomic changes, such as increased heart rate and salivation. *Vomiting* is forceful expulsion of gastric contents from the mouth. In 2015, diarrheal disease caused an estimated 688 million illnesses and 499,000 deaths worldwide among children <5 year. In India, approximately 140,000 deaths among children under-5 were attributable to diarrhea in 2013. Diarrhea is a leading cause of malnutrition in children under 5-year-old.

ETIOLOGY

Table 1 shows the common infectious agents of acute diarrhea. *Rotavirus* accounts for 40% of all hospital admission worldwide. Rotavirus was identified as an etiological agent in 5.2–80.5% cases of nosocomial diarrhea. Compared with other viral infections, rotavirus infection is associated with fever, more frequent diarrheal episodes (>7/day) and longer lasting diarrhea. Although it is difficult to differentiate clinically but presence of high fever, overt fecal blood, abdominal pain, or central nervous system (CNS) involvement favors bacterial origin. **Table 2** highlights etiology of acute vomiting in infants and children.

TABLE 1: Etiology of acute diarrhea.

Viruses	*Bacterial*	*Parasites*
• Rotavirus • Norwalk virus • Adenovirus • Astrovirus • Calicivirus	• *E. coli* • *Shigella* • *Salmonella* • *V. cholera* • *Campylobacter jejuni* • *Clostridium difficile*	• *Giardia* • *Entamoeba* • *Cryptosporidium* • *Isospora belli*

ASSESSMENT OF CHILD WITH VOMITING AND DIARRHEA

Child with diarrhea *should be assessed for* (1) dehydration, (2) blood in diarrhea, (3), coexisting malnutrition, and (4) serious nonintestinal infections.

History should focus on duration of diarrhea and number of watery stools per day; volume of water in stool; presence of blood in the stool; frequency of urination; presence of vomiting, fever, cough, or seizures; preillness feeding practices; and fluids, food and drugs taken during illness, and immunization history.

Examination should include general condition of child; signs of dehydration; nutritional status [weight/weight for height/mid-upper arm circumference (MAC)] and severity of malnutrition if any; and presence of blood in stool besides general physical and systemic examination. Classification of dehydration (**Table 3**) is of utmost importance in the management.

TABLE 2: Causes of acute vomiting in infants and children.

Infants	*Children*
Viral gastroenteritis	Viral gastroenteritis
Gastroesophageal reflux	Sepsis
Pyloric stenosis	Meningitis/encephalitis
Intussusception	Appendicitis/pyelonephritis
Sepsis	Hepatitis
Malrotation	Raised intracranial tension
Food intolerance	Toxic ingestion
Metabolic disorders	Adverse drug reactions
	Cyclic vomiting syndrome

TABLE 3: Classification of dehydration.		
Severe (two of the following are present)	***Some (two of the following are present)***	***No dehydration***
Lethargy/unconscious	Restless, irritable	Not enough signs to classify some or severe dehydration
Sunken eyes	Sunken eyes	
Not able to drink/ drinking poorly	Drinks eagerly, thirsty	
Skin pinch goes back very slowly	Skin pinch goes back slowly	

DEHYDRATION IN DIARRHEA

During diarrhea, there is an increased loss of water and electrolytes (sodium, chloride, potassium, and bicarbonate) in the liquid stool. Water and electrolytes are also lost through vomit, sweat, urine, and breathing. Dehydration occurs when these losses are not replaced adequately and a deficit of water and electrolytes develops.

How to assess skin pinch?

Locate the area on the child's abdomen halfway between the umbilicus and the side of the abdomen. Use your thumb and first finger to pinch. The fold of the skin should be in a line up and down the child's body. Firmly pick up all of the layers of skin and the tissue under them. Pinch the skin for one second and then release it. When you release the skin, look to see if the skin pinch goes back: Very slowly (>2 sec), slowly (skin stays up even for a brief instant), and immediately (normal).

For children with vomiting history should determine onset and frequency of vomiting; character of episodes (projectile, bilious, or small in amount and more consistent with spitting up); any precipitating factor to vomiting (only with specific foods, after feeding, primarily in the morning or in recurrent cyclic episodes). Any associated symptoms including diarrhea (with or without blood), fever, anorexia, and abdominal pain, distention should be looked for. Stool frequency and consistency and urinary output should also be noted.

General examination should include signs of distress (e.g., lethargy, irritability, and inconsolable crying) and signs of weight loss. Skin and extremities should be examined for purpura or petechiae (sepsis) or any other rash (possible viral infection or atopy), jaundice (hepatitis/metabolic disorder), and signs of dehydration (e.g., poor skin turgor and delayed capillary refill). The head and neck examination should focus on signs of infection (e.g., red, bulging tympanic membrane; bulging anterior fontanel; and erythematous tonsils). *Systemic examination* should seek symptoms suggestive of causative disorders, including weakness, poor suck, and failure to thrive (CNS infections/metabolic disorders); abdominal distention (intestinal obstruction); headache, nuchal rigidity, and vision changes (intracranial etiology); ear pain or sore throat (focal infection); and fever with headache, neck or back pain, or abdominal pain (meningitis, pyelonephritis, or appendicitis). Cardiac examination should note presence of tachycardia (dehydration, fever, and distress). Abdominal examination should note distension; presence and quality of bowel sounds (high-pitched, normal, and absent); tenderness and any associated guarding, rigidity, or rebound (peritoneal signs); and presence of organomegaly or mass.

Features of concern (red flags):

- Bilious emesis
- Peritoneal signs or abdominal distention (surgical abdomen)
- Persistent vomiting with poor growth or development
- Lethargy or listlessness
- Inconsolability and bulging fontanel in infant
- Nuchal rigidity, photophobia, and fever in older child

TREATMENT

Plan of treatment for acute diarrhea has been shown in **Table 4**. Management of acute vomiting consists of assessment and correction of dehydration and correction of specific etiology besides symptomatic management. Since acute vomiting is mostly seen as a part of acute gastroenteritis, our discussion here will be focused on that objectives—(1) prevent and treat dehydration, (2) drugs (antibiotics, zinc), (3) nutritional management, and (4) education. *Indications for hospital admission are* (1) shock, (2) severe dehydration, (3) neurological abnormalities (lethargy, seizures), (4) intractable or bilious vomiting, (5) failure of oral rehydration, (6) suspected surgical condition, and (7) conditions for a safe follow-up and home management are not met.

Plan A: No Dehydration—Home Care

No blood tests are required. Give the child more fluids than usual, to prevent dehydration. Low osmolarity oral rehydration solution (ORS) is the preferred solution for this. Currently in India, only low osmolarity ORS (**Table 5**) is available. If ORS is not available or child is not taking it, other fluid like salted drinks (e.g., salted rice water or a salted yoghurt drink), vegetable, or chicken soup with salt or yoghurt drinks without salt or coconut water can be used. Commercial carbonated beverages or fruit juices should not be used.

TABLE 4: Plan of treatment for dehydration.		
Severe dehydration	***Some dehydration***	***No dehydration***
Plan C	*Plan B*	*Plan A*
Urgent care in hospital	Treat dehydration with ORS/ IV fluid	Home care

TABLE 5: Composition of standard and low osmolarity ORS solutions.		
	Standard ORS solution (mEq)	***Low osmolarity ORS (mmol/L)***
Glucose	111	75
Sodium	90	75
Chloride	80	65
Potassium	20	20
Citrate	10	10
Osmolarity	311	245

Up to 5–10 mL/kg fluid should be given orally after each loose stool depending upon the volume of stool. Older children can have as much as they want. Continuation of normal (age appropriate) feeding is advised and it should not be stopped as it can aggravate existing malnutrition.

Red flag signs: Educate patient to return to hospital if any one of the flowing occurs, high purge rate; repeated vomiting; very thirsty; oral intake poor; develops fever or blood in stools; and failure to pass urine for >6 hours.

Plan B: Some Dehydration

Routine blood tests are again not indicated in some dehydration. ORS is the mainstay of management along with nutrition. Approximately 75 mL/kg of ORS should be given in around 4 hours to correct dehydration. Asses the child regularly during rehydration to know the purge rate; whether the child is able to accept the ORS and whether signs of dehydration are not worsening. In infants, continue breastfeed as often and as long as the infant wants. For older children, offer as much plain water to drink as they wish, in addition to ORS solution.

How to give ORS?

The solution should be given to infants and young children using a spoon or cup. For young infants, a dropper or syringe can also be used. Children under 2 years of age should be offered a teaspoonful every 1–2 minutes; older children may take frequent sips directly from the cup. If the child vomits, wait 10 minutes and then give ORS solution again, but slowly.

After 4 hours: Asses the Child Again

If the child still has signs indicating some dehydration, continue oral rehydration therapy by repeating treatment plan B. If signs of severe dehydration, give IV fluids as in plan C (discussed later). This can be there in children who drink ORS solution poorly and pass large watery stools frequently during the rehydration period. If there are no signs of dehydration, the child should be considered fully rehydrated and can be sent home.

Before Sending the Child Back

Teach the mother how to treat her child at home with ORS solution and food (treatment plan A). Ensure she has enough ORS packets. Also educate about red flag signs (as described in plan A).

Plan C: Severe Dehydration

Investigations

Complete blood count (CBC), electrolytes, venous blood gas (VBG), and renal function test (RFT) are preferred. Stool for hanging drop and culture should be sent when cholera is suspected *(If clinical suspicion)*. Stool routine and culture is normally not indicated in management of acute watery diarrhea as they do not change the management. Assess the child carefully for presence of shock as early recognition of shock is important. Though isonatremic dehydration is most common but hypo- or hypernatremic dehydration can be present and should be treated as per protocol. There is no role of intravenous (IV) bicarbonate in correction of acidosis and IV fluid alone is sufficient (**Table 6**).

TABLE 6: Treatment plan C (severe dehydration).

Age	*First give 30 mL/kg in:*	*Then give 70 mL/kg in:*
Infants (under 12 months)	1 hour	5 hours
Older	30 minutes	2.5 hours

Intravenous fluid with close monitoring is the mainstay of treatment. Establish IV or intraosseous access (if IV access not available). Ringer's lactate (RL) is preferred fluid. It can be used in all age groups for the initial treatment of severe dehydration caused by acute diarrhea of any etiology. Normal saline is a good alternative (dextrose normal saline is preferred for malnourished). Plain dextrose solution should not be used since it does not contain electrolytes and thus does not correct the electrolyte losses or the acidosis. It does not effectively correct hypovolemia.

Reassess the patient every 15 minutes till strong radial pulse is felt. Thereafter assess every 1–2 hours. If hydration is not improving, increase the IV drip infusion. If the patient is able to drink, give ORS by mouth. *Beware of fluid overload (congestive cardiac failure and hepatomegaly) in severely malnourished children.*

ORS in Severe Dehydration

Children who can drink, should be given ORS until the IV drip is running. In addition, all children should start to receive ORS solution (about 5 mL/kg/h) when they can drink without difficulty, which is usually within 3–4 hours for infants or 1–2 hours for older children. ORS provides additional base and potassium, which helps in recovery. Oral/IV ondansetron is the preferred and safe antiemetic in case of vomiting and it is preferred over oral domperidone.

Reassess after Resuscitation

After 6 hours in infants and 3 hours for older patients, evaluate hydration status again and choose the appropriate plan (A, B, or C) (*see* **Table 4**). Observe for at least 8–12 hours after the child has been fully rehydrated. Give extrafluids, zinc supplement, feeding advice, and counseling regarding when to return immediately as in plan A before discharge.

Role of Nutrition

Age appropriate feeding during diarrhea is encouraged to decrease stool output, shorten the duration of illness, and to improve nutritional status. *Early feeding* enhances enterocyte regeneration, promotes recovery of brush border disaccharidases, nutrient absorption, and weight gain. On demand, breastfeeding should be continued for infants who are already breastfed. Infants who are not breastfed should be given their usual milk or formula feed at least every 3 hours. Infants >6 months should be given mashed cereals, vegetables, and other complimentary foods in addition to milk. Recommended foods should be culturally acceptable, readily available, and should have a high energy content, and provide adequate micronutrients. Frequent, small feedings are tolerated better than large feedings. Same energy-rich foods should be continued even after the diarrhea stops.

If the child is malnourished, extrameals should be given until the child has regained normal weight-for-height.

Role of Antibiotics in Acute Diarrhea

Most cases of acute watery diarrhea are viral and are self-limiting. Blanket antibiotic cover is not justified. Unnecessary use of antibiotics leads to destruction of normal gut flora and can be a risk factor for persistent diarrhea. They may increase costs, prolong diarrheal episodes, and contribute to spreading antibiotic resistance. Indications for use of antibiotics in diarrhea:

- Dysentery
- Presence of systemic infection/sepsis
- Associated infection—urinary tract infection (UTI), acute suppurative otitis media (ASOM), and pneumonia
- Severe malnutrition
- Cholera
- Cryptosporidium
- Immune deficiency
- Proven giardiasis/amoebiasis

Zinc Supplementation in Diarrheal Diseases

20 mg per day of zinc for 14 days should start as early as possible after onset of diarrhea and 10 mg per day for infants 2–6 months should be given. Zinc sulfate, acetate, and gluconate are all acceptable zinc salt formulations. There is no need to repeat zinc in case of a second attack of diarrhea within next 3 months.

Mechanism of action—(1) improves absorption of water and electrolytes by the intestines by regeneration of gut epithelium, (2) enhances immunologic mechanisms for the clearance of infection including T cell-mediated immunity and induces higher levels of secretory antibodies, and (3) increases level of enterocyte brush-border enzymes.

SUMMARY

Diarrhea contributes significantly to under-5-year age mortality and morbidity (malnutrition) in our country. Assessment of dehydration is the most important step in the management of acute diarrhea. It is important to identify patients with severe malnutrition. Rehydration and zinc supplementation are the mainstay of management. Low osmolarity ORS should be used for prevention and correction of dehydration. Patient with some dehydration should be under observation for 4–6 hours to ensure dehydration is corrected and not progressive. Patients with severe dehydration are at a very high risk and should receive IV fluids and should be appropriately investigated and closely monitored. Antibiotics are indicated in dysentery, severely protein-energy malnutrition (PEM), immunocompromised, and in presence of systemic infection, cholera, or giardiasis. Oral ondansetron is the preferred antiemetic to control vomiting. Antimotility agents can be harmful in children and are to be avoided in acute diarrhea.

168 CHAPTER

Pediatric Fluid and Electrolyte Therapy

Devendra Richhariya

INTRODUCTION

Fluid and electrolyte therapy are an important part of the care in hospitalized children in emergency department, and emergency physician should have a thorough knowledge of the changing requirements of growing children along with pharmacokinetic changes that occur from birth to adulthood. For practical purpose, fluid therapy can be divided into maintenance therapy, calculating fluid deficit, and fluid replacement as per deficit, patient response to fluid therapy and then monitoring makes fluid therapy manageable.

PHYSIOLOGIC DIFFERENCES

As the age, increases from birth until 1 year of age total body water content changes drastically. A baby's total body water content is close to 80% of total body weight at 24 weeks gestational age, slowly decreases (60% of total body water) around 1 year of age; in most adults, total body water is between 50% and 60% of total body weight. Infants loss about 5–15% of their body weight after birth, newborn babies have more extracellular water (45% of total body weight)—compared with intracellular water (35% of total body weight). Total body fluid has important role in drug therapy, especially for water soluble drugs.

FLUID THERAPY

Physiologic differences and changes that take place as a child grows have a great effect on fluid requirements. Special attention is required while deciding fluid therapy essential in pediatric age group. Fluid therapy can be divided into three part, (1) maintenance, (2) deficit estimation, and (3) replacement. Careful consideration should be paid to each component of fluid therapy while choosing the type of fluid and volume to be administered.

Maintenance Fluids

Ongoing fluid losses are compensated by maintenance fluids and are required for all patients. Maintenance fluids are frequently given through an intravenous access, but if the patient is able to tolerate oral therapy can also be given orally. Majority of ongoing losses are sensible losses (urine output and fecal water), adding with insensible losses such as respiration and perspiration. Fluid requirements are higher for children than adults for multiple reasons. First, greater caloric expenditure in children due to the higher metabolic rate, which needs higher fluid requirements. Secondly, children, especially infants, have higher body surface area to weight ratio so more water loss from skin compared with adults. In addition, higher respiratory rates in children and infants translate in more insensible losses from the respiratory tract.

Maintenance fluid requirements are determined by many mechanisms for children. When calculating maintenance fluids, emergency physician must aware about factors that may affect fluid balance. Maintenance fluid requirements are increased in hospitalized children due to their illness and associated problems such as fever, burn injuries, hypermetabolic states, pain, asthma, and increased intestinal losses. Holliday-Segar method is most commonly used technique to calculate maintenance fluids for children. The Holliday-Segar method is usually preferred due to its ease of calculation; however, the other methods are also exists employed in some instances but an expensive piece of equipment. The Holliday-Segar method may be simplified by estimating the fluid requirements in rate required per hour (**Table 1**).

Deficit Fluids

"Fluids deficit" means fluids lost prior to get medical care, e.g., clinical conditions in which patient present to emergency department with fluid deficit includes acute gastroenteritis with vomiting and diarrhea, significant blood loss in traumatic injuries, and inadequate fluids intake over a period of time. Most of the conditions associated with fluid deficit

TABLE 1: Holliday-Segar method for calculating maintenance fluid requirements in children.

	Holliday-Segar method	***Holliday-Segar estimate***
First 10 kg	100 mL/kg/day	4 mL/kg/h
Second 10 kg	50 mL/kg/day	2 mL/kg/h
Every kg thereafter	20 mL/kg/day	1 mL/kg/h

TABLE 2: Clinical signs of dehydration.

Clinical signs	*Mild dehydration*	*Moderate dehydration*	*Severe dehydration*
Weight loss in %	3–5	6–9	>10
Alertness	Normal	Listless	Normal lethargic coma
Thirst	Slight	Moderate	Intense
Mucus membrane	Normal	Dry	Dry
Anterior fontanel	Flat	Sunken	Sunken
Eyes	Normal	Sunken	Deeply sunken
Skin turgor	Normal	Decreased	Decreased
Blood pressure	Normal	Normal	Normal to decreased
Heart rate	Normal	Increased	Increased
Urine output	Decreased	Markedly decreased	Anuria
Degree of dehydration			
Older	3% (30 mL/kg)	6% (60 mL/kg)	9% (90 mL/kg)

can be approached by systematic manner. Clinical signs of dehydration provide useful insight into the fluid needs of the patient. Weight loss one of the important clinical sign of dehydration which can be used frequently by pediatrician, and compared with preillness weight. Other clinical signs include increased thirst, dry mucous membranes, and decreased urine output (**Table 2**). Clinical signs are important part of the physical examination for a dehydrated patient as they correlate fairly well with the degree of dehydration. After clinical signs have been observed, the degree (%) of dehydration should be determined. Degree of dehydration is calculated by dividing the difference between the preillness and illness weights by the preillness weight, then multiplying by 100. If a 10-kg patient, lost 1 kg is 10% dehydrated. Every 1 kg of weight lost is equivalent to 1 L of fluid loss. The degree of dehydration should be always be compared to the clinical signs, which may be better indicators of hydration status and useful when a preillness weight is unknown. Once the degree of dehydration is established, serum sodium concentrations, needs to be determined to ascertain the type of dehydration. Mostly patients have an isotonic dehydration, a serum sodium concentration of <135 mEq/L is considered hypotonic dehydration, while >145 mEq/L is considered hypertonic dehydration.

Oral rehydration therapy is required for patients with mild-to-moderate dehydration, even if diarrhea and vomiting continue. For mild dehydration volume of 50 mL/kg over 4 hours should be given in small quantity. Moderate dehydration patient should receive 100 mL/kg over 4 hours. The oral rehydration solutions (ORS) available commercially generally have appropriate amounts of carbohydrates and electrolytes, usually about 140 mmol/L of carbohydrate, 45 mmol/L (mEq/L) of sodium, and 20 mmol/L (mEq/L) of potassium. Liquids such as milk, juice, soda, tea, and sports beverages are not the substitute for ORS because they do not contain appropriate amounts of carbohydrates and electrolytes to fulfill the requirement of dehydrated patients. However, breastfeed may continue for infants if they have diarrhea.

Rehydration therapy is divided into three phases. *In phase I*, a bolus of fluid is recommended which restores blood volume and adequate perfusion of critical organs, such as the brain is maintained. Bolus fluids should be isotonic; either normal saline or ringers' lactated solution is recommended at a rate of 20 mL/kg, given over 60 minutes. If necessary, repeat boluses are given to maintain adequate perfusion. Isotonic fluids are preferred as they provide rapid volume expansion in the plasma and extracellular fluid. For estimation of amount of fluid required in phases II and III, the fluid volume given during phase I should be subtracted from the deficit fluid. *Phase II fluid therapy* should be given over 8 hours. Fluid requirement in phase II is equivalent to one-third of the daily maintenance plus one-half of the remaining deficit. During phase II, 5% dextrose with 0.45% sodium chloride should be used, with 20–30 mEq/L of potassium chloride added only if the patient has urine output. *Phase III fluid therapy* is given over 16 hours. The amount of fluid in phase III is equivalent to two-thirds of the daily maintenance plus the remaining deficit. During phase III, 5% dextrose with 0.2% sodium chloride should be used, again with 20–30 mEq/L of potassium chloride added only if the patient has urine output. So in short, in phases II and III of rehydration therapy maintenance fluid plus deficit fluid, given over 24 hours, with half of the deficit fluid given in the first 8 hours, and the second half of the deficit fluid given in the last 16 hours (**Table 3**).

Hypertonic dehydration (hyperosmolar state of their circulating blood) approach is quite different. The deficit fluid

TABLE 3: Method for calculating rehydration fluid in isotonic or hypotonic dehydration.

Rehydration phase	*Fluid volume*	*Example 10-kg child with 1-kg weight loss (deficit = 1,000 mL)*
Phase I (Emergency)	20 mL/kg may repeat if necessary	200 mL (remaining deficit = 800 mL)
Phase II (First 8 hours)	1/2 remaining deficit + 1/3 daily maintenance	400 mL + 333 mL = 733 mL = 92 mL/h
Phase III (Next 16 hours)	1/2 remaining deficit + 2/3 daily maintenance	400 mL + 666 mL = 1,066 mL = 67 mL/h
Monitoring parameters for parenteral fluid therapy: Oral intake, weight changes, urine volume and specific gravity physical signs and symptoms of dehydration, and serum electrolytes		

volume should be added to the maintenance fluid volume needed for 48 hours, and the total should be administered over 48 hours. Administering the deficit fluid faster causes osmotic fluid shifts, which can result in cerebral edema and convulsions. To avoid too quick rehydration, serum sodium should be checked frequently (every 2–4 hours) and serum sodium should not be corrected >10 mEq/L in 24 hours. The hypotonic fluid should be used, such as 5% dextrose with 0.2% sodium chloride.

Replacement Fluids

Replacement fluids are defined as fluids which are given to correct the ongoing losses during the medical treatment. Replacement fluids are required in various medical and surgical problems such as uncontrolled vomiting, continuing diarrhea, or cerebrospinal fluid shunts and in patients with chest tubes in place. In each of these situations, only maintenance fluids are not enough to recover the ongoing fluid loss. Replacement fluids differ from deficit fluids in that they are ongoing, as opposed to a loss of fluid that occurred prior to receiving medical treatment.

MAINTENANCE ELECTROLYTES

Renal functions represent the concentrations of electrolytes, vitally important for patient's clinical status. Frequent electrolyte monitoring is required in renal dysfunction. Components of intravenous fluids include electrolytes, sodium, potassium, and chloride. Requirements of chloride 5 mEq/kg/day, sodium 3 mEq/kg/day, and potassium 2 mEq/kg/day are usually fulfilled by administering the sodium and potassium as sodium chloride and potassium chloride salts. When choosing a maintenance fluid for a child, it is important to consider maintenance electrolyte requirements also. Commercially available fluids are adequately fulfilling requirements of electrolyte in children. For most children, a 5% dextrose solution with 0.2% sodium chloride provides the estimated needs of sodium when used as a maintenance fluid.

ELECTROLYTE ABNORMALITIES

Severe Hyponatremia

Serious central nervous system symptoms; lethargy followed by seizures is common in patients with serum sodium of <125 mEq/L. Hypertonic saline, usually 3% sodium chloride, is recommended due to emergent situation. The total volume of 3% sodium chloride required can be estimated by equation: (desired serum sodium concentration – current serum sodium concentration) × 0.6 × (weight in kg) Multiplying the sodium deficit by 2 gives the volume of 3% sodium chloride needed. Serum sodium should be checked periodically throughout the infusion order to avoid hypernatremia. Serum sodium should not be corrected faster than 12 mEq/L within 24 hours.

Hyperkalemia

Serum potassium of >6 mEq/L is considered as hyperkalemia this is where the electrocardiogram changes are usually seen. Before treating the hyperkalemia, check this is not a falsely elevated serum potassium. In infants, blood is acquired frequently from heel stick, which causes cell lysis due to the trauma of the needle and can cause rise in intracellular potassium. Hyperkalemia can be treated with a variety of medications which work through multiple mechanisms. In emergencies, those agents are helpful which cause a rapid influx of potassium intracellularly and provide an acute decrease in serum levels. These medications that can cause rapid decrease in serum potassium are insulin and beta adrenergic (albuterol). Sodium bicarbonate response is generally not immediate and mechanism in lowering the potassium is also not known. Sodium polystyrene sulfonate is an exchange resin, generally used for less emergent situations which exchanges sodium for potassium in the gut; diuretics such as furosemide is also used to increase potassium excretion into the urine, diuretics should be used cautiously in volume depleted situation. Calcium antagonizes the membrane effects of potassium so used in symptomatic patients for cardioprotective effects. Once emergent situation is managed, evaluation and long-term treatments are needed to control the cause of the hyperkalemia.

MONITORING FLUID AND ELECTROLYTE THERAPY

As per need of the children, initial fluid rate is determined. In hospitalized patient, need of fluid therapy frequently changes, so appropriate monitoring is necessary. The first parameter for monitoring is oral intake is preferred as soon as it is clinically indicated, as any intravenous administration brings with it the risk of infection. Patients with uncomplicated surgery who are not allowed anything by mouth for a short period of time, maintenance fluids are required, later fluids can be decreased and eventually stopped once they tolerate oral hydration. Patients who are on maintenance and deficit fluids therapy for dehydration, the most important monitoring parameters are clinical features of dehydration, such as skin turgor, urine output, and thirst. It is important to monitor patients' weights particularly in infants, as younger patients present with significant weight loss when dehydrated. Urine specific gravity can also be important for assessment of hydration status. Also, important to monitor, fluid which is given with parenteral antibiotics infusion, help in ensuring that the patient is not getting an excessive amount of fluids in medications can help prevent overhydration. The type of fluid used for medication should also be monitored using large volume of 5% dextrose for medication infusion could put the patient at risk for hyponatremia. If the patient has electrolyte abnormalities, monitoring serum electrolytes is necessary, but for hydration monitoring, the most important indices to watch are the clinical parameters mentioned earlier.

SUMMARY

Adopting a systematic, understandable approach for fluid therapy management and dividing fluid needs into maintenance, deficit, and replacement therapy can provide better monitoring in dehydrated child. By paying close attention to the fluid needs of pediatric patients and monitoring response to fluid therapy, the physician can have a positive influence on the health of the child. Stepwise approach should be adopted for determine the fluid requirement in child (**Table 4**). Particular attention should be given to the hydration status of patients, as the volume of drug is drastically affected by a change in volume status. Knowledge of fluid and electrolytes in children can help emergency physician to individualize medication therapy to the specific needs of the patient.

TABLE 4: Step-by-step determining maintenance fluids.

	Example determine the appropriate fluid and delivery rate for maintenance fluids and electrolytes for a 28-kg child	
Steps	***Calculation***	***Solution***
Step 1: Determine daily maintenance fluid requirement, using the Holliday-Segar method, determine the patient's fluid requirements (volume in liters) for 24 hours	• 100 mL/kg × 1st 10 kg = 1,000 mL • 50 mL/kg × 2nd 10 kg = 500 mL • 20 mL/kg × each additional kg (8) = 160 mL	1660 mL = 1.66 L
Step 2: • Deliver appropriate dose of electrolytes • Choose a commercially available fluid and determine how much sodium and potassium will be delivered considering the volume that will be administered	*Sodium requirements*: 3 mEq/kg × 28 kg = 84 mEq sodium: • D5 ¼NS × 1.66 L = 38.5 mEq sodium/L × 1.66 L = 63.9 mEq sodium • D5 ½NS × 1.66 L = 77 mEq sodium/L × 1.66 L = 128 mEq sodium • D5 NS × 1.66 L = 154 mEq sodium/L × 1.66 L = 255.6 mEq sodium *Potassium requirements*: 2 mEq/kg × 28 kg = 56 mEq potassium: • 10 mEq/L × 1.66 L = 16.6 mEq potassium • 20 mEq/L × 1.66 L = 33.2 mEq potassium • 30 mEq/L × 1.66 L = 49.8 mEq potassium • 40 mEq/L × 1.66 L = 66.4 mEq potassium	D5 ¼NS provides the most appropriate amount of sodium for this patient Generally, when beginning fluid therapy, more conservative potassium amounts, in this case 20 mEq/L, are used due to the risk of accumulation, particularly in hospitalized children
Step 3: Choose a fluid: Pick a commercially available fluid that delivers the desired amount of electrolytes		Answer D5 ¼NS with 20 mEq KCl per L at 69 mL/h
Step 4: Monitoring monitor patient fluid status and electrolytes and adjust the rate and fluid type accordingly

CHAPTER

Respiratory Problems in Infants and Children

Sandip Kumar

INTRODUCTION

In infants and children, respiratory problems are the most common illness requiring emergency room visit. Also, it remains one of the significant causes of mortality in children under 5 years of age (normal respiratory rate **Table 1**) although the mortality rates have fallen in past few decades due to increased vaccination. The principal cause of "pediatric medical" attendances at emergency departments is associated with "breathing difficulties", respiratory problems leading requiring emergency treatment and admission in hospital for management, presents to emergency department with respiratory failure which due to any airway, pulmonary parenchyma, or due to neuromuscular disorders which can lead to impairment in oxygenation and removal of carbon dioxide.

Largely the diagnosis of respiratory diseases is made clinically along with the history and physical examination, and chest radiography aids to the diagnosis when necessary. Although many of respiratory illnesses are milder and usually self-limiting, but others being life threatening require prompt diagnosis and management. Prompt recognition, assessment, and expert management of respiratory emergencies are critical to obtaining the best possible outcome. Therefore, it is very important that the emergency clinicians be able to promptly recognize and manage these illnesses. Signs, which demonstrate significant work of breathing and respiratory failure, are given in **Table 2**.

Emergency physician must be able to recognize the feature of severe respiratory distress like on examination severe chest wall retraction, paradoxical breathing pattern, head bobbing, cyanosis and pallor while on auscultation snoring, grunting stridor and wheezing. Altered sensorium, decreased or absence of breath sound on either side, evidence of shock (bradycardia, tachycardia, extended capillary filling time) are the features of worsening of the condition.

Among the multiple potential causes of respiratory emergencies in children, including infections/inflammatory causes and noninfectious causes (allergic processes, foreign body aspirations, trauma, chemical injuries, neoplasms, and neurological syndromes), we will focus on some of the most common encountered problems and their management in this chapter.

TABLE 1: Normal respiratory range in children.

<2 months	>60/min
2 months–1 year	>50/min
1–5 year	>40/min
5 years	>30/min

ETIOLOGY

Infants and young children presenting with common emergencies are as follows:

- *Infections-related problems involving upper airway*:
  - *Croup (laryngotracheobronchitis)* is seen in children of age from 3 months–3 years and common cause is viral infections like parainfluenza, influenza, respiratory syncytial virus (RSV), and adenovirus.
  - *Epiglottitis* is seen in children above 3 years of age up to 7 years during winter months and caused mainly by *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Group A streptococcus*, and *Staphylococcus aureus*.
  - *Bacterial tracheitis* is an invasive exudative bacterial infection of trachea affecting children of age group as early as 1 month till 15 years of age. It is caused by *S. aureus*, *Streptococcus pyogenes*, *S. Pneumoniae,* and *H. Influenza B* (Hib).
  - *Stridor* is a high-pitched, sound caused by disrupted airflow due to multiple reasons such as spasmodic

TABLE 2: Features of respiratory distress.

Respiratory distress (early signs)	*Respiratory failure (late signs)*
Tachypnea	Bradypnea
Increased respiratory efforts, chest wall retraction	Head bobbing, see-saw breathing
Tachycardia	Bradycardia
Irritability	Decreased level of consciousness
O_2 sat > 94%	<94% with high flow O_2

cough, retropharyngeal abscess, foreign body, tracheomalacia, vascular rings, pulmonary artery sling, inhalation injuries, and few other infective causes such as tracheitis, croup, and diphtheria.

- Infections-related problems involving lower airways:
  - *Bronchiolitis*: It is primarily seen in infants from 2 months up to 2 years of age and has viral etiology, such as RSV, influenza, parainfluenza, adenovirus, and others.
  - *Pneumonia* involves lower airway in almost all age groups, though younger patients and chronically ill and immunocompromised patients may be at higher risk. It can be caused by both bacteria and viruses.
- *Noninfectious causes of respiratory emergencies*: Retropharyngeal abscess, foreign body aspiration, tracheomalacia, vascular rings, and inhalation injury.

PATHOPHYSIOLOGY

In children, the subglottis is the narrowest part of the airway, and the cartilage rings are completely encircling which does not allow any further expansion. The loose connective tissue of the airway obstructs the lumen whenever gets inflamed of edema develops. And this reduction in lumen caliber leads to higher resistance to air flow which is apparent by Poiseuille's law.

Infants and younger children are more susceptible for airway compromise as compared to adults and adolescent, mainly due to anatomical differences. Younger children have much prominent occiput and relatively larger head size and lesser cervical support, which results in higher chances of acute airway compromise in supine position. Also, a relatively smaller oropharynx and larger tongue also contributes to more airway issues with this background of information, now we will discuss the disease-specific pathophysiology:

- *Croup* manifests as inflammation of the larynx, trachea, and large bronchi due to infiltration of white blood cells leading to the partial airway obstruction. As the inflammation progresses, it leads to increased work of breathing due to narrow lumen. When it causes significant obstruction, during respiration due to the negative-pressure inspiration pulls airway walls closer together, causing turbulence and noisy breathing called stridor (**Table 3**).
- *Epiglottitis* is the soft tissue swelling of epiglottis and its surrounding. Causative bacteria such as Hib or *S. pneumoniae* once penetrates, the mucosal barrier enters into the blood stream and subsequently seeds into epiglottis causing acute inflammatory edema. The inflammation usually begins from the lingual surface as the mucosa is loosely attached, and later progresses to aryepiglottic folds, arytenoids, and entire supraglottic larynx. The swelling is further halted at the vocal cords as the epithelium is tightly bound. The swelling significantly reduces the airway aperture and can lead to frank airway obstruction, aspiration of secretions, or mucus plugging leading to respiratory distress. Also, the noninfectious inflammation of any of the structures around the epiglottis may also result from thermal or chemical injury or from local trauma, including blunt trauma to the neck. Rarely, the inflammation may lead to necrotizing epiglottitis in case of infections such as cytomegalovirus (CMV) and Epstein–Barr virus (EBV) in immunocompromised population.
- *Bacterial tracheitis* is caused by opportunistic bacteria, which invades and damages the mucosa and stimulates local and systemic inflammatory response. Tracheitis is most commonly seen in healthy children presiding a viral infection or in a patient with tracheostomy, due to seeding from colonized tracheostomy tube. The response to the infection-caused edema, thick mucopurulent secretion, ulceration, and mucosal sloughing which results in subglottic narrowing. On the other hand, the systemic inflammation may sometimes lead to sepsis in immunocompromised children. Pathophysiology of stridor depends on the anatomical location involved and the disease process. The supraglottic area does not contain any cartilage, hence it can collapse rapidly. In infants even a minimal narrowing of the airway results in dramatic increase in airway resistance, hence the subglottic area is of most concern. Any obstruction in the extrathoracic region causes inspiratory stridor, and the obstruction in intrathoracic region leads to expiratory stridor.
- *Bronchiolitis* occurs due to the bronchiolar injury and its interplay with the inflammatory and mesenchymal cells. The effect of these damages is caused due to inflammation usually seen in between 18 and 24 hours postinfection. Injury to the bronchioles leads to increased mucus secretions, obstruction of bronchus, air trapping, and atelectasis ventilation perfusion mismatch. Immunologic mechanisms also play a role in the pathogenesis of bronchiolitis. Cytokines released by infected respiratory epithelial cells, aggravates the immune response by increasing cellular recruitment into infected airways. Interferon and interleukin (IL)–4, IL-8, and IL-9 are found in high concentrations in respiratory secretions of infected patients. Allergic reactions mediated by IgE may account for clinically significant bronchiolitis. Infants who are breastfed with colostrum rich in immunoglobulin A (IgA) appear to be relatively protected from bronchiolitis.

TABLE 3: Westley croup score.

	0	*1*	*2*	*3*	*4*	*5*
Stridor	Nil	When agitated	At rest			
Intercostal recession	Nil	Mild	Moderate	Severe		
Decreased air entry	Normal	Mild	Severe		When agitated	At rest
Cyanosis	None					Altered
Consciousness level	Normal					
Possible score 0–17: 0–3 = mild croup, 4–6 = moderate croup, >6 = severe croup						

- *Pneumonia*: The organism which causes pneumonia and enters alveoli are likely to be highly virulent as they have already evaded host's physical defenses. Due to the infection, the macrophages activity is overwhelmed which in-turn results in production of high fibrin rich exudates which fills the infected and neighboring alveolar spaces. As a result of the ongoing inflammatory process, the alveolis becomes nonaerated and neutrophil proliferation is triggered. Once the inflammatory process is un-checked, it leads to the damage of lung tissue, fibrosis, and pulmonary edema which impairs total lung expansion.

CLINICAL PRESENTATION

The clinical sign and symptoms largely vary in pediatric patients due to the peculiarities discussed above. The presentation depends upon the age of the child, the specific pathogen and also the severity, and the duration of disease onset. Usual presentation of a young infant (3–5 months) of age is predominantly respiratory symptoms such as tachypnea, cough, chest wall retractions, noisy breathing, and grunting. Often pediatric patients may present without any localizing symptoms as well, and may show features as isolated fever, irritability, lethargy, and refusal of feeds also. Clinical features of concern *(red flag sign)* to be considered in case of any respiratory emergencies—respiratory distress, decreased level of consciousness, stridor or grunting, sudden onset dyspnea, cyanosis, sweating, seizures/abnormal tone, or posturing. Disease-specific clinical presentation is summarized in **Table 4**.

TABLE 4: Disease-specific clinical presentation.

Disease	*Clinical presentation*
Croup	Acute stridor, barking cough after mild URI, and low grade fever
Retropharyngeal abscess	Fever, toxicity, distress after URI or pharyngitis, drooling, and neck pain/swelling
Bacterial tracheitis	Acute onset high grade fever, toxic appearance, harsh cough, no drooling, chest pain, and distress+
Foreign body aspiration	Choking episode resulting in immediate or delayed respiratory distress, unilateral wheeze
Peritonsillar abscess	Acute onset high grade fever, toxicity, distress with unilateral throat pain, "hot potato speech"
Epiglottitis	Drooling, high grade fever, toxic, muffled voice, cough minimal, and sitting forward, open mouth
Anaphylaxis/angioneurotic edema	Swelling of lips, erythematous rash with itching
Bronchiolitis/pneumonia	Fever, cough, coryza, post-tussive vomiting, irritability, and refusal of feeds

EVALUATION

All children arriving to emergency room should be presumed to be sick and requires immediate help or rescue from the problem. To ensure the safety of the child and initiation of the management pertinent to the condition, it is very important to collect relevant history quickly from the caregiver and examine the child to pick up danger signs.

History

Collecting a quick and relevant history is the most important step in understanding the general wellbeing and the probable cause which had led to this emergency situation. The main points which should always be included in history taking are as follows:

- General growth and development of the child and vaccination history
- Duration of illness
- Sudden or gradual onset
- Any other associated complaints (fever, loose stools, and vomiting)
- History suggestive of aspiration, nasal regurgitation
- Noisy breathing
- Birth history, neonatal intensive care unit (NICU) stay with ventilator/oxygen requirement
- Increased sweating, suck-rest-suck cycle
- Accidental ingestion of any foreign body or drugs
- Any bad child rearing practices (oil, camphor nasal instillation).

Physical Examination

In pediatric, the evaluation starts with primary assessment, with "pediatric assessment triangle-pentagon" which consists of:

- Appearance; interaction, muscle tone, consolability, cry, and speech
- Airway/Breathing; work of breathing, use of assessor muscles
- Circulation; abnormal skin color, pallor, or cyanosis.

Assessment pentagon:

- *Airway*—assessment of the airway should be aimed to decide whether the airway is clear, i.e., whether it is open and unobstructed.
  - Maintainable airway: Example, is the airway is maintained by simple measures like position, suction, etc.
  - Nonmaintainable airway: Example, any need of advance airway measures like intubation. Any audible sounds, such as stridor, grunting, and wheezing usually point toward airway narrowing or laryngomalacia/tracheomalacia, pooling of secretions, or a foreign body in the airway.
- *Breathing*—infants and young children most commonly present with fast breathing which is usually noted by mother or caregiver. Child may present with bradypnea, chest wall indrawing, or abnormal chest wall movement during quiet respiration, these are the signs which are noted by physician on careful examination. Paradoxical breathing (sea saw respiration) pattern usually indicates that the child is in respiratory failure and requires

immediate intervention. Pulse oximetry can help in picking up hypoxemia early.
- *Circulation*—checking both peripheral and central pulses, capillary refill time and blood pressure helps to identify shock, or compromised perfusion.
- *Disability*—as a result of reduced oxygen supply to brain, the level of consciousness, pupillary reaction, and muscle tone may be affected. Child may be irritable, agitated, or through seizures due to prolonged hypoxia.
- *Exposure*—if indicated, it is done to look for evidence of trauma, petechiae and purpura, etc. After completing, the physical examination findings are interpreted (**Table 5**).

INVESTIGATIONS

For all children presenting to emergency, once the clinical assessment is done and the management is initiated, it is very important to plan investigations to narrow down the diagnosis and to provide specific treatment:
- Basic blood investigations—complete blood count, serum electrolytes, blood gas analysis, urea, creatinine, and liver function test
- Sepsis workup—C-reactive protein (CRP), procalcitonin, and blood culture
- Radiological—chest X-ray PA view/lateral view, lung ultrasonography
- Direct laryngoscopy and flexible fiberoptic bronchoscopy in suspected upper airway obstruction or foreign body aspiration.

TREATMENT

General Considerations

- First step in the management of a sick child is to stabilize *A*irway, *B*reathing, and *C*irculation; once *A-B-C* have been taken care of, proceed toward the disease-specific treatment.
- Leave the child with parent in a comfortable position (even sitting is fine if unable to lie down).
- Do not insert tongue depressor or attempt IV access or blood tests.
- Give oxygen in non/least threatening way. Do not force an oxygen mask over face.
- Supplement oxygen even if the oxygen saturation is normal to decrease work of breathing.
- Do not sedate the child until airway is secured.
- Pulse oximetry is a poor indicator of severity of obstruction especially when supplementary oxygen is being given.
- Always anticipate difficult airway while intubation and so high level of anticipation with multidisciplinary team including anesthetists, ENT, and pulmonologists may be required for good outcomes.
- Disease-specific treatment is summarized in **Table 6**.

TABLE 5: Interpretation of common findings.

Sign	*Extrathoracic airway obstruction*	*Intrathoracic airway obstruction*	*Intrapulmonary airway obstruction*	*Parenchymal pathology*
Tachypnea	+	+	++	++++
Retractions	++++	++	++	+++
Stridor	++++	++	–	–
Wheezing	+/–	+++	++++	+/–
Grunting	+/–	+/–	++	++++

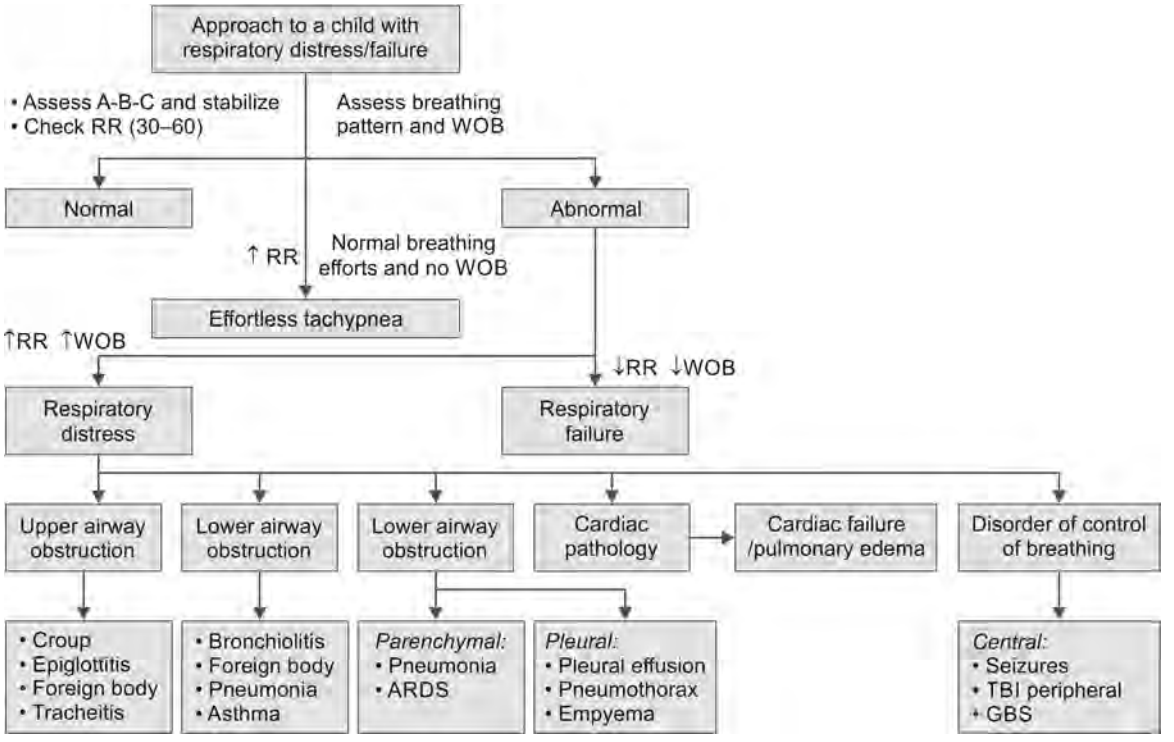
TABLE 6: Disease-specific treatment.

Disease	*Management*
Croup	Managed as per severity. IV dexamethasone, nebulized adrenaline
Acute epiglottitis	• Give oxygen at any comfortable position in nonthreatening manner, do not upset child, nebulized adrenaline (1:1,000) 5 mL till help arrives • If epiglottis visualized by direct laryngoscopy and if obstruction severe and airway not secure call for help (ENT/anesthesia) immediately and intubate in OT with inhalational anesthesia. Start antibiotics (ceftriaxone). Rifampicin for contacts
Foreign body aspiration	High degree of suspicion as clinical findings varies widely. Heimlich maneuver or back slap and chest thrust in infants if complete obstruction. Rigid bronchoscopy is procedure of choice
Anaphylaxis/ angioneurotic edema	May need fluid bolus, intubation if stridor present, immediate I/M injection adrenaline (1:1,000) 0.01 mL/kg (max 0.3 mL), hydrocortisone 10 mg/kg, antihistamines
Bacterial tracheitis	Endotracheal intubation if audible stridor (low threshold), IV antibiotics—cloxacillin, clindamycin, and amikacin*
Retropharyngeal abscess	Lateral neck and chest X-ray, CT neck, orotracheal intubation is preferred if needed because chance of abscess rupture. IV antibiotics (cloxacillin, clindamycin, and amikacin)*, surgical drainage by ENT surgeon
Subglottic stenosis	Early tracheostomy and subglottic dilatation
Airway burns	Intubate early if facial burns with smoke inhalation present before complete obstruction by soot, plan tracheostomy if stridor, simultaneously manage surface burns with other supportive measures

* Cloxacillin (50 mg/kg/dose q 6 hourly), amikacin (15 mg/kg/day in once a day dose), and clindamycin (10 mg/kg/dose TID).

SUMMARY

In pediatric population, most common presentation is seen as obstructive respiratory emergencies. Many of these entities can progress rapidly, leading to a life-threatening situation. Thus systematic approach is adopted (**Flowchart 1**). The clinician must have a high index of suspicion and makes a rapid and precise diagnosis, oftentimes based solely on the patient's brief history and a limited examination. In the setting of obstructive airway or respiratory failure emergencies, appropriate treatment needs to be implemented without delay. This generally involves assuring the presence of a patent airway while time, supportive therapies, and appropriate antibiotics contribute to the resolution of the baseline process.



(ARDS: acute respiratory distress syndrome; GBS: Guillain–Barré syndrome; RR: respiratory rate; TBI: traumatic brain injury; WOB: work of breathing)

FLOWCHART 1: Approach to a child with respiratory distress or respiratory failure.

CHAPTER

Pediatric Cardiac Emergencies

Munesh Tomar, Aditi Gupta

INTRODUCTION

Cardiac emergencies in children can be either due to congenital or acquired causes. The prevalence of congenital cardiac diseases has been reported to be 8–10/1,000 and is responsible for most of the morbidity and mortality in pediatrics. It has the highest risk of presenting with life-threatening emergencies. While most of pediatric cardiac emergencies eventually require treatment at multidisciplinary centers with pediatric cardiologist, pediatric cardiovascular surgeon, and pediatric cardiac anesthetist, the suspicion of the cardiac disease and its initial stabilization and management lies on the neonatologist, primary pediatrician, and the emergency physician. Pediatric cardiac emergencies can be broadly classified into two groups depending on the age of presentation—(1) neonatal cardiac emergencies and (2) presentation in postneonatal period. Both can be further subclassified into congenital and acquired causes. Common causes are given in **Table 1**.

Most neonates with heart disease presenting in emergency have duct-dependent circulation either:

- To ensure adequate mixing as in conditions with parallel nonmixing circulations such as complete transposition [dextro-transposition of the great arteries (d-TGA)]
- To maintain adequate pulmonary blood flow in lesions causing right ventricular outflow tract obstruction (RVOTO) or
- To maintain adequate systemic perfusion as in left-sided obstructive [left ventricular outflow tract obstruction (LVOTO)] or hypoplastic lesions
- *These neonates require intervention (surgical or catheter) within the first weeks of life in order to sustain life or prevent major morbidity.*

NEONATAL CARDIAC EMERGENCIES: AN OVERVIEW

Heart disease in newborn can have varied presentations. The diagnosis is usually not straightforward because of the nonspecific clinical picture of various congenital heart defects and difficult interpretation of electrocardiogram (ECG) and chest X-ray (CXR). Neonates with pulmonary symptoms unresponsive to standard therapies indicate strong suspicion for congenital heart disease.

They are mainly classified into those who need an immediate intervention (catheter/surgical) and those who have a nonurgent disease and require medical management or close follow-up. In neonates, many patients show acute worsening on day 3–4 of life after discharge due to restriction or closure of ductus arteriosus which compromises the cardiac defects with duct-dependent circulation. Prostaglandin E1 (PGE1) infusions or emergency interventional cardiac catheterization is used as life-saving initial measures.

PRESENTATION

Almost half of congenital heart diseases present in the neonatal period with an incidence reported to be around 3–3.5/1,000 live births. The various presentations in the neonatal period include cyanosis, shock, congestive cardiac failure, and rarely with arrhythmias. As the diagnosis and pick up rate of congenital heart disease in antenatal period by level II antenatal fetal scan followed by detailed fetal echocardiography continues to be low because of lack of expertise and resources, majority of the neonates with critical congenital heart defect (CHD) are detected for the first time after birth. Neonates with CHDs usually present to the emergency with: cyanosis shock acute congestive heart failure (CHF) tachyarrhythmias/bradyarrhythmia.

CASE SCENARIOS—CYANOSIS

Case Scenario

A 15-day-old neonate, born at full-term gestation via normal vaginal delivery was noted to have respiratory distress and bluishness by parents. The baby was referred to tertiary center for further management where at presentation, the baby was found to be lethargic, in distress and had central cyanosis. On auscultation, no significant murmur could be appreciated. His arterial blood gas showed severe hypoxemia with metabolic acidosis. CXR had mild cardiomegaly with increased pulmonary vascular markings (**Fig. 1**). Respiratory and cardiac pathologies are the main differential diagnoses with such presentations, and it is very important to distinguish between respiratory and cardiac causes of cyanosis so that the management can be done accordingly (**Table 2**).

TABLE 1: Causes of pediatric cardiac emergency.

	Congenital	*Acquired*
Neonatal	• Duct dependent pulmonary blood flow • Critical pulmonary stenosis/pulmonary atresia with ventricular septal defect (VSD) or with intact ventricular septum • Duct dependent systemic blood flow • Critical aortic stenosis • Critical coarctation of aorta • Hypoplastic left heart syndrome • Admixture lesion with restrictive interatrial communication • Transposition of great vessels • Total anomalous pulmonary venous connection (TAPVC) • Obstructed TAPVC • Anomalous origin of left coronary artery from pulmonary artery (ALCAPA) • Ventricular dysfunction due to inborn error of metabolism E.g., glycogen storage defects, fatty acid oxidation defects, and mitochondriopathies	Ventricular dysfunction due to: • Sepsis • Metabolic and electrolyte imbalance (metabolic acidosis and hypocalcemia) • Hypothermia
Older children	• Severe obstructive lesions (left side/right side) with ventricular dysfunction, e.g., severe aortic stenosis, severe pulmonary stenosis, and severe coarctation • Shunt lesions decompensated by infection or arrhythmia • Anomalous origin of left coronary artery from pulmonary artery	• Rheumatic heart disease with severe valvular stenosis/regurgitant lesions (mitral, aortic, and/or tricuspid) • Bacterial endocarditis • Kawasaki disease
All age groups	• Arrhythmias	• Arrhythmias • Dilated cardiomyopathy • Pericardial tamponade

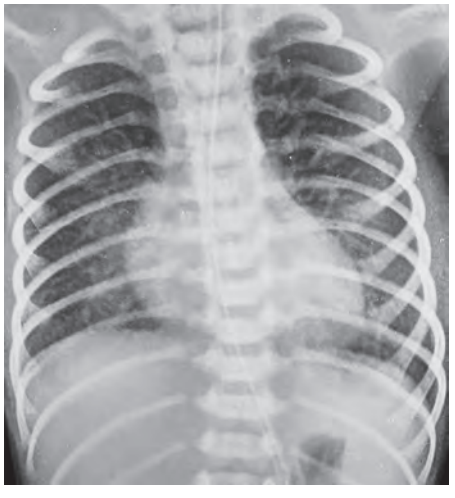

FIG. 1: Chest X-ray (frontal view) of 15 days old neonate with cyanosis showing cardiomegaly, increased pulmonary blood flow with narrow mediastinum (Egg-on-side appearance).

TABLE 2: Differentiation between cardiac and respiratory causes of cyanosis.

	Respiratory	*Cardiac*
History	H/o meconium aspiration, prematurity, risk factors for sepsis	Diabetic mother, H/o previous child affected with CHD
Examination	Respiratory distress—grunting cyanosis and tachypnea	Cyanosis disproportionate to respiratory distress
Onset	Usually at birth or within hours of birth	Hours/days after birth
Auscultation	Altered air entry, lung crepts/wheeze	Clear lungs, normal air entry, murmur may or may not be present
Blood gas	High pCO_2, Low pO_2	Normal/low PCO_2, Low PO_2
Hyperoxia test	Passed	Failed
Chest X-ray	Lung infiltrates, normal heart size	Clear lung fields, heart ± enlarged, oligemic/plethoric lung fields
ECG	Normal	May be abnormal

Hyperoxia test differentiates cardiac from pulmonary causes of cyanosis. Arterial oxygen tension is measured in the right radial artery (preductal) while the patient on 100% oxygen for 10 minutes. Oxygen is administered via hood or endotracheal tube if the patient is already intubated. The preductal oxygen tension while breathing 100% oxygen concentration rarely exceeds 150 mm Hg in cyanotic heart disease and usually exceeds this value in pulmonary disease. In case of failed hyperoxia test, an echocardiogram is needed to establish the underlying diagnosis.

A pulse oximeter should not be used for the hyperoxia test because it may not detect an inadequate increase in oxygen tension. Because of the characteristics of the oxygen dissociation curve, normal hemoglobin is fully saturated with

oxygen when the arterial PO_2 exceeds 70 mm Hg. Therefore, a patient receiving 100% inspired oxygen concentration may have an oxygen saturation of nearly 100% associated with an arterial PO_2 of 75 mm Hg, a value that is abnormal. Thus, discrimination between cardiac lesion and pulmonary disease may be limited. *It is useful to remember the most common CHDs that present with neonatal cyanosis include*—Complete TGA, tetralogy of Fallot (TOF) (with critical pulmonary stenosis or pulmonary atresia), obstructive total anomalous pulmonary venous connection, single ventricle with critical pulmonary stenosis/pulmonary atresia, tricuspid atresia with critical pulmonary stenosis/pulmonary atresia, and critical pulmonary stenosis/pulmonary atresia with intact interventricular septum (**Flowchart 1**).

Management

The definitive diagnosis is readily established by detailed echocardiography. PGE1 (alprostadil) intravenous (IV) infusion is done to keep the patent ductus arteriosus (PDA) open (dose 10–60 ng/kg/min, if poor response saturations and acidosis are not improving), the dose can be increased to max 300–400 ng/kg/min. Apnea is a common side effect of PGE1 so infusion should be started in ICU settings with ventilator support available. Flushing, diarrhea, and hypotension are other common side effects. IV fluid for blood volume expansion 10 mL/kg 0.9% saline bolus improves preload repeat until liver edge is palpable, and enhances further opening of the PDA and pulmonary blood flow through the duct. Correction of metabolic abnormalities, e.g., hypoglycemia, hypocalcemia, acidosis, and sepsis. Oxygen to maintain the saturations 75–85% (do not give 100% oxygen by mask in patients with duct-dependent lesions as high level of oxygen triggers closure of ductus arteriosus). Inotropes/vasopressors are required to maintain adequate systemic perfusion. If above measures are not helpful, intubation and ventilation with adequate sedation are required to improve oxygenation and minimize the metabolic demands.

Definitive management includes—for transposition of great vessels—arterial switch operation, total anomalous pulmonary venous connection—surgical rerouting of pulmonary veins, severe valvular pulmonary stenosis—balloon valvotomy, and ductal stenting/Blalock—Taussig (BT) shunt for duct-dependent pulmonary circulation.

CASE SCENARIO—CARDIOVASCULAR COLLAPSE

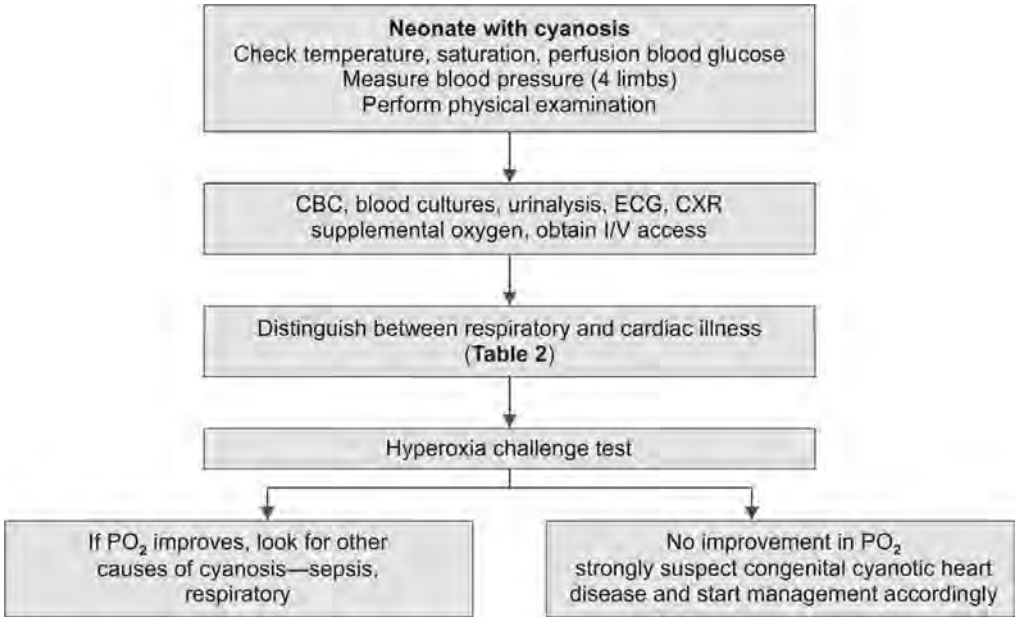
Case Scenario

A 6-day-old term neonate presented in medical emergency with complaints of lethargy, increased respiratory rates and refusal to feed. The baby was mottled in color with poor peripheral perfusion. While the central pulses were palpable, the lower limb pulses were feeble.

Chest X-ray revealed cardiomegaly with prominent pulmonary vascular markings (**Fig. 2**). On echocardiography, the baby was diagnosed to have interrupted aortic arch and restrictive PDA which was supplying descending aorta. Baby also had severe LV dysfunction with ejection fraction (EF) 15–20% (**Fig. 3**). Further restriction and impending closure of the ductus on day 5–6 of life had led to acute loss of lower body perfusion causing shock and severe metabolic acidosis. Patients with this presentation are grouped under lesions with duct-dependent systemic circulation. These babies can present directly with cardiovascular collapse after ductal closure and are therefore often critically ill at presentation.

It is very important to have a high index of suspicion for congenital heart disease in neonates presenting with shock as most commonly it is mistakenly diagnosed and managed as neonatal sepsis. While babies with sepsis are medically managed those with duct-dependent systemic circulation need aggressive resuscitation and prompt intervention usually.

Lesions presenting with duct-dependent systemic circulation include the critical left-sided outflow tract



Neonate with cyanosis
Check temperature, saturation, perfusion blood glucose
Measure blood pressure (4 limbs)
Perform physical examination
CBC, blood cultures, urinalysis, ECG, CXR
supplemental oxygen, obtain I/V access
Distinguish between respiratory and cardiac illness
(Table 2)
Hyperoxia challenge test
If PO2 improves, look for other causes of cyanosis—sepsis, respiratory
No improvement in PO2
strongly suspect congenital cyanotic heart disease and start management accordingly

(CBC: complete blood count; CXR: chest X-ray; ECG: electrocardiogram)

obstructions—critical aortic stenosis (AS), hypoplastic left heart syndrome (HLHS), severe coarctation of aorta, and interrupted aortic arch.

Management includes prostaglandin therapy, blood volume expansion, stabilization with inotropes and oxygen, and mechanical ventilation in unresponsive cases. Confirmation of diagnosis by echocardiography is followed by relief of obstruction by surgical correction.

CASE SCENARIO—ACUTE CONGESTIVE HEART FAILURE

Case scenario

A 3-week-old neonate presented with tachypnea, tachycardia, and refusal to feed for 3 days. There was hepatomegaly and cardiomegaly on examination. Auscultation revealed gallop rhythm, no significant murmur. CXR *frontal view showed cardiomegaly, no parenchymal lesion. 12-lead ECG showed sinus tachycardia, deep "q" wave in I, aVL, V_5, and V_6 with ST-T wave changes* (**Fig. 4**). *Echocardiography revealed severe LV dysfunction with EF—15–20%. On echocardiography, left coronary was seen arising anomalously from pulmonary artery and baby was diagnosed to have anomalous origin of left coronary artery from pulmonary artery (ALCAPA).* The baby underwent successful surgical correction of ALCAPA with slow but complete recovery of ventricular function in postoperative period.

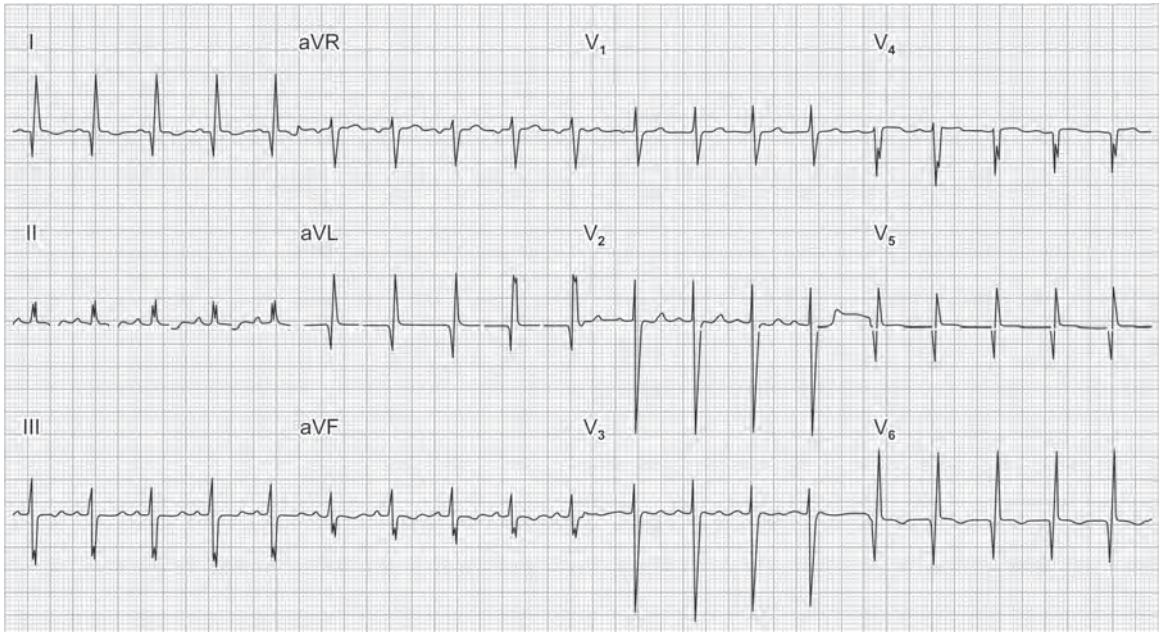
In ALCAPA, the babies usually present with features of CHF due to myocardial ischemia leading to LV dilatation and dysfunction. The presentation can be delayed up to 3–4 weeks of age till the pulmonary vascular pressures fall substantially. Babies with CHF (**Table 3**) usually present with feeding difficulties and excessive sweating. They are tachypneic and tachycardiac at rest and can have wheeze due to LV failure. Gallop rhythm, hepatomegaly, and cardiomegaly are other important signs. Cold extremity and low blood pressure are signs of low pulse volume and indicate CHF. However, bounding pulses may be present in CHF due to lesions causing aortic runoff like PDA and arteriovenous malformations. CXR is especially useful in evaluation of neonates. Cardiac enlargement is always present if CHF exists, in addition, pulmonary pathologies can also be detected. It is important to differentiate neonatal CHF from respiratory distress due to lung disease and neonatal sepsis clinically. This differentiation is difficult due to overlapping signs such as Rales and Rhonchi. The most important signs for diagnosing heart failure are cardiomegaly and hepatomegaly.

Management

- Oxygen therapy is very useful in babies with CHF with pulmonary edema as the cause of hypoxia. Oxygen raises the alveolar PO_2 and helps alleviate hypoxia.
- General neonatal care which includes maintenance of temperature and glucose levels.
- Nasogastric feeding is preferred over oral feed to avoid aspiration in the distressed infant and also to increase the amount of caloric intake.
- Diuretics, usually furosemide 1–4 mg/kg 8–12-hourly IV (bolus or continuous infusion) or orally with spironolactone 1 mg/kg 12-hourly to decrease pulmonary congestion.
- Correction of coexistent metabolic derangements such as anemia, hypoglycemia, electrolyte imbalance, and acidosis.
- Inotropes/vasodilators such as low-dose dobutamine, dopamine, and milrinone to decrease systemic vascular resistance and improve cardiac contractility.
- Mechanical ventilation is usually required in heart failure with impending cardiogenic shock.

PEDIATRIC CARDIAC EMERGENCIES

The various presentations of pediatric cardiac emergencies include CHF cyanotic spell, pericardial tamponade, arrhythmia/palpitations, and sudden death. Among the various presentations, CHF and spell attribute to 70–80% of pediatric cardiac emergencies. In neonates while structural diseases of the heart are the most common causes of CHF, in older children acquired causes are also attributed. Fluid restriction and inotropic support followed by definitive correction of the



(ALCAPA: anomalous origin of left coronary artery from pulmonary artery; ECG: electrocardiogram)

established cause mainstay of treatment. Cyanotic congenital heart disease such as TOF and pulmonary atresia presents with cyanotic spells. They usually occur in the morning and can be provoked by stress crying, or periods of dehydration. Their presentation can vary from minor spells to seizure to severe life-threatening episodes. Isolated arrhythmias though relatively less common can present with palpitations or hemodynamic instability in infants and children. Supraventricular tachycardia (SVT) is the most common presentation in the pediatric population. Early recognition and appropriate therapy in pediatric cardiac emergencies are essential for better outcomes.

Congestive Heart Failure

Case Scenario

An 8-year-old boy presented to the medical emergency department with complaints of respiratory distress. Patient had history of breathlessness on exertion and orthopnea since months. Patient had past history of swelling in left knee followed by swelling of left ankle 2 months ago. He had tachycardia, cardiomegaly, and a loud apical pansystolic murmur with radiation to axilla. He also had hepatomegaly with liver 5 cm below costal margin. CXR showed cardiomegaly with straightening of left heart border (left atrial enlargement), LV type of apex and signs of pulmonary venous hypertension (**Fig. 5**). *Echocardiography revealed rheumatic involvement of mitral valve with thickened leaflets and ruptured chordae leading to severe mitral regurgitation (MR).* Congenital cardiac defect associated with CHF in pediatric age-group is large/multiple VSD, complete AV canal defect with AV regurgitation, large PDA, and AV malformation. Acquired causes of pediatric CHF are rheumatic heart disease, cardiomyopathy arrhythmia,

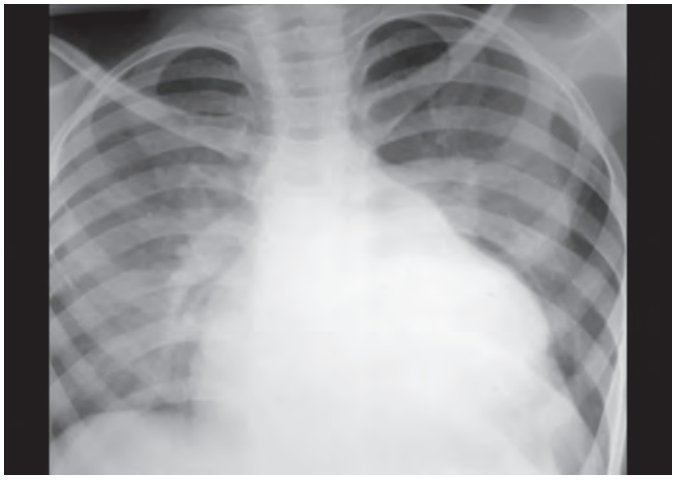

FIG. 5: Chest X-ray frontal view of an 8 years old child with rheumatic heart disease, severe mitral regurgitation. There is cardiomegaly with pulmonary venous hypertension. Features of LA dilatation, i.e., straightening of left heart border and widening of carinal angle are seen.

and pericardial tamponade. Heart failure secondary to congenital heart disease is a gradual process while heart failure due to acquired causes is more commonly an acute process.

Clinical Features

Common manifestations of CHF in the infant in the approximate order of frequency include tachypnea, tachycardia, liver enlargement, cardiomegaly, pulmonary Rales and Rhonchi, and feeding difficulties. Less common signs and symptoms include peripheral edema, measurable elevated systemic venous pressure, inappropriate diaphoresis at normal room temperature, gallop rhythm, pulsus alternans, and ascites. A child with large left to right shunt usually presents with CHF at 6–8 weeks of age when the pulmonary vascular resistance naturally drops, while a child with myocarditis may present at any age.

Management

Treatment of the precipitating factors such as infective endocarditis, intercurrent infections, anemia, electrolyte imbalances, arrhythmia, pulmonary embolism, and drug toxicity should be done. Treatment of the congested state includes:

- Nonpharmacological measures, e.g., modest fluid restriction, propped up posture, supplemental humidified oxygen if desaturated, and optimization of nutrition.
- Diuretics, usually furosemide 1–4 mg/kg 6–12-hourly IV or orally provide quick relief in systemic and pulmonary venous congestion. If child is having grossly edematous or in pulmonary edema, IV infusion of furosemide (0.1–0.4 mg/kg/h) should be given. After stabilization, patient can be shifted to bolus doses of furosemide.
- Secondary hyperaldosteronism occurs in infants with CHF and addition of spironolactone 1 mg/kg single dose to other diuretics helps with diuresis as well as conserves potassium.
- Vasodilators, e.g., angiotensin-converting enzyme (ACE) inhibitors, are useful in the presence of large shunts, or in those with an elevated systemic vascular resistance. These drugs are contraindicated in patients with obstructive lesions such as aortic or mitral stenosis. Enalapril is most commonly used ACE inhibitor in pediatric age-group. It is important to ensure normal renal function and K^+ during therapy.
- Augmenting myocardial contractility by inotropic drugs such as dopamine, dobutamine, milrinone, levosimendan and digitalis improves cardiac output and is useful in low cardiac output states. Digitalis is especially useful as it decreases heart rate and increases myocardial contractility, however, its use has to be closely monitored in view of its narrow therapeutic index (**Fig. 6**).
- Coexistent metabolic derangements such as anemia, hypoglycemia, electrolyte imbalance, and acidosis should be evaluated and corrected. Hypocalcemia and vitamin D deficiency must always be ruled out as a cause in cases of dilated cardiomyopathy.
- *Treat underlying pathology*: Corrective surgery for structural defect—the curative therapy is directed toward the cause of CHF, wherever possible, e.g., surgical correction of congenital or acquired heart defects. Precipitating factors—Hypocalcemia secondary to vitamin D deficiency, hypoparathyroidism, anemia, hyper-/hypothyroidism, and Beriberi

Cyanotic Spell

It usually occurs in children with unrepaired TOF or other cardiac defects with large interventricular communication and pulmonary outflow tract obstruction. Cyanotic spell is a clinical

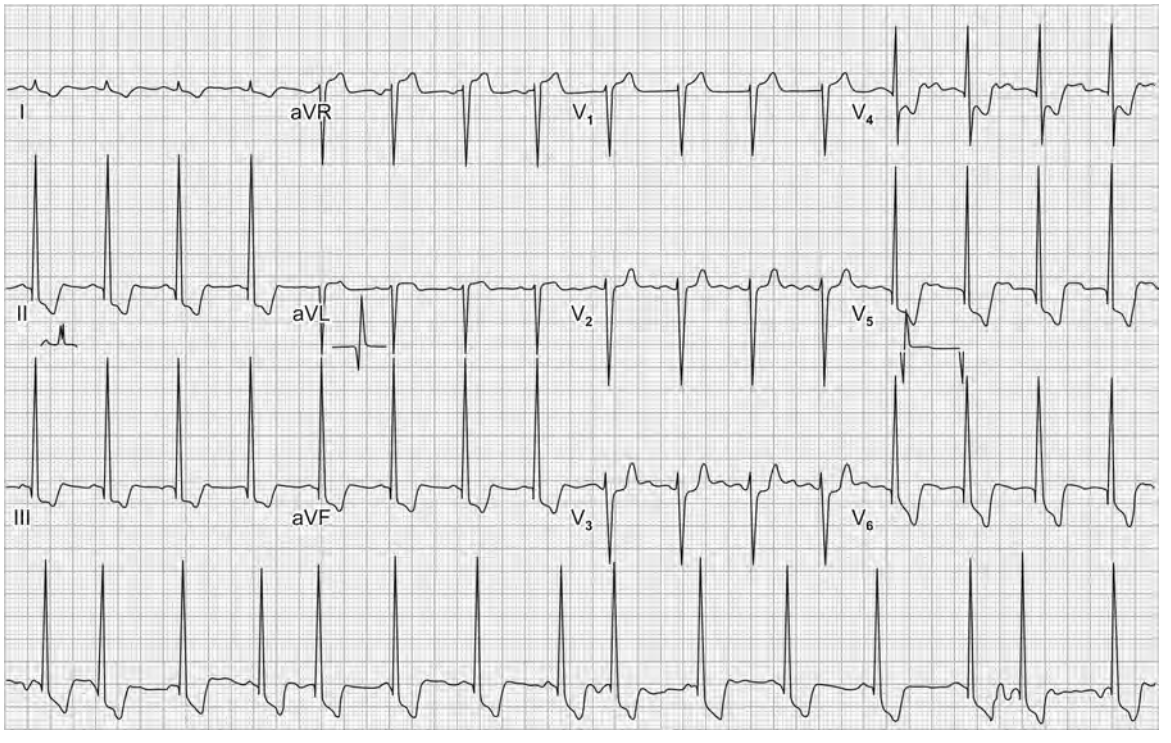

FIG. 6: 12-lead ECG of an infant taking high dose of digoxin by mistake. ECG shows digitalis effect, i.e., prolongation of PR interval with sagging of ST segment.

state of acutely reduced pulmonary blood flow which leads to severe hypoxemia and metabolic acidosis. They are usually self-limited and may last from few minutes to few hours. They may occur at any time of day, but are most common in the morning with defecation, crying, and feeding as usual triggers. The spells may also occur after episodes of stress such as excess activity and dehydration. They can even occur without a precipitating cause. During the spell, the infant becomes hyperpneic and restless, and as cyanosis increases, syncope, convulsions, or cerebrovascular accidents can develop rarely. Hypoxic spells are most common between 1 and 12 months of life and are a particular problem during the 2nd–6th month of life. Structural anomalies presenting with cyanotic spells are the most common are TOF, double outlet right ventricle with pulmonary stenosis, tricuspid atresia with pulmonary stenosis, transposition of great vessels, and single vessel physiology.

One of the mechanisms of cyanotic spell is believed to be acute infundibular spasm of right ventricular outflow tract precipitated by endogenous catecholamines which results in markedly decreased pulmonary blood flow along with right to left shunting across the ventricular septal defect. An alternative explanation is sudden increase in activity causes increased oxygen demand which stimulates respiratory center and leads to hyperpnea. Hyperpnea reduces intrathoracic pressure which decreases systemic and pulmonary resistance and leads to greater right to left shunt in view of increased systemic flow which is not matched by pulmonary flow.

Management

- The first step is to attempt and place the infant in knee-chest position which increases systemic vascular resistance and decreases right to left shunting at VSD level.
- Keep the child calm and quiet and to avoid any painful procedures.
- It is reasonable to administer oxygen, however, if it causes agitation, then oxygen should be removed.
- Sedation in the form of morphine (0.1–0.2 mg/kg IM/IV/SC) or ketamine (1–2 mg/kg IV) can be given and repeated as necessary. Morphine not only helps to keep child calm but also decreases patient's respiratory drive and hyperpnea which may help abort the spell.
- Blood volume expansion with crystalloids like initial IV saline bolus @10 mL/kg which can be repeated as per the hydration status until the liver is palpable. They increase the RV preload and therefore may increase the RV output.
- Metabolic acidosis usually develops when arterial PO_2 falls below 40 mm Hg, rapid correction with IV sodium bicarbonate (1–2 mEq /kg IV) is especially necessary if the spell is unusually severe and the child shows a lack of response to the ongoing therapy. Once the pH has returned to normal recovery from the spell is usually rapid.
- If spell continues, phenylephrine 0.01 mg/kg IV slowly or 0.1 mg/kg SC, or norepinephrine (0.05–0.5 μg/kg/min infusion) may be attempted which may help by increasing the systemic vascular resistance (the dose has to be titrated according to the BP response).
- Beta-blocker—injection metoprolol 0.1 mg/kg over 5 minute can be repeated every 5 minutes to max of three doses, or infusion can be given at dose of 1–5 μg/kg/min. Alternatively, esmolol can be given with loading dose of 500 mg/kg/dose followed by maintenance infusion of 50–100 μg/kg/min. IV beta-blockade helps by combination of relief of infundibular spasm and prevention of ventilatory response.
- In refractory cases, when there is no response to any of these measures intubation with ventilation and urgent transfer to a tertiary facility, where facilities of emergent surgical systemic-to-pulmonary shunt (BT Shunt) or definitive corrective procedure are available, should be done.
- *Response of treatment can be assessed in the form of increasing intensity of the ejection systolic murmur and rising oxygen saturations both the signs being reassuring.*

Pericardial Tamponade

Cardiac tamponade is one of the life-threatening emergencies which is caused due to slow or rapid accumulation of pericardial fluid, pus, blood which increases the intrapericardial pressure and causes compression of the heart. The clinical features depend not only on amount of fluid, but also on the speed of fluid accumulation. Patients can present with chest pain, impalpable apex beat, muffled heart sounds on auscultation, and pericardial friction rub. Rapid fluid accumulation can lead to cardiac tamponade which may present as cardiogenic shock. Beck's triad comprising hypotension, diminished heart sounds, and venous hypertension may not be evident until late in course in cardiac tamponade and therefore is not a sensitive indicator of tamponade. Straightening of the left heart border on chest radiograph is a useful finding. A progressively enlarging globular heart also is a reliable indicator of pericardial effusion, but this is characteristically a late finding (**Fig. 7**). Echocardiography is diagnostic modality of choice for diagnosing and evaluating a pericardial effusion (**Figs. 8** and **9**). Diastolic collapse of atria and ventricles is considered pathognomonic for cardiac tamponade on echocardiography.

Management

In hemodynamically stable patient with no features of cardiac tamponade, a definitive diagnosis by echocardiography and drainage via pericardiocentesis or surgical drainage is required. Urgent decompression of the pericardial space is mandatory and lifesaving if signs of cardiac tamponade are present. This is achieved by aspirating from a subxiphoid

FIG. 7: Chest X-ray (frontal view) showing cardiomegaly with globular heart shadow in a child with large pericardial effusion.

FIG. 8: Echocardiography of a child presenting with features of cardiac failure in emergency. Subcostal coronal view showing large pericardial effusion. On pericardial tap, serous fluid was drained and was of tubercular etiology.

approach with a cannula aiming at left shoulder and at angle of 30–45 from skin and obtaining as much fluid as possible before removing cannula. Blood volume expansion with 20 mL/kg crystalloid IV bolus, repeated as necessary.

Arrhythmias

Several types of arrhythmias are seen in neonatal and pediatric age-group. They are broadly classified as tachyarrhythmias and bradyarrhythmias. The most common conditions predisposing to arrhythmias in children include congenital heart disease and postoperative cardiac surgery. Rhythm disturbances can cause hemodynamic compromise in children due to rate abnormalities or loss of synchrony. An appreciation of normal variation and disturbances in pediatric ECG with age and maturation is essential for interpretation of pediatric rhythm disturbances (**Table 4**).

TABLE 4: Heart rates and PR and QRS intervals according to age.

Age	*Heart rate/min*	*PR interval*	*QRS interval*
0–1 day	94–155 (122)	0.08–0.16 (0.107)	0.02–0.07 (0.05)
1–3 days	91–158 (122)	0.08–0.14 (0.108)	0.02–0.07 (0.05)
3–7 days	90–166 (128)	0.07–0.15 (0.102)	0.02–0.07 (0.05)
7–30 days	96–182 (149)	0.07–0.14 (0.100)	0.02–0.08 (0.05)
1–3 months	120–179 (149)	0.07–0.13 (0.098)	0.02–0.08 (0.05)
3–6 months	105–185 (141)	0.07–0.15 (0.105)	0.02–0.08 (0.05)
6–12 months	108–169 (131)	0.07–0.16 (0.106)	0.03–0.08 (0.05)
1–3 years	89–152 (119)	0.08–0.15 (0.113)	0.03–0.08 (0.06)
3–5 years	73–137 (109)	0.08–0.16 (0.119)	0.03–0.07 (0.06)
5–8 years	65–133 (100)	0.09–0.17 (0.128)	0.04–0.09 (0.06)
8–12 years	62–130 (91)	0.09–0.17 (0.128)	0.04–0.09 (0.06)
12–16 years	60–120 (80)	0.09–0.18 (0.135)	0.04–0.09 (0.07)

Tachyarrhythmias

An electrocardiography is essential for critical evaluation of tachycardia. They are suspected when the heart rate >180 beats/min in children and >220 beats/min in infants and is usually fixed between 250 and 280 beats/min with no variability, atrioventricular dissociation, abnormal P wave axis, narrow complex tachycardias (<90 ms) are due to AV re-entrant tachycardia via an accessory pathway (SVT) (**Fig. 10**). Nodal/junctional ectopic tachycardia, ectopic and multifocal atrial tachycardias, and atrial flutter (**Fig. 11**), wide complex tachycardia (>90 ms)—wide complex tachycardia in children is ventricular tachycardia until proven otherwise. So, all monomorphic wide complex tachycardias should be treated as VT without delay, especially if hemodynamically unstable (**Fig. 12**).

- *Clinical presentation*: Wide range of clinical presentation, asymptomatic to cardiogenic shock and even sudden cardiac death. Palpitations are the usual presenting symptom in older children with paroxysmal tachycardia, but other nonspecific symptoms such as light-headedness, syncope, chest pain, pallor, or nausea may occur. Tachycardia may go unrecognized for many hours and significant hemodynamic compromise may result. If the duration of the tachycardia exceeds 6–12 hours, symptoms and signs of HF may become apparent.
- *Management*: 12-lead ECG recording with a rhythm strip. Reversible causes of arrhythmias should be identified and treated, e.g., 5 Hs and 5 Ts that includes hypoxemia, hypovolemia, hypo- or hyperthermia, hyper- or hypokalemia, acidosis, and tamponade (cardiac), tension pneumothorax, and toxins, e.g., digoxin, beta-blockers, calcium channel blockers, and thrombosis (coronary and pulmonary).

Narrow Complex Tachycardia

- *Atrial flutter*: The treatment of choice is synchronized DC cardioversion, as little as 0.5 J/kg is often enough to

FIG. 10: Supraventricular tachycardia. HR—270 beats/min with narrow QRS complexes and P waves not seen.

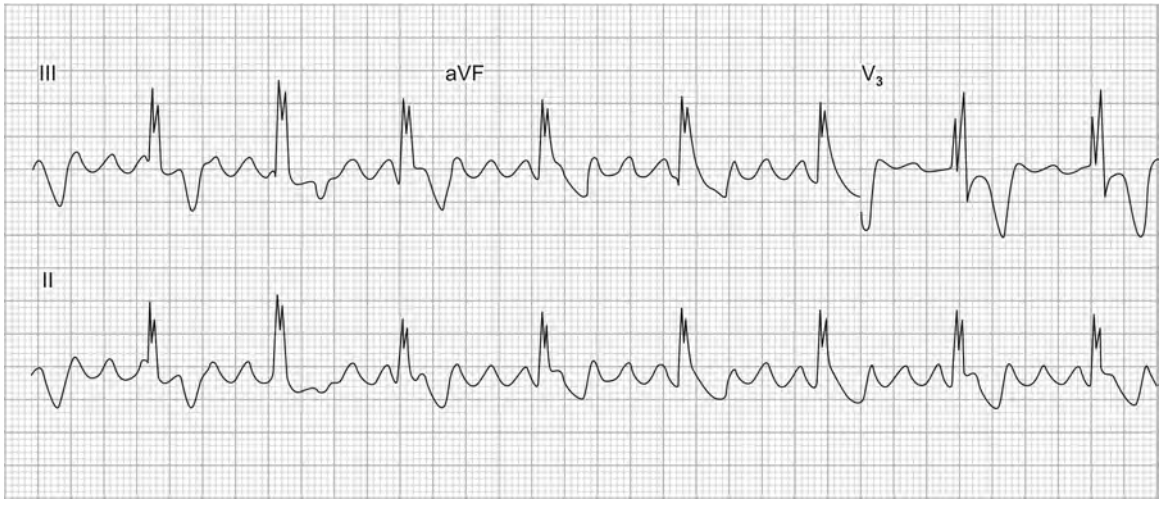

FIG. 11: A trial flutter: Ventricular rate—75 beats/min with 3:1 AV conduction. Sawtooth pattern P waves seen.

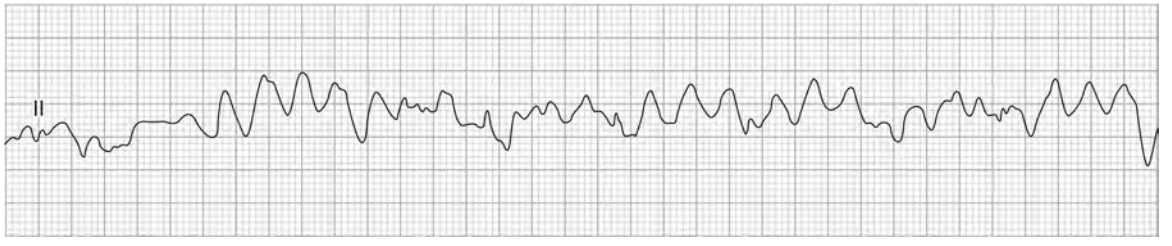

FIG. 12: Torsades de pointes with prolonged QT interval and changing ventricular rate in a child with long QTc syndrome (Jervell Lange-Nielsen syndrome).

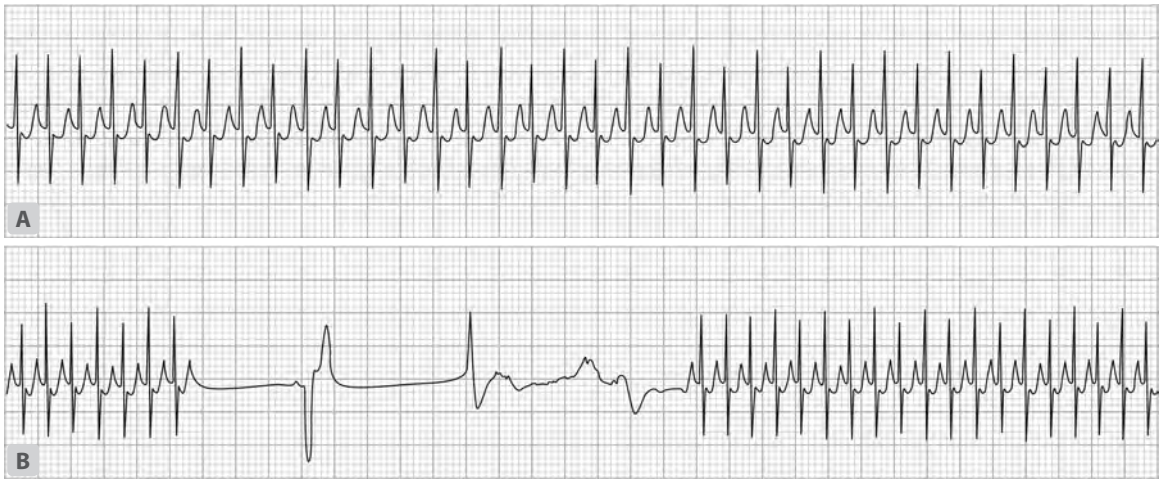
cardiovert to sinus rhythm. Pediatric paddles should be used with electrode jelly and should be correctly applied. Children should be sedated for comfort. Adenosine is usually not effective.

- *Supraventricular tachycardia (SVT)*: In hemodynamically stable children, vagal maneuvers should be attempted and if arrhythmia does not resolve within 10–15 seconds, Adenosine should be administered. The IV line should be located as centrally as possible. In adults and children weighing 50 kg or more, the recommended initial adenosine dose is 6 mg. If the patient does not convert to normal sinus rhythm, a 12 mg dose may be given within 1–2 minutes. In children weighing <50 kg, IV adenosine dose is 0.05–0.1 mg/kg. If there is no response, subsequent doses may be increased by 0.5–0.1 mg/kg increments up to a maximum single dose of 0.3 mg/kg. In hemodynamically unstable children (**Figs. 13A** and **B**), synchronized DC cardioversion is the first-line therapy.
- *Wide complex tachycardia* (probable VT): In stable patients, consider amiodarone 5 mg/kg IV over 20–30 minutes or procainamide, If medical therapy is unsuccessful or in hemodynamically unstable patients synchronized cardioversion 0.5–2 J/kg should be attempted.

Bradyarrhythmia

- *Sinus bradycardia*: The most common cause of bradycardia is hypoxemia, which is an ominous sign and should be managed aggressively. Other causes include hypothermia, hypothyroidism, raised intracranial pressure, and drug intoxication. The diagnosis of sinus bradycardia is easily made by establishing the 1:1 relationship between P waves and QRS complexes on the surface ECG. An upright P wave in leads I, II, and aVL, and a negative P wave in lead aVR, indicates a sinus origin of the bradycardia. The three main causes of bradyarrhythmia include (1) sinoatrial (SA) node dysfunction, (2) second-degree AV block, and (3) complete AV block. The main cause of bradycardia in children presenting as cardiac emergency is complete heart block (CHB) (**Fig. 14**).
  - *Clinical presentation*: Dizziness or syncope is distressing symptom, which occurs at a heart rate below 40–45/min may present as cardiogenic shock or sudden cardiac death. May present as heart failure in congenital heart block.
- *Management*: In symptomatic bradycardias drugs used include atropine given at a dose of 20 μg/kg as bolus (minimum dose 100 μg, maximum 600 μg), adrenaline



FIGS. 13A AND B: (A) Supraventricular tachycardia; (B) supraventricular tachycardia treated with IV adenosine with only transient response.

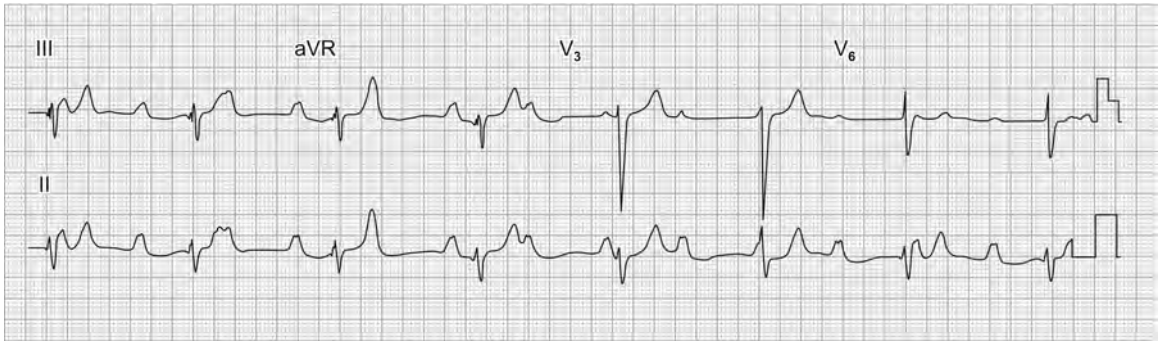


FIG. 14: Complete heart block with no relation between P waves and QRS waves with slow ventricular rate of 50 beats/min.

(10 μg/kg bolus) followed by infusions or isoprenaline infusion. Crystalloid bolus of 10–20 mL/kg IV is given if the patient is hypotensive or in shock. Patient should be referred to a tertiary care center where expertise for pacing is available and temporary pacing should be promptly instituted. In refractory cases, the definitive treatment is insertion of permanent pacemaker which can be endocardial or epicardial in position.

DRUGS COMMONLY USED IN CARDIAC EMERGENCIES

Prostaglandin E1 (alprostadil): 60 μg/kg in 50 mL 0.9% saline 0.5–3 mL/h (starting dose 10–60 ng/kg/min), if poor response (saturations and acidosis not improving), the dose can be increased to max 100–200 ng/kg/min.

Diuretics

- *Furosemide*: 0.5–1 mg/kg (adult 20–40 mg) 6–24 hours oral, IM or IV over 20 minutes. IV Infusion 0.1–0.4 mg/kg/h.
- *Spironolactone*: 1–3 mg/kg 6–12 hourly orally.

ACE Inhibitor

Enalapril: Test dose 0.05 mg/kg (adult 2.5 mg) oral with BP monitoring, increase over 2 weeks if required to max 0.5 mg/kg (adult 5–20 mg) twice daily orally.

Beta-blockers

- *Propranolol*: 0.2–0.5 mg/kg (Adult 10–25 mg) 6–12 hours oral, increase to max 1.5 mg/kg (max 80 mg) 6–12 hours, if required. IV 0.02 mg/kg (adult 1 mg) test dose then 0.1 mg/kg (adult 5 mg) over 10 minutes
- *Metoprolol*: IV 0.1 mg/kg (adult 5 mg) over 5 minutes, repeat every 5 minutes to max three doses, then 1–5 μg/kg/min. Oral 1–2 mg/kg (adult 50–100 mg) 6–12 hours.
- *Esmolol*: 0.5 mg/kg (500 μg/kg) IV over 1 minute, repeated if required. Infusion 25–300 μg/kg/min (undiluted 10 mg/mL solution) rarely given for >48 hours.
- *Carvedilol:* 0.1 mg/kg (adult 3.125 mg) 12 hours oral, if tolerated, increase by 0.1 mg/kg (adult 3.125 mg) every 1–2 weeks to max 0.5–0.8 mg/kg (adult 25 mg)12 hours.

TABLE 5: Digoxin doses in different pediatric ages.

Digoxin	*Digitalizing dose (mg/kg)*	*Maintenance dose (fraction digitalizing dose)*
Premature, neonates	0.04	1/4th
1 month–1 year	0.08	1/3rd to 1/4th
1–3 years	0.06	1/3rd to 1/4th
Above 3 years	0.04	1/3rd

Inotropes

- *Dopamine*: 5–20 μg/kg/min IV infusion. Central line preferred
- *Dobutamine:* 5–20 μg/kg/min IV infusion. Central line preferred
- *Milrinone* :50 μg/kg IV bolus over 10 minutes, 0.3–0.8 μg/kg/min IV infusion
- *Levosimendan:* Start with a bolus dose of 12–24 μg/kg IV over 10 minutes followed by 0.1 μg/kg/min IV infusion. Increase the dose slowly to 0.2 μg/kg/min and usually the total duration of the infusion was 24–48 hours. The bolus dose may be omitted in unstable hypotensive patients.

Digoxin

Digoxin doses in different pediatric age are summarized in **Table 5**.

SUMMARY

There are a number of congenital and acquired heart diseases in neonates, infants, and children that may present as life-threatening emergencies. These may be undiagnosed and present for the first time as emergencies, or they may present with complications in a child with a known diagnosis. Entertaining the possibility of a cardiac problem in neonates with pulmonary symptoms unresponsive to standard therapies is crucial for successful management of patients with CHD. In addition to ventilatory support, PGE1 infusions or emergency interventional cardiac catheterization is often a lifesaving initial measure in patients with acutely decompensated congenital cardiac lesions that require a PDA for survival. Every health practitioner caring for children should be aware of the common diagnoses, expected complications and their immediate management. The most commonly encountered emergencies are cyanosis or hypercyanotic spells, acute CHF, cardiogenic shock, tachyarrhythmias or bradyarrhythmia, and pericardial effusion or cardiac tamponade. The emphasis should be on early recognition of hemodynamic derangements and immediate appropriate intervention in order to prevent death and significant morbidity. Early consultation with a pediatric cardiologist is desirable especially if there is doubt as to the diagnosis or poor response to initial treatment. Once a child is stabilized, prompt referral to a tertiary pediatric cardiac center is usually required for definitive diagnosis and management.

171
CHAPTER

Pediatric Diabetic Ketoacidosis

Devendra Richhariya

INTRODUCTION

Diabetes mellitus is one of the most common chronic diseases among children and adolescents worldwide. Over the past 20 years, the incidence of type 2 diabetes mellitus (T2DM) (formerly known as adult-onset diabetes) has increased among children. A major complication of diabetes, diabetic ketoacidosis (DKA), is characterized by the metabolic triad of hyperglycemia, anion gap metabolic acidosis, and ketonemia that develops from an absolute or relative insulin deficiency and excess of counterregulatory hormone. DKA results in dehydration and electrolyte derangements. This combination, along with the major complication of cerebral edema, is the most important cause of morbidity and mortality among children with DKA. The mainstay of therapy is rehydration with intravenous (IV) fluids, insulin, and potassium repletion, as needed. Bicarbonate therapy is rarely, if ever, indicated and can lead to complications.

EPIDEMIOLOGY

Despite significant advances in diabetes management, the incidence of DKA and diabetes complications remains high, probably as a result of the alarming increase in childhood obesity and its direct link to diabetes. The incidence of DKA at the time diabetes is diagnosed varies by geographic location, ranging from 12 to 80%; approximately one-third of type 1 diabetes mellitus (T1DM) patients have DKA at the time of diagnosis. Young children, especially those younger than 5 years of age, are at high risk for DKA. The severity of DKA is also inversely related to age, placing the youngest children at the greatest risk. Other factors that increase the likelihood of DKA at the time of diagnosis of diabetes include lower body mass index, missed diagnosis at previous healthcare visits, delayed treatment, and preceding infection. The incidence of DKA among established diabetics is 25%. T2DM is becoming increasingly common among children as a result of obesity. DKA also occurs in T2DM patients; 5–25% of T2DM patients present with DKA at the time of diagnosis. In a study of T1DM and T2DM patients, the most common cause of DKA was insulin omission, especially in T1DM patients. Although less common overall, infection is more often associated with DKA in T2DM patients. Although acidosis tends to be more severe in T1DM patients, T2DM patients require a longer duration of insulin infusion to achieve ketone-free urine, possibly because of underlying insulin resistance. DKA is associated with significant cost and morbidity.

Although the mortality rate associated with DKA is <1%, this imbalance accounts for most diabetes-related deaths in children, most of which result from cerebral edema that progresses to brain herniation. Cerebral edema, a rare and devastating complication of DKA, is clinically apparent in 1–5% of patients with DKA. Mortality rates ranging from 20 to 90% have been reported. A large proportion of survivors, up to 26%, experiences permanent neurologic deficits. Studies have also demonstrated risks of long-term memory dysfunction in children who experienced DKA without cerebral edema.

PATHOPHYSIOLOGY

Insulin is the primary hormone of blood glucose regulation. It is responsible for increasing peripheral glucose uptake and stopping hepatic gluconeogenesis. As blood glucose levels increase, counter-regulatory hormones (glucagon, catecholamines, cortisol, and growth hormone) play reciprocal roles with insulin in attempts to maintain glucose homeostasis. DKA results from an absolute or relative deficiency of insulin and the resulting excess of counter-regulatory hormones. Absolute insulin deficiency occurs in new-onset T1DM as a result of pancreatic β-cell failure and in established diabetes as a result of insulin omission or insulin pump failure. Relative insulin deficiency can be attributable to insulin resistance or inadequate insulin dosing to balance the increased counter-regulatory hormone levels present during infection, trauma, or other physiologic stressors.

Medications such as high-dose glucocorticoids, atypical antipsychotics, and immunosuppressive drugs can also trigger DKA. Insulin deficiency leads to impaired glucose uptake and use by tissues. Counterregulatory hormone excess leads to increased glycogenolysis, gluconeogenesis, proteolysis (which creates more substrates for gluconeogenesis), and lipolysis. Lipolysis generates free fatty acids, which normally undergo β-oxidation to generate acetyl coenzyme A, an entry molecule for the citric acid cycle. In the absence of insulin, the significant lipolysis and fatty acid burden is diverted toward ketogenesis instead.

The two main ketones produced are acetoacetate and β-hydroxybutyrate, which dissociate fully at physiologic pH. Acetone is the least abundant product of ketogenesis but does not contribute to acidosis, as it does not dissociate to yield hydrogen ions. It is metabolized through the lung and produces the fruity breath characteristic of DKA. The ratio of β-hydroxybutyrate to acetoacetate, normally 1:1, increases to as high as 10:1 in DKA. Although ketones are weak acids, their severe overproduction overwhelms the buffering capacity of the body, which leads to an anion gap metabolic acidosis. Lactic acidosis and renal dysfunction are caused by prerenal azotemia and dehydration may also contribute to acidosis.

Respiratory compensation for this acidosis results in the classic shallow rapid breathing (Kussmaul respirations). Dehydration is a significant consequence of DKA and has several causes. Decreased glucose uptake and increased glucose production via glycogenolysis and gluconeogenesis lead to hyperglycemia, causing extracellular fluid and electrolyte shifts. An osmotic diuresis results when serum glucose levels increase above the renal threshold for glucose reabsorption. This causes free water, glucose, and electrolytes to be lost in urine. Ketone-induced nausea and vomiting, along with the insensible losses associated with Kussmaul respirations, compound fluid losses.

Multiple electrolyte abnormalities occur in the setting of DKA. Sodium, potassium, chloride, phosphorus, calcium, and magnesium are all affected. The most significant and imminently life-threatening electrolyte imbalance is hypokalemia. Potassium shifts out of the cells because of insulin deficiency and the exchange of hydrogen ions to compensate for acidosis. This can cause the serum potassium level to be normal or even increased, despite the total body depletion of potassium that results from osmotic diuresis, gastrointestinal losses, and volume depletion. Under these conditions, the renin-angiotensin-aldosterone system is activated, exacerbating renal potassium excretion via urine.

CLINICAL PRESENTATION

Diabetic ketoacidosis can develop quickly in patients with established diabetes, especially when it is related to insulin omission. However, when DKA acts as the first presentation of diabetes, the symptoms emerge over several days. Typical symptoms are the classic triad of polyuria, polydipsia, and weight loss with or without polyphagia. These symptoms are easy to miss in children who are wearing diapers and being fed by multiple caretakers. Abdominal pain, nausea, and vomiting are also common complaints. Dehydration and electrolyte derangements can lead to muscle pains and cramping. The abdominal pain can mimic an acute abdomen. It can also be an indication of an underlying cause, so further evaluation is warranted if the pain does not resolve with hydration and resolution of ketoacidosis.

Late findings include changes in mental status, Kussmaul respirations, and fruity, sweet, and ketotic breath. Because the presentation of DKA may vary and be subtle in children who may not have an established diagnosis of diabetes or be able to communicate their complaints verbally, a high degree of suspicion is needed to diagnose DKA in the pediatric population. Complaints of headache or changes in mental status are worrisome as indications of cerebral edema. Focal neurologic deficits can also be seen. Hemodynamic instability and shock are rare in children with DKA, but patients are often dehydrated to varying degrees as a result of fluid shifts, osmotic diuresis, gastrointestinal losses, and insensible losses.

DIAGNOSIS

The biochemical criteria for DKA are—hyperglycemia with blood glucose concentration >200 mg/dL (>11 mmol/L), venous pH <7.3, or bicarbonate concentration <15 mmol/L ketonuria and ketonemia. The severity of DKA can be categorized as follows:

- *Mild*: Venous pH <7.3, HCO_3 <15 mmol/L
- *Moderate*: Venous pH <7.2, HCO_3 <10 mmol/L
- *Severe*: Venous pH <7.1, HCO_3 <5 mmol/L

The basic *initial diagnostic tests* that should be obtained in all patients suspected of having DKA are listed in **Box 1**. Although hypotension is not common in straightforward DKA, but tachycardia can be present. Fever may occur in the setting of infection but is not caused by DKA inherently. Tachypnea is present in later compensatory stages of DKA. It is imperative to weigh all patients so that accurate medication and fluid doses can be calculated. The measurement of glucose levels in capillary blood samples with bedside meters provides information immediately and is adequate for monitoring changes during treatment. Values should be obtained at least every hour during acute management.

An *electrocardiogram* must be obtained if potassium measurement is not available immediately, such as via point-of-care testing, as early detection of arrhythmogenic electrolyte imbalances is crucial. U waves are suggestive of hypokalemia, whereas short QT intervals and peaked T waves may progress to prolonged PR intervals, widened QRS complexes, or a sine wave pattern in hyperkalemia. The complete blood count might show leukocytosis, which is not specific for infection in the setting of DKA and could be related to dehydration. An infectious workup should be initiated if the patient has a history of fever or other suggestive symptoms.

Serum chemistry is obtained for both the individual electrolyte values and to perform the calculations listed in **Box 1**. The serum sodium concentration is corrected to account for the dilutional effect of the degree of hyperglycemia. The anion gap, however, is calculated using the measured serum sodium level rather than a corrected sodium level because glucose is electrically neutral and does not contribute to the anion gap. The anion gap is determined by negatively charged ions and proteins such as albumin. Therefore, in the setting of albumin deficiency, the anion gap should be corrected, assuming a normal serum albumin concentration of 4 g/dL and an expected reduction in the anion gap by 2.5 mEq/L for every 1 g/dL decrease in serum albumin. Albumin levels should be obtained if there is a concern about nephrotic syndrome or severe malnutrition but not necessarily in a previously healthy child.

Venous Blood Gas Analysis

It is well-established that venous and arterial pH are well correlated in DKA. Consensus guidelines for management now include venous pH, rather than arterial pH, as part of the biochemical definition of DKA. This eliminates the added

BOX 1: Initial diagnostic workup for diabetic ketoacidosis patient.

- Vital signs
- Weight
- Capillary blood glucose
- Electrocardiogram
- *Serum Chemistry*: Glucose, sodium, potassium, chloride, blood urea nitrogen, creatinine, calcium magnesium, and phosphorus
- Complete blood count
- Venous blood gas
- β-hydroxybutyrate or urine ketones

Calculation using serum chemistry:

- Corrected sodium = serum sodium + 1.6 × [(serum glucose in mg/dL – 100)/100]
- Anion gap = serum sodium – (serum chloride + serum bicarbonate)
- Anion gap corrected for albumin = anion gap 2.5 × (4-serum albumin in g/dL)

risk of pain, hemorrhage, fistula formation, thrombosis, and infection when obtaining a sample for analysis of arterial blood gases. Although arterial blood gases used to be considered essential in the diagnosis of DKA, they have not been found to influence decision making in the emergency department when treating patients with DKA. Based on various studies, the mean difference between arterial and venous pH ranges from 0.015 to 0.05, and venous pH accurately measures the degree of acidosis in adult patients with DKA. Subtle differences are not likely to be clinically significant. Venous blood gas (VBG) electrolyte testing is a newer aspect of DKA diagnosis and monitoring that may allow the rapid assessment of essential data in a single test.

Ketone Testing

Although β-hydroxybutyrate is the predominant ketone produced in DKA, urine, and serum ketone assays typically use the nitroprusside reaction, which detects only acetone and acetoacetate and is semiquantitative using dilutions. During treatment with insulin therapy, β-hydroxybutyrate is oxidized to acetoacetate, causing β-hydroxybutyrate levels to decrease before acetoacetate levels. A ketone assay may give the false impression that the patient is not improving, when, actually, the overall quantity of ketones has decreased. Therefore, when interpreting ketone tests, both the time delay before the development of ketonemia and ketonuria must be considered in diagnosing DKA as well as the earlier clearance of β-hydroxybutyrate rather than urine ketones alone.

Urine ketone testing is affected by hydration status and urine stagnation in the bladder, and false-positive results can be encountered if patients are taking captopril, penicillamine, N-acetylcysteine, mesna, dimercaprol, or isopropyl alcohol. To more precisely measure ketone burden, a quantitative serum β-hydroxybutyrate test should be used.

The use of β-hydroxybutyrate testing has been proposed ahead of urine ketone testing as an end point to monitor resolution of ketosis and direct insulin infusion therapy. However, because serum β-hydroxybutyrate assays are not available at all institutions, the anion gap, pH, or bicarbonate can be used to direct DKA treatment.

EMERGENCY DEPARTMENT MANAGEMENT

First and foremost, pediatric resuscitation principles should be followed. Airway, breathing, and circulation should be secured. IV access must be obtained. Aspiration precautions should be taken if the patient has an altered level of consciousness. Continuous cardiac monitoring and pulse oximetry are imperative to assess for arrhythmias secondary to hyperkalemia or hypokalemia and to ensure adequate oxygenation. Frequent neurologic monitoring is also warranted. The best outcomes are achieved when children are monitored closely and continuously, with prompt attention to any changes. Additional hourly monitoring should include vital signs, neurologic checks, blood glucose, and accurate fluid intake and output. Frequent neurologic checks are particularly important in patients at greater risk for cerebral edema, such as those with new-onset diabetes, patients younger than 5 years old, and patients with greater degrees of acidosis, hypocapnia, or azotemia.

Capillary blood glucose levels should be confirmed with laboratory venous values. Initially, VBGs and chemistries should be checked every 2 hours, but depending on those initial values, may require more frequent monitoring. As previously mentioned, ketone testing should not guide treatment. The serum β-hydroxybutyrate concentration is ideal for monitoring progress; if that reading is not available, anion gap, pH, and bicarbonate can also be used as endpoints. Specific aspects of DKA management are—fluid resuscitation to rehydrate and improve tissue perfusion and glomerular filtration rate. Correction of ketoacidosis and hyperglycemia is acheived through inhibition of lipolysis and ketogenesis with insulin, restoration of electrolyte balance, and avoidance of complications, specifically cerebral edema.

Fluids

Intravenous fluids are administered for resuscitation and rehydration as well as to decrease the blood glucose level by improving the glomerular filtration rate and, thus, glucose and ketone clearance. Although adults tend to present with large volume deficits requiring aggressive fluid repletion, a more restrictive strategy must be used in the pediatric setting to avoid potential complications. The initial resuscitation of a pediatric patient in DKA calls for administration of an isotonic crystalloid solution as a bolus of 10–20 mL/kg over 1–2 hours. The dose can be repeated if the patient is hemodynamically unstable.

Children rarely present in hypovolemic shock caused by DKA alone. If a child does not respond to the initial resuscitation bolus, search for other causes of shock. To avoid increasing the risk of cerebral edema and herniation, resuscitation volumes should not exceed 40–50 mL/kg during the first 4 hours of treatment, unless the patient is in shock. After the initial bolus of IV fluid, the goal of rehydration is to administer the remainder of replacement fluids evenly over 24–48 hours with 0.45–0.9% saline.

Overzealous fluid resuscitation could lead to further complications, particularly cerebral edema, although no

data have demonstrated increased safety with rehydration over 48 hours. The rate of total fluid administration includes maintenance plus replacement of the fluid deficit based on the patient's estimated degree of dehydration (*see* section on degree of dehydration) and should not exceed two times the maintenance volume. Fluids that were administered before arrival should be accounted for in these calculations, but urinary losses should not.

Weight-based 24-hour maintenance fluid requirements can be calculated as follows:

- 100 mL/kg for the first 10 kg of body weight
- 50 mL/kg for the second 10 kg of body weight
- 20 mL/kg for each kilogram above 20 kg of body weight

Using the 4-2-1 rule, the requirements can be estimated as follows:

- 100 mL/kg/24 h = 4 mL/kg/h for the first 10 kg of body weight
- 50 mL/kg/24 h = 2 mL/kg/h for the second 10 kg of body weight
- 20 mL/kg/24 h = 1 mL/kg/h for each kilogram above 20 kg of body weight

Fluid Type

Normal saline (NS) (0.9% NaCl) is commonly used as the replacement fluid for patients with DKA and can be switched to half NS (0.45% NaCl) once the corrected sodium concentration normalizes (*see* section on sodium).

Recent evidence implicates the administration of large volumes of saline in the development of hyperchloremia with a nonanion gap metabolic acidosis, which increases with treatment duration and can mask the resolution of DKA if base deficit alone is being monitored as an endpoint for treatment. The clinical significance of hyperchloremia with acidosis is unclear, but concerns about possible deleterious effects from excessive saline administration have raised controversy with respect to fluid choice. A small blinded, randomized controlled trial failed to show any difference in time to normalization of pH and resolution of DKA between patients resuscitated using NS and others who received Ringer's lactate. Recent literature comparing noncalcium-containing balanced crystalloid such as Plasma-Lyte (Plasma-Lyte or Plasma-Lyte A, Baxter healthcare, Deerfield, IL) with NS administration to patients with DKA reported lower serum chloride levels and higher bicarbonate concentrations after resuscitation in the Plasma-Lyte group, consistent with prevention of hyperchloremia and acidosis. The effect of these changes on outcome and mortality rate is unknown. Chua and colleagues reported no difference in the rate of resolution of hyperglycemia, the duration or total dose of IV insulin administration, or length of ICU stay.

Further investigation is needed to determine whether the administration of a saline solution to patients with DKA carries any clinically significant risks; there is no evidence of associated morbidity. Currently, the use of saline remains the standard of care.

Rate of Rehydration

Because of conflicting theories on the underlying mechanism of cerebral edema in patients with DKA, arguments for both slower and faster rehydration have been put forth. If cerebral edema results from osmotic changes or vasogenic edema associated with a compromised blood-brain barrier, slower rehydration might limit edema. On the other hand, if ischemia and hypoperfusion are the major insults to the brain, then more rapid rehydration could rectify the problem sooner and prevent ischemia when intracellular fluid shifts during treatment with insulin. Unfortunately, little evidence is available to definitively guide the rapidity of fluid therapy.

Degree of Dehydration

The clinical assessment of dehydration such as reduced skin turgor, increased capillary refill time, dry tongue, and sunken eyes or fontanel, in assessing degree of dehydration, none of these parameters have been found to be accurate predictors of hydration status in DKA because they might not reflect only fluid losses. Acidosis can make a child seem more dehydrated because of the tachypnea of Kussmaul respirations, which results in dry mucous membranes, and vasoconstriction, which leads to cooler extremities. The ongoing lipolysis, proteolysis, and weight loss caused by insulin deficiency can also make a child seem clinically more dehydrated. On the other hand, hyperosmolarity tends to preserve intravascular volume (and thus pulses, blood pressure, and urine output) until extreme volume depletion and shock occur. Therefore, physical examination findings are often unreliable in estimating dehydration in the setting of DKA. Based on the available data, it might be excessive to estimate up to 10% dehydration in patients. Administration of maintenance fluids, based on an assumed 6% deficit, seems more reasonable.

Two-bag System

Because of rapid fluctuations in fluid, electrolyte, and dextrose requirements, patients with DKA require frequent adjustments in fluid and insulin administration. This system consists of two bags of fluids with identical electrolyte content but different dextrose concentrations (0% and 10%) that are administered simultaneously into the same IV line. The rate of fluid delivery is determined by the degree of dehydration and individual patient needs, whereas the concentration of dextrose depends on the patient's serum glucose level and its rate of decline during treatment. These factors can be manipulated independently, as different proportions of fluid from each bag are administered.

Initially, no dextrose is given; as hyperglycemia resolves with the infusion of insulin, dextrose is titrated up to control the rate of decrease in blood glucose while continuing the insulin infusion. The IV fluids can therefore be customized to meet the patient's individual glucose, fluid, and insulin needs by creating a fluid dextrose concentration that ranges between 0 and 10% to control the rate of blood glucose decline and prevent hypoglycemia. If >250 mg/dL (13.8 mmol/L), give NS alone, If <250 mg/dL (13.8 mmol/L), give half of the rate from each bag to make 5% dextrose (D5) NS. If <150 mg/dL (8.33 mmol/L), give 10% dextrose (D10) NS alone at a predetermined rate.

Studies have shown multiple advantages to the two-bag system. Rather than changing an individual IV fluid bag each time the dextrose concentration needs to be adjusted during correction of hyperglycemia and acidosis, which can take >30 minutes, the two-bag system allows rapid transitioning of fluids when necessary, taking as little as 1 minute.

The two-bag system is superior to the single-bag system with respect to flexibility, timeliness, and cost-effectiveness. The rate and dextrose concentration of the fluids can be adjusted independently, and the dextrose concentration can be changed quickly in response to updated serum glucose levels without discarding partially used bags of fluids. Studies have not yet demonstrated clinical benefit, but the two-bag system does not increase the risk of complications from DKA and could have clinical benefits in addition to its more practical advantages.

Insulin

Rehydration alone can decrease the blood glucose concentration, but insulin is required to suppress the lipolysis and ketogenesis that drive DKA. Insulin therapy is initiated after volume resuscitation has been started and after the serum potassium level is known. Low-dose insulin is the standard of care. Start and maintain a low-dose regular insulin IV infusion at 0.1 units/kg/h and continue until the ketoacidosis resolves or until the anion gap closes. Although still a point of contention in the management of adults with DKA, an initial bolus of insulin is not necessary in pediatric patients and may even be harmful by predisposing patients to hypoglycemia and increasing the risk of cerebral edema. Theoretically, rapid correction of hyperglycemia may shift osmolarity and lead to cerebral complications, but the rate of glucose correction has not been shown to increase the risk of cerebral edema or brainstem herniation.

Hyperglycemia usually resolves before the acidemia, but the insulin infusion must be continued to achieve full resolution of the ketoacidosis (pH >7.3, bicarbonate >15 mmol/L, β-hydroxybutyrate <1 mmol, and/or closure of anion gap). The target serum glucose level during treatment is approximately 200 mg/dL. To avoid hypoglycemia during insulin infusion, dextrose should be added to IV fluids when the blood glucose concentration reaches 250–300 mg/dL or if the decline in the blood glucose level exceeds 100 mg/dL/h (5.6 mmol/L/h). This practice is facilitated by the two-bag fluid system as described earlier. If hypoglycemia occurs on the maximum dextrose concentration of D10, then lower the insulin drip to no <0.05 units/kg/h, as rates less than this can prevent full resolution of the ketoacidosis.

The transition from IV to subcutaneous insulin should occur after ketoacidosis resolves. Subcutaneous insulin is given at least 30 minutes before discontinuing the insulin infusion to allow time for absorption and prevent rebound hyperglycemia. The patient must be able to tolerate oral fluids and should begin to eat at that time. Endpoints used to determine the transition from IV to subcutaneous insulin vary, mainly because no evidence-based guidelines have been established. Using a pH of 7.3 as a signal to make the transition might be inadequate, as patients have been found to be ketotic at this pH. Vanelli and colleagues used normalization of the β-hydroxybutyrate concentration as the signal to change the route of administration and reported financial savings and patient benefit stemming from a shorter ICU stay.

Route of administration IV insulin is indicated for patients with T1DM and moderate-to-severe DKA (pH <7.2 and bicarbonate <10 mmol/L) while mild DKA (pH 7.2–7.3 and bicarbonate 10–15 mmol/L) can be treated with either subcutaneous or IV insulin, depending on the clinical situation. Several studies have compared different dosages and schedules.

Sodium

The corrected sodium concentration should be calculated and monitored and should increase with treatment. A failure of the serum sodium level to increase or a decrease in the level despite treatment is associated with an increased risk of cerebral edema. In this situation, the sodium content of the fluid being administered may need to be increased.

Potassium

As previously mentioned, despite total body potassium depletion, serum potassium levels might be normal or even increased in response to transcellular shifts resulting from insulin deficiency and acidosis. Potassium levels quickly decrease with insulin therapy; therefore, to prevent fatal arrhythmias secondary to severe hypokalemia, insulin should not be given until an initial potassium level is obtained. If the serum potassium concentration cannot be measured immediately, an electrocardiogram should be obtained to assess for signs of hyperkalemia or hypokalemia. Potassium needs to be replaced depending on the initial serum concentration. The level must be checked at least hourly. If the initial serum potassium level is increased, give insulin without supplemental potassium until the patient's ability to urinate is ensured. If the initial serum potassium level is normal, give potassium (40 mEq/L) with IV fluids when insulin administration is started. If the initial serum potassium level is low, replete potassium when beginning volume resuscitation and before initiating insulin. IV potassium administration should not exceed a rate of 0.5 mEq/kg/h. If the serum potassium level remains low despite supplementation during insulin infusion, consider adding oral potassium supplementation or slightly decreasing the insulin infusion rate. Potassium can be given as potassium chloride, potassium phosphate, or potassium acetate. To avoid administering excess chloride and exacerbating hyperchloremia associated with saline administration, potassium can be replenished with half potassium phosphate and half potassium chloride or acetate, as long as serum calcium levels are monitored to avoid hypocalcemia resulting from phosphate administration.

Phosphate

Like potassium, phosphate is lost with osmotic diuresis. IV fluids decrease phosphate levels, and insulin exacerbates this change by causing the intracellular movement of phosphate. Symptoms of profound hypophosphatemia emerge with decreasing intracellular concentrations of adenosine triphosphate and 2,3-diphosphoglycerate, that is, when the plasma levels decrease to <0.32 mmol/L. Severe hypophosphatemia can occur in the setting of prolonged fasting (>24 hours). No data have demonstrated significant clinical benefits from phosphate repletion, and phosphate administration can result in hypocalcemia. However, if the patient has unexplained severe muscle weakness or decreased cardiac function, phosphate administration should be considered.

Magnesium

Serum magnesium levels can be low in patients with DKA, but they tend to normalize with resolution of the acidosis and with oral intake. There is no evidence supporting repletion of magnesium in the management of DKA.

Bicarbonate

Bicarbonate administration is not recommended or indicated in the management of DKA. Studies suggest that bicarbonate administration is associated with longer hospital stays for children, paradoxical worsening of ketosis in adults, and hypokalemia. Not only can bicarbonate exacerbate hypokalemia and decrease tissue perfusion by decreasing oxygen delivery but it has also been strongly associated with the development of cerebral edema in children. The mainstay of treatment of acidosis is fluid replacement and insulin. Fluids improve tissue perfusion and increase the glomerular filtration rate, enhancing the excretion of acid, and insulin inhibits the underlying ketone production.

COMPLICATIONS

The most common complications of DKA are hypokalemia and hypoglycemia, which occur in response to treatment. Thus, blood glucose and electrolyte concentrations must be monitored frequently throughout the course of DKA management. Cerebral edema, the most feared complication, is exclusive to pediatric patients with DKA.

Cerebral edema is a potentially devastating complication of pediatric DKA. It occurs in up to 1.5% of cases, with a mortality rate as high as 24%. Numerous factors have been implicated in the pathophysiology of DKA-related cerebral edema, but no single mechanism has been definitively proven as causative. Ischemic and cytotoxic edema secondary to acidosis decrease cerebral perfusion. Vasogenic edema that causes direct damage to cerebral vascular endothelium increases blood-brain permeability. Risk factors for DKA-induced cerebral edema are listed in **Box 2**. Typically, cerebral edema occurs within 4–12 hours after initiation of treatment, but its onset can be delayed up to 24–48 hours after initiation of treatment.

BOX 2: Risk factors for pediatric DKA-induced cerebral edema.

- New-onset diabetes
- Younger age
- Longer duration of DKA symptoms
- Degree of acidosis at presentation (pH 50 mL/kg in the first 4 h)
- Administration of insulin during the first hour of fluid resuscitation
- Higher blood urea nitrogen at presentation
- Slower increase in measured serum sodium concentration during treatment of DKA
- Bicarbonate treatment

Regular neurologic checks along with assessment of vital signs are crucial. Mental status changes, which can range from somnolence to irritability, are worrisome, as are focal neurologic deficits. Age-inappropriate incontinence can be a sign of cerebral edema. Complaints of headache should be considered seriously. The combination of hypertension, bradycardia, and irregular respiration (Cushing triad) is a sign of increased intracranial pressure. Hypoxemia can also result from compression of the brain's respiratory center, leading to impending brain herniation. When it is suspected based on clinical signs and symptoms, treatment should be initiated immediately. Treatment should never be postponed to wait for confirming computed tomography (CT) imaging; changes that indicate cerebral edema that can be seen on CT images occur late in its development.

Treatment includes elevation of the head of the bed and reduction of IV fluids by one-third. Mannitol should be administered at a dose of 0.5–1 g/kg IV over 20 minutes. This regimen can be repeated if there is no clinical response within 30–120 minutes. Mannitol decreases blood viscosity and thus improves cerebral blood flow acutely. Caution with its use is warranted, however, because mannitol can induce diuresis, thereby decreasing intravascular volume and causing hypokalemia. This may result in hypotension and, subsequently, decreased cerebral blood flow. Alternatively, 3% hypertonic saline can be given at a dosage of 5–10 mL/kg over 30 minutes, either instead of or along with mannitol. Hypertonic saline lowers intracranial pressure, increases intravascular volume, and increases mean arterial pressure. Patients might require intubation and mechanical ventilation to manage respiratory depression and avert impending respiratory failure. Patients with intracranial hypertension may be cautiously hyperventilated; however, hyperventilation to a PCO_2 <22 mm Hg should be avoided.

DISPOSITION

Established diabetics with mild DKA who are alert and tolerating oral fluids can be treated in the emergency department and discharged, provided they have close supervision at home, possess the proper medications and supplies, have been educated about insulin administration, have the ability to monitor their blood glucose level, and have access to close follow-up. Patients with new-onset diabetes must be admitted. Patients requiring IV rehydration over an extended period need to be admitted to a unit capable of hourly blood glucose measurement and frequent measurement of vital signs and neurologic checks. Patients with severe DKA should be admitted to the ICU, especially if they have had a long duration of symptoms, any hemodynamic instability, altered mental status, a high risk of cerebral edema [e.g., age <5 years low PCO_2 high blood urea nitrogen (BUN)].

SUMMARY

Despite advances in research and treatment, the incidence of pediatric-onset diabetes and DKA is increasing. Diabetes mellitus is one of the most common chronic pediatric illnesses

and, along with DKA, is associated with significant cost and morbidity. DKA is a complicated metabolic state hallmarked by dehydration and electrolyte disturbances. Treatment revolves around proper fluid resuscitation with insulin and electrolyte replacement under constant monitoring for cerebral edema, which is the deadliest complication. When DKA is recognized and treated immediately, the prognosis is excellent. However, when a patient has prolonged or multiple courses of DKA or if DKA is complicated by cerebral edema, the results can be devastating.

CHAPTER

Pediatric Seizure

Devendra Richhariya

INTRODUCTION

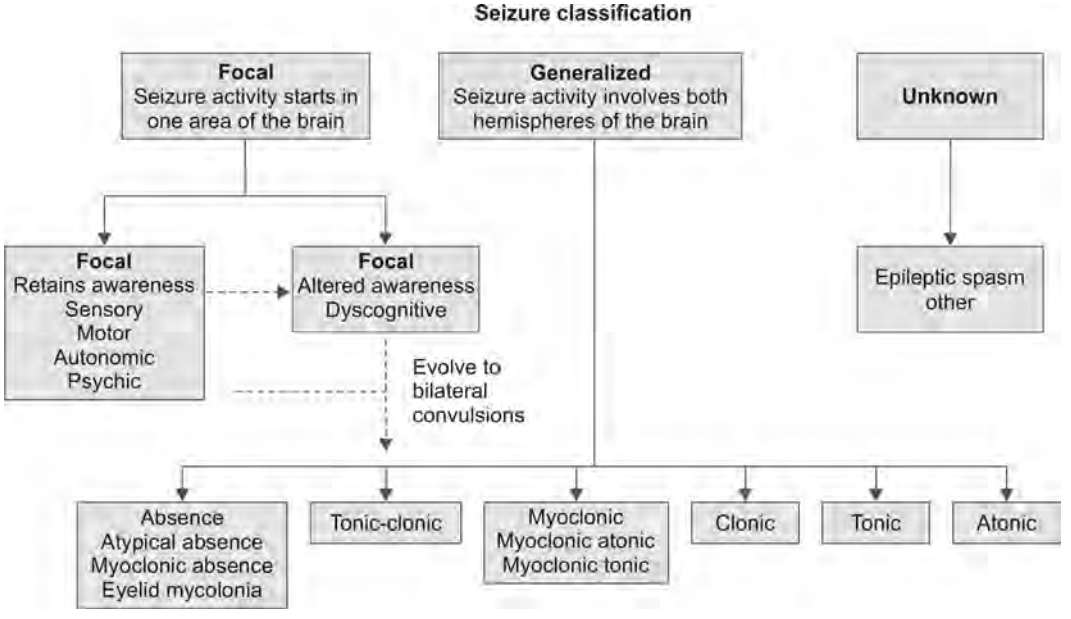
Seizure is paroxysmal involuntary motor activities, which cause changes in behavior, sensation, and/or consciousness due to abnormal electrical discharge in the brain. Seizures are most common neurologic emergency in pediatric age group. Seizures occur in approximately 1% of children up to 14 years of age. Incidence is highest in the first year of life (120 per 100,000). Seizure may be classified as focal and generalized (**Flowchart 1**). Seizure may range from subtle, nonconvulsive episodes to stereotypic movements to major generalized convulsions. Severity of seizures varies widely. It may be self-limited episodes with no hemodynamic compromise like febrile convulsions to prolonged events that may ultimately be fatal in as many as 3–4% of patients. Extensive evaluation and emergency management are essential in high-risk patients as in status epilepticus, neonatal seizures.

CAUSES

A seizure is a single event characterized by the abnormal excessive synchronized firing of cortical neurons that usually results in altered perception or behavior and recurrent unprovoked seizures labeled as epilepsy. Seizures could be multifactorial **Table 1**. A cause is identifiable in <20% of children with seizures. The most common etiology of neonatal seizures is hypoxic-ischemic encephalopathy (initial 48 h of life) and meningoencephalitis.

PATHOPHYSIOLOGY OF THE CONDITION

A seizure is a single event, which is characterized by the abnormal excessive synchronized firing of cortical neurons which causes involuntary muscle contractions with or without alteration in mental status. Focal seizure starts from unilateral



FLOWCHART 1: Classification of seizures.

area of brain (**Fig. 1**) while generalized seizures arise from both cerebral hemispheres at once. The manifestations of focal seizures depend on the area of the brain involved. Localized seizures may then spread to adjacent areas or to contralateral or other more distant regions through thalamocortical and interhemispheric pathways (**Fig. 2**), eventually resulting in secondarily generalized seizures. Aberrant electrical activity and subsequent manifestation of the seizure may range from subtle, nonconvulsive events to stereotypic movements to dramatic generalized convulsions. Neonatal seizures are typically subtler than seizures in older children and adults, in view of the immature nervous system of the neonates.

Benign febrile seizures (convulsions) are an inherited predisposition to developing a tonic-clonic seizure with a high fever (**Fig. 3**). The description is limited to convulsions associated with high fever in children under the age of 5 (usually between 6 and 36 months of age), with no cause for the seizure other than the fever. Benign febrile seizures are common, occurring in 3–5% of children under the age of 5. Most patients have only one or two seizures. Recent genetic analysis of families with febrile convulsions has defined specific associated gene defects.

TABLE 1: Causes of seizures.

Provoked seizures (seizure with an acute antecedent cause)	*Unprovoked seizures (no immediate provoking factor)*

• Hypoglycemia
• Toxic exposure
• CNS infection (meningitis, encephalitis)
• Head injury
• Other precipitating factors:
  ○ Fever
  ○ Immunization
	• Cryptogenic (no known cause)
	• Idiopathic (genetic)
	• Remote symptomatic (preexisting brain abnormality or insult):
	  ○ Hydrocephalus
	  ○ Disorders of brain development
	  ○ Neoplasms

Autonomic and Metabolic Changes due to Seizures

Patients of seizure may present with changes in autonomic system such as changes in pulse rate, sweating, salivation,

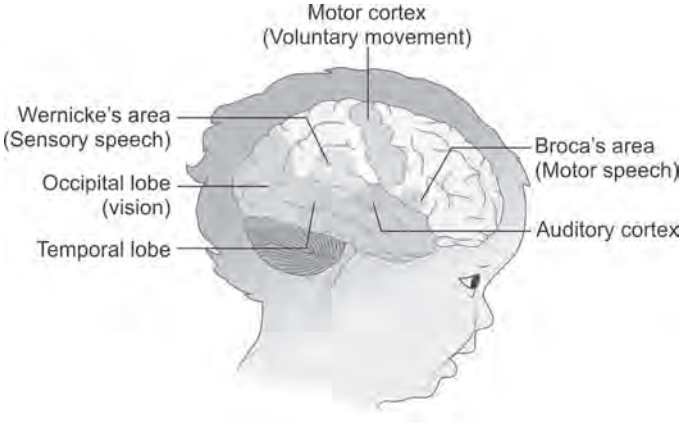


FIG. 1: Brain areas affected by Focal seizures.

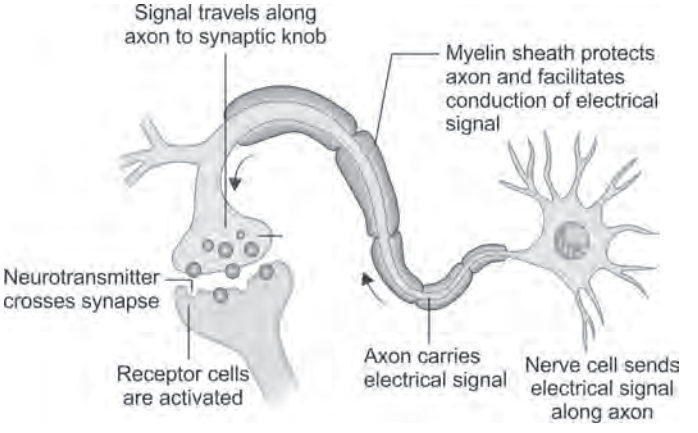

FIG. 2: Propagation of Focal seizures.

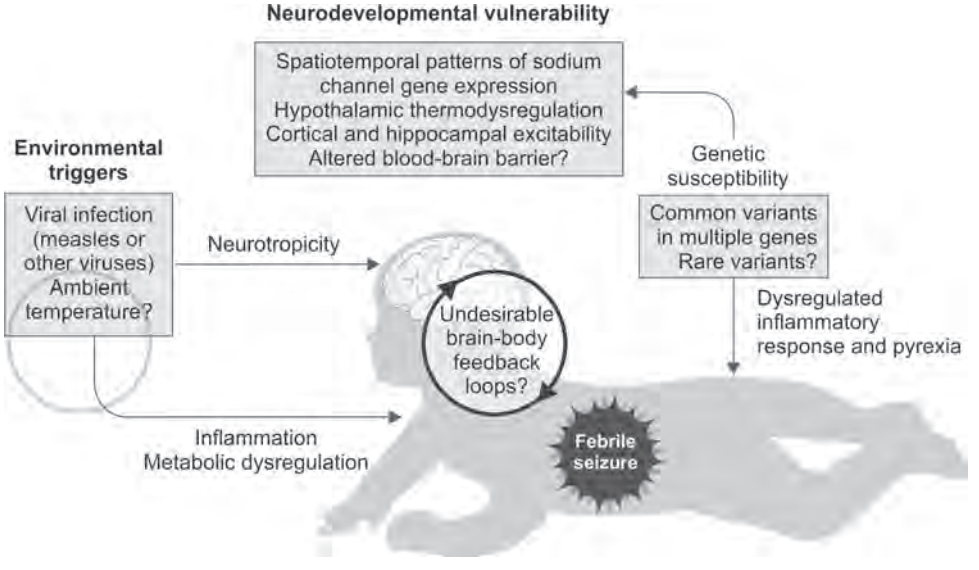

FIG. 3: Etiopathogenesis of the febrile seizure.

pupillary dilatation, and incontinence. And patient of generalized tonic-clonic seizures presents with an increase in blood pressure and pulse rate, increased autonomic nervous system activation, a metabolic acidosis, a drop in PO_2 and an increase in PCO_2 during the apneic tonic phase, and, rarely, hyperkalemia or rhabdomyolysis. Prolonged generalized tonic-clonic seizures may have serious consequences.

In seizure, following changes occur in blood. Blood flow to brain and glucose utilization increased. Increase in lactate, extracellular potassium, and serum prolactin, and a decrease in extracellular calcium are helpful in identifying true seizure. Prolactin also may be elevated after syncope and hence cannot differentiate seizures from syncope.

CLINICAL PRESENTATION

Depending upon the area in the brain where the seizure initiates and how it propagates symptoms could vary widely.

- Generalized seizures cause loss of consciousness along with purposeless full-body tonic (sustained)-clonic (interrupted) movements, atonia, and/or myoclonic jerking.
- Focal seizures can manifest as disturbances in motor/sensory/autonomic function, emotional state, cognition, behavior, or memory with or without alteration in consciousness
- At the cessation of seizure activity, the patient will enter the postictal period, characterized by confusion, fatigue, lethargy, and/or irritability.
- Neonatal seizures may present with subtle findings, such as ocular movement or lip smacking or abnormal vitals.
- Nonconvulsive status epilepticus can present as altered mental status, mild confusion, and subtle physical movements, inexplicable sudden changes in mental status or delayed recovery after a seizure.
- *Clinical features of concern (red flags) are* seizure in clinically unwell child, such as symptoms of infection, meningeal signs, dehydration, complex febrile seizure, altered level of consciousness, and additional risks for serious bacterial infection (age <6 months or >60 months with first febrile seizure, age <12 months with incomplete or unknown immunization history and febrile status epilepticus) and first nonfebrile seizure.

FEBRILE CONVULSION

Febrile convulsion is defined as seizure in neurologically normal child of 6 months–5 years with a temperature of >38°C (100.4°F) which has no identifiable cause or previous history of afebrile seizures. Febrile convulsion is the most common seizure disorder in childhood. It affects 2–5% of children between 6 months and 5 years age group, with peak incidence at 18 months. Around 6–15% occurs after 4 years, onset after 6 years is unusual. Febrile seizures generally occur during viral or bacterial infections. They sometimes occur after vaccinations such as measles, mumps, and rubella. Genetic and familial factors increase the susceptibility to febrile seizures. Febrile seizures usually take place during the initial rapid rise in body temperature, and mostly develop within 24 hours of fever onset. Typically, seizures are generalized; most are clonic, but some can manifest as periods of atonic or tonic posturing. Febrile seizures may be simple or complex:

- *Simple febrile seizures*:
  - Brief (<15-min) generalized seizures
  - Association with fever (temperature >38.0°C)
  - Predominantly generalized tonic-clonic seizure activity
  - Only one convulsion in a 24-hour period
  - Brief postictal period
  - Absence of preexisting neurological abnormality (intracranial infection, metabolic disturbance, or history of afebrile seizures)
- *Complex febrile seizures*:
  - Last ≥15 minutes continuously or with pauses
  - Have focal features
  - Recur within 24 hours

Febrile convulsion is established after exclusion of other possible causes. Fever may trigger seizures in a child with previous afebrile seizures and such events are not considered febrile seizures. >90% febrile seizures are simple. Routine testing is not required for simple febrile seizures other than to evaluate the source of the fever. Complex seizures, seizures with neurologic deficits, or signs of a serious underlying disorder (e.g., meningitis and metabolic disorders) warrant appropriate investigations.

- *Recurrence and subsequent epilepsy*: Recurrence rate of febrile seizures is nearly 35%. Risk of recurrence is higher if first seizure occurs in <1 year of age or history of febrile seizure is positive in first-degree relatives. Risk of developing an afebrile seizure disorder after having ≥1 simple febrile seizure is slightly higher (2–5%) than the baseline risk of developing epilepsy (2%). In children who have additional risk factors (e.g., complex febrile seizures, family history of seizures, and developmental delay); this risk is increased up to 10%. Prolonged febrile status epilepticus may be associated with damage to vulnerable parts of the brain such as the hippocampus.
- *Afebrile seizures*: A vast differential is to be considered in afebrile child with seizures. It could be a presentation of epilepsy or could be a symptom of another process, such as intracranial tumor or infection, metabolic derangement, toxic ingestion, neurocutaneous syndrome, or trauma.

STATUS EPILEPTICUS

Status epilepticus is a state of continuous seizures without return of normal neurologic function between them. Any of the classified seizures types may progress to status epilepticus. Status epilepticus can be convulsive or nonconvulsive. Convulsive status epilepticus is a medical emergency that can be produced by either primary generalized or secondary generalized tonic-clonic seizures. Nonconvulsive status epilepticus refers to either absence or complex partial status epilepticus. In either case, the patient does not have major motor seizures but is abnormal cognitively and may appear to be in a fugue state. Absence status appears to have no morbidity (unless injuries occur during the status), but complex partial status may lead to permanent cognitive deficits.

Status epilepticus is defined as—three or more seizures in an hour, a single prolonged seizure lasting at least 30 minutes with a motor component, and two or more convulsions without complete recovery of consciousness between seizures. Approximately 10% of children presenting with active seizure to the hospital are in status epilepticus. Nearly, one-third of them are related to fever, other etiologies include central nervous

system infections, ingestions and trauma, and antiepileptic drug withdrawal (most common cause in emergency department). Metabolic abnormalities, brain tumors, cerebral infarction, cerebral hemorrhages, and meningitis are the important causes of status epilepticus. Metabolic causes of status epilepticus are hypocalcemia, hyponatremia, hypoglycemia, liver failure, renal failure, and anoxia.

Open head trauma produced by bullets or shrapnel is associated with a 50% or greater chance of developing epilepsy. Closed head trauma, such as after automobile accidents or blunt injuries, carries a much lower risk (5% or less). Factors that predispose to the development of epilepsy after head trauma include a seizure within 2 weeks of injury, depressed skull fracture, loss of consciousness for longer than 24 hours, cerebral contusion, subdural hematoma, or subarachnoid blood, and age >65.

Nonconvulsive status epilepticus no convulsive status epilepticus can present as a continuous or fluctuating "epileptic twilight" state or as a prolonged postictal state. It must be considered in any child with altered mental state where no other cause could be diagnosed.

Neonatal seizures: The most common etiology of neonatal seizures is hypoxic-ischemic encephalopathy, usually manifesting within 48 hours of life. Still infection can be a significant trigger for seizures in neonates. So, possible meningoencephalitis is to be ruled out in this population.

EVALUATION

Most of the seizure activities stop before reaching emergency department so the detailed history usually is the guide to the diagnosis. In children presenting with seizure attack, a physical examination should address their cardiac, neurological, and mental status, and should include a developmental assessment where appropriate. Some findings are important in some specific conditions (**Box 1**).

Seizures can be partial (simple or complex partial, or partial with secondary generalization), generalized tonic-clonic, or tonic seizures. After stabilization of the child, it is important to determine if a seizure has occurred, and if so, if it is the child's first episode. Children can present with seizure-like symptoms that may not in fact represent actual seizures, but rather breath-holding spells, syncope, gastroesophageal reflux, pseudoseizures (psychogenic), and other nonepileptic events. The determination that a seizure has occurred is usually based on a detailed, careful history, and neurologic examination. Tests to exclude other disorders are determined clinically.

BOX 1: Evaluation of seizures.

History

- Age of child
- Onset, duration, progress and description of seizure activity
- History of trauma
- History of possible ingestion
- History of fever
- History of associated illness (vomiting or diarrhea)
- Feeding problems (especially in an infant)
- Changes in behavior
- Previous history of seizures and type of seizures
- Anticonvulsants dose and recent changes/missed doses
- Recent new medications (may alter metabolism of antiepileptic drugs)
- Allergies
- Other medical history
- Developmental history
- Family history of seizures
- Seizure-specific questions can be asked:
  - Was there a warning right before the convulsion (behavioral arrest, affective change)?
  - Did the head/eyes deviate upward or to one side?
  - Did the movements start unilaterally or bilaterally?
  - What was the child like immediately after and how long to recover to baseline?

Physical examination:

- *CNS infection*: Fever, headache, prolonged seizure, prolonged postictal state, Stiff neck, and confusion
- *Head trauma*: History, external evidence, and focal deficit
- *Brain tumor*: Headache, focal seizure, and focal deficits
- *Genetic syndromes and brain malformations*: Developmental delay and dysmorphism
- *Cerebral hemorrhage*: Trauma, family history of cerebral cavernous malformations, focal seizures, and focal deficits
- *Neurocutaneous disorders*: Birthmarks (hypopigmented macules, café au lait spots, etc.)

INVESTIGATIONS

- *Serum laboratory studies*: Serum glucose, sodium, calcium, magnesium, phosphorus, complete blood count, and liver and kidney function tests to rule out metabolic disorders if the history includes recent vomiting, diarrhea, or impaired fluid intake; if there are signs of dehydration or edema; or if a complex febrile seizure occurs. They are not required routinely in simple febrile seizures.
- *Electroencephalography (EEG)*: EEG should be performed within 24–48 hours only to support a diagnosis of epilepsy, in seizures with focal features, recurrent seizures, and first afebrile unprovoked seizures (**Fig. 4**). It is not recommended after an initial simple febrile seizure in children with a normal neurologic examination. When a standard EEG is not contributory, sleep EEG or long-term video or ambulatory EEG can be considered where appropriate. EEG and magnetic resonance imaging (MRI) are helpful in localizing the brain lesions (**Table 2**).
- *Neuroimaging computed tomography (CT)/MRI*: Neuroimaging should be used to identify underlying structural abnormalities that cause certain epilepsies. *MRI brain* is investigation of choice in children with epilepsies especially in these situations; epilepsies before the age of 2 years, signs of raised intracranial pressure, failure to control the seizures, and worsening of seizures. *CT brain is recommended* in suspected gross pathology, if MRI is unavailable or is contraindicated, in an acute emergency, CT can be used to determine whether a seizure has been due to acute neurological lesion or illness.

- *Lumbar puncture (LP) and cerebrospinal fluid (CSF) analysis are indicated*—seizure in a child <6 months, persistent alteration of mental status of unknown cause or failure to return to baseline, seizure with suspected meningitis or meningitis or intracranial infection by history or examination, seizures after several days of febrile illness, and seizure with fever in those who are not fully immunized or taking antibiotics.

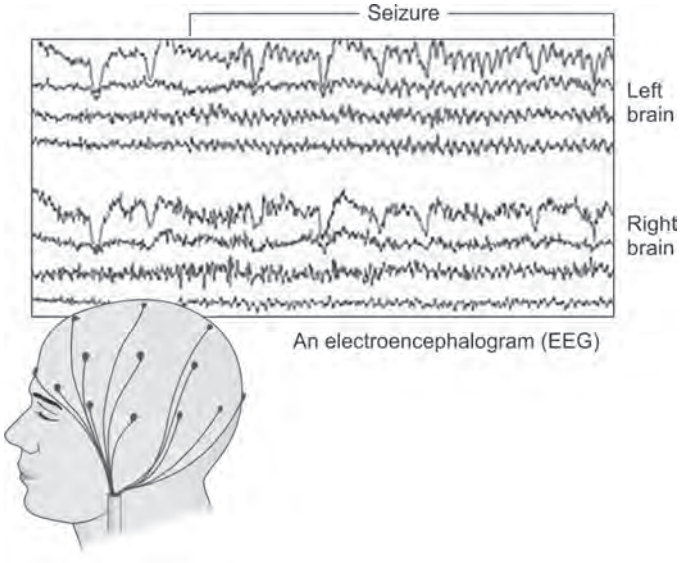

FIG. 4: EEG for localizing the seizure activity.

If increased intracranial pressure is suspected, the LP should be preceded by an imaging study of the head.
- *Other test like 12-lead electrocardiogram (ECG)* should be considered only in cases of diagnostic uncertainty in pediatric age group. *Neuropsychological assessment* is suggested in selected patients.

ANTIEPILEPTIC DRUGS

The choice of antiepileptic drugs is dictated by the types of seizures that the patient has (**Table 3**). If possible, monotherapy should be used. The selections are based on side effects as well as effectiveness. Phenobarbital and primidone are as efficacious as phenytoin and carbamazepine but are more likely to produce side effects. Tonic and atonic seizures are often resistant to therapy, and valproate seems to be most efficacious. Tonic and clonic seizures may be secondarily generalized, and phenytoin, carbamazepine, lamotrigine, topiramate, and felbamate can be helpful.

TREATMENT

There are limited data on pediatric seizures to lead to a consensus protocol. There are varieties of guidelines and algorithms endorsed by different organizations and institutions around the globe. Though they have variations, the essential management pathways are quite similar. Immediate measures for a seizing child in ED, should be taken and they are secure airway, give high-flow oxygen, assess breathing and circulation, assess vital signs, check blood glucose,

TABLE 2: EEG localization features and common causes of seizures.

Region	*Typical semiology*	*EEG*	*Etiology*
Frontal	Often nocturnal, occurs in clusters, often brief <30 sec. Other symptoms relate to subregion of frontal lobes (adversive turning). Complex motor automatisms such as bicycling, pelvic thrusting or other sexual gestures. Vocalizations common, minimal postictal symptoms	Frontal or anterior vertex epileptiform discharges. Occasionally frontal bisynchronous discharges	Trauma, malformations such as cortical dysplasia or cavernous angiomas, strokes, tumors, infections, and anoxia. Some genetic syndromes
Mesial temporal	*Auras common*: Olfactory, gustatory, rising epigastric sensation, déjà vu, experiential phenomenon behavioral arrest, automatisms of the mouth (oroalimentary), and ipsilateral hand (manual). Semipurposeful or repetitive stereotypical movements. Contralateral dystonic posturing. Significant postictal confusion	Temporal epileptiform discharges localized to anterior temporal region or sphenoidal electrodes, if used. Rhythmic theta activity	Mesial temporal sclerosis, postinfectious, and trauma
Lateral temporal	Auras more likely to be auditory, vertiginous, visual distortions, and early aphasia symptoms	Lateral temporal epileptiform discharges and rhythmic theta activity	Lateral cortical lesions and dysplasias. Cavernous angiomas. Genetic
Parietal	Rare. May reflect activity of association cortex activity and include elementary or unusual formed sensory phenomena, nausea/abdominal, dysphasia, or speech arrest	Parietal epileptiform discharges	Usually due to cortical lesions such as infarcts, cortical dysplasia, and malignancies
Occipital	Usually consists of unformed visual phenomena. May be negative visual symptoms	Occipital epileptiform discharges, unilateral, or bisynchronous	Cortical lesions such as infarcts, dysplasia, or malignancies, but also as an idiopathic epilepsy syndrome (benign epilepsy with occipital paroxysms)

TABLE 3: Choice of antiepileptic drugs for specific type of seizures.

	Seizures			*Epilepsies*	
	Partial seizures and localization-related seizures	***Tonic-clonic***	***Generalized absence***	***Myoclonic***	***Atonic/tonic***
First-line drugs	Carbamazepine, phenytoin lamotrigine, valproate, and oxcarbazepine	Valproate, lamotrigine, phenytoin, and carbamazepine	Ethosuximide and valproate	Valproate, lamotrigine, and topiramate	Valproate, lamotrigine, and topiramate
Second-line drugs	Primidone, phenobarbital, felbamate	Topiramate, primidone, phenobarbital, and felbamate	Topiramate, lamotrigine, and clonazepam	Primidone, phenobarbital, clonazepam, ethosuximide, and felbamate	Phenytoin, phenobarbital, primidone, clonazepam, and felbamate
Add-on drugs	Topiramate, levetiracetam, zonisamide, gabapentin, and tiagabine	Levetiracetam and zonisamide	Zonisamide	Levetiracetam and zonisamide	Levetiracetam and zonisamide

- *Decision regarding stopping the antiepileptic should be taken only after consulting the pediatric neurologist*
- *Recurrence of seizure* can occur when following abnormalities are present: neurologic abnormalities, mental retardation, complex partial seizures, and consistently abnormal EEGs

secure IV access in a large vein, place patient on full monitor, and followed by medications depending on seizure type and underlying cause.

Treatment of Febrile Seizure

Antipyretic therapy is to be given to relieve symptoms of associated febrile illness but they do not reduce seizure activity. Supportive therapy is usually sufficient for seizures lasting <15 minutes as most of the seizures are brief and self-limiting. Rectal diazepam can be used. Seizures lasting ≥15 minutes are treated in the line of status epilepticus. Maintenance drug therapy is usually not indicated.

Treatment of Neonatal Seizure

Maintain airway, breathing, circulation, and temperature. Collect blood for biochemistry. Check blood glucose immediately, correct glucose and calcium, and administer IV phenobarbitone 20 mg/kg. Repeat in 5 mg/kg boluses every 15 minutes, if seizure continues up to a maximum dose of 40 mg/kg. IV phenytoin 15-20 mg/kg diluted in same amount of normal saline at a maximum rate of 1 mg/kg/min over 35–40 minutes. IV lorazepam (0.05–0.1 mg/kg) or diazepam (0.25 mg/kg bolus or 0.5 mg/kg rectal) or IV midazolam as a continuous infusion an initial IV bolus of 0.15 mg/kg, followed by continuous infusion (1 μg/kg/min) increasing by 0.5–1 μg/kg/min every 2 minutes until a favorable response or a maximum of 18 μg/kg/min 100 mg pyridoxine IV or oral (if IV not available) should be given.

Treatment of Status Epilepticus

- *In the community*, prolonged (lasting 5 minutes or more) or repeated (3 or more in an hour) generalized, convulsive (tonic–clonic, tonic or clonic) seizures in the community should receive immediate emergency care. If history of previous episode of prolonged or serial convulsive seizures is present, buccal midazolam or rectal diazepam can be given. Care must be taken to secure airway and assess respiratory and cardiac function. *Patient in ED*—convulsive status epilepticus can lead to permanent neuronal injury. Majority of the seizures are brief and self-limiting. If a seizure activity lasts for >5 minutes, the chances are more that the seizure is likely to be prolonged. Keeping that in mind, all the status treatment protocols have used a 5-minute definition. Early treatment minimizes risk of seizures reaching 30 minutes and subsequent neuronal damage. Moreover, the adverse outcomes associated with needlessly intervening on brief, self-limited seizures are eliminated by avoiding aggressive therapy before 5 minutes.
- *Stabilization (0–5 minutes)*: Assess and stabilize patient's airway, breathing, and circulation. Give high-flow oxygen, if oxygenation is impaired. Consider intubation if assisted ventilation is required. Take quick history. Perform physical examination with stress on neurological examination. Check blood glucose and correct with IV dextrose if CBG <60 mg%. For children of ≤2 years: 4 mL/kg, for children >2 years: 25D 2 mL/kg 2 mL/h. Secure IV or IO access immediately. Collect blood for complete hemogram, electrolytes, toxicology screen, and antiepileptic drug levels where appropriate.
- *First-line therapy (5–20 minutes):* Benzodiazepines are the initial therapy of choice. Any one of the three benzodiazepines can be used: IM midazolam (10 mg for >40 kg, 5 mg for 13–40 kg, single dose) or IV lorazepam (0.1 mg/kg/dose, max: 4 mg/dose, may repeat dose once) or IV diazepam (0.15–0.2 mg/kg/dose, max: 10 mg/dose, one repeat dose can be given). If none of the above options are available, any one of the following drugs can be used:

IV phenobarbital (15 mg/kg/dose, single dose), rectal diazepam (0.2–0.5 mg/kg, max: 20 mg/dose, single dose), and intranasal/buccal midazolam.

- *Second-line therapy (20–40 minutes):* If there is a lack of response to the therapy administered in the previous phase, the following can be administered as a single dose: IV fosphenytoin (20 mg PE/kg, max: 1,500 mg PE/dose, single dose), IV valproic acid (40 mg/kg, max: 3,000 mg/dose, single dose), and intravenous levetiracetam (60 mg/kg, max: 4,500 mg/dose, single dose). If none of the above are available, intravenous phenobarbital (15 mg/kg, single dose), if not given already.
- *Third-line therapy (40–60 minutes):* At this juncture, no clear evidence is there to guide the therapy.
- If the seizure continues, second-line therapy can be repeated or anesthetic doses of thiopental, midazolam, pentobarbital, or propofol can be administered. EEG monitoring is necessary at this phase. Based on the cause and severity of the seizure, the second- of third-line therapy can be initiated at an earlier time, if necessary. If at any point the patient responds to therapy and is at baseline, symptomatic medical care should be initiated. Treatment of nonconvulsive status epilepticus is less well defined. Most forms are not life-threatening. Initial treatment is similar to generalized convulsive status epilepticus. Treatment of status epilepticus is summarized in **Table 4**.

TABLE 4: Protocol for treatment of status epilepticus.

0–5 min	• Provide for maintenance of vital signs. Maintain airway. Give oxygen. Observe and examine patient • Obtain 50 mL of blood for glucose, calcium, magnesium, electrolytes, blood urea nitrogen, liver functions, anticonvulsant levels, CBC, and toxicology screen. Begin normal saline IV and give 50 mL of 50% glucose and 100 mg of thiamine. Monitor EKG, blood pressure, and if possible, EEG
5–20 min	• Use intravenous lorazepam to stop seizures, 0.1 mg/kg at 1–2 mg/min • If seizures continue, load with phenytoin using fosphenytoin 20 mg phenytoin equivalents (PE)/kg at 150 mg PE/min. If cardiac arrhythmia or hypotension occurs, slow the infusion rate
20–40 min	If seizures persist 10–20 min after administration of phenytoin, give an additional 10 PE/kg. If seizures continue, intubate patient. Consider phenobarbital at a rate of 50–100 mg/min until seizures stop or 20 mg/kg is given. Alternatively move to anesthetic agents
40–60 min of status	Review laboratory results and correct abnormalities. Arrange for anesthesia, neuromuscular blockade, and EEG monitoring. Options include midazolam (0.15–0.2 mg/kg load, then 0.06–1.1 mg/kg/h) or propofol (1–2 mg/kg load, then 3–10 mg/kg/h), or barbiturate anesthesia (pentobarbital, 6–15 mg/kg loading dose, then 0.5–5 mg/kg/h). Pentobarbital often causes circulatory collapse, so be prepared to administer a pressor agent such as dopamine

(CBC: complete blood count; EEG: electroencephalogram; EKG: electrocardiogram)

SUMMARY

Admission should be considered for infants <6 months, children with complex features, seizures are uncontrolled or prolonged, and social concerns. Management of seizures includes airway, breathing, circulation, check glucose, stop seizures, prevent, or correct metabolic complications. Identify and treat underlying causes.

173 CHAPTER

Pediatric Oral and Dental Emergencies

Trevor L Tredway

INTRODUCTION

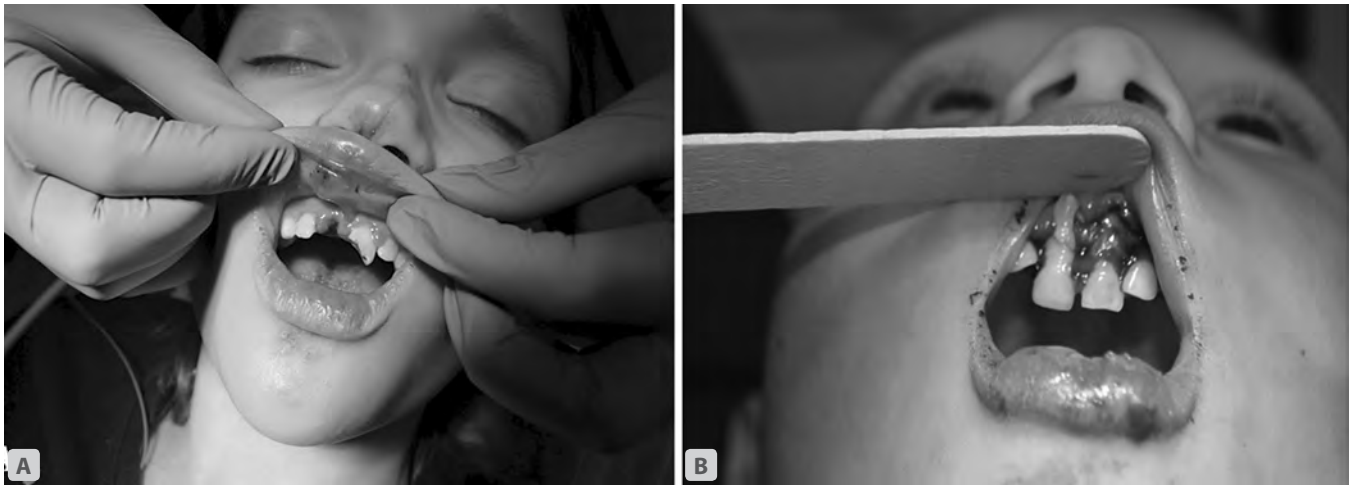
Oral injuries are a very common occurrence in childhood. It has been reported that traumatic dental injuries comprise 5% of the injuries for which people seek treatment. A child's oral cavity and teeth can be injured by accidental falls, motor vehicle accidents, or during sports activities. Trauma to the oral structures can involve the teeth and the surrounding tissues and supporting structures. A literature review in 2008 revealed that about 25% of all schoolchildren experience dental trauma and 33% of adults have had some type of dental injury to their permanent dentition usually by 19 years of age. Types of oral and dental injuries that may present to the emergency department (ED) are represented in **Figures 1A** and **B**. The majority of hospitals do not have dental services available to handle these types of traumatic injuries. Therefore, proper ED evaluation, diagnosis, treatment, and follow-up planning are warranted to ensure the best clinical outcome. The International Association of Dental Traumatology developed guidelines for evaluation and management of traumatic dental injuries.

Tooth Anatomy

Anatomically a tooth has a crown and root portion (**Fig. 2**). The external surface of the crown is covered by white enamel and the external surface of the root is covered by cementum. The cementoenamel junction (cervical line) is the point where the crown and root meet. The second layer of the tooth is composed of yellow/tan dentin, which makes up the majority of the tooth. The center of the tooth consists of the pulp tissue where the neurovascular supply is located. The pulp has a red to pink color when visible. Understanding the anatomy of the tooth enables the provider to evaluate the dental injury appropriately and determine the best course of action for treatment.

Pediatric Soft Tissue Injuries of the Oral Cavity

Pediatrics soft tissue injuries of the oral cavity can include abrasions, lacerations, and perforations. Soft tissue injuries may occur in isolation but they can also be associated with injuries to the dentition. Every assessment of oral soft tissue injuries must include adequate attention and examination of the dentition.



FIGS. 1A AND B: Pediatric oral and dental trauma. (A) 12 years of age female that fell while riding her bike and sustained oral/dental injuries. (B) 3 years of age male that fell onto a concrete sidewalk and sustained a dental injury. ***(For color version, see plate 29)***

- *Abrasions*: Superficial abrasions will usually heal without any complications and routinely do not require any intervention or repair in the ED. Abrasions can also be associated with other underlying injuries so as with contusions, careful examination and inspection of all adjacent structures are indicated.
- *Lacerations*: Intraoral lacerations are very common in children. Small intraoral lacerations with well-approximated margins do not require intervention or repair. Bleeding usually subsides spontaneously and healing takes place by itself. Children are often placed on soft diets with avoidance of salty or spicy foods until the wound has healed. Large lacerations with extensive tissue damage or uncontrolled bleeding will require careful examination and repair. Additionally, intraoral lacerations have communication between the intraoral surface and the outer skin surface ("through-and-through") will require surgical closure. This should be done in layers with the mucosal layer being closed first, then the muscle layer next and then finally the skin surface layer. Intraoral lacerations should always be investigated for possible foreign bodies but specifically those caused by tooth penetration.
- *Special lacerations*: Lacerations of the frenulum and the tongue tend to bleed profusely and can be very traumatizing to the patient and their parents. Hemostasis of frenulum lacerations can be achieved by direct pressure. These frenulum lacerations do not require any type of intervention or repair just parental reassurance (**Fig. 3**).

  Most tongue lacerations do not require repair and heal spontaneously. However, tongue lacerations with certain characteristics do require repair (**Figs. 4A** and **B**). These include bisecting lacerations, large flap-like lacerations, gaping lacerations, U-shaped lacerations, partial amputation type lacerations, or those lacerations where hemostasis cannot be achieved with direct pressure.

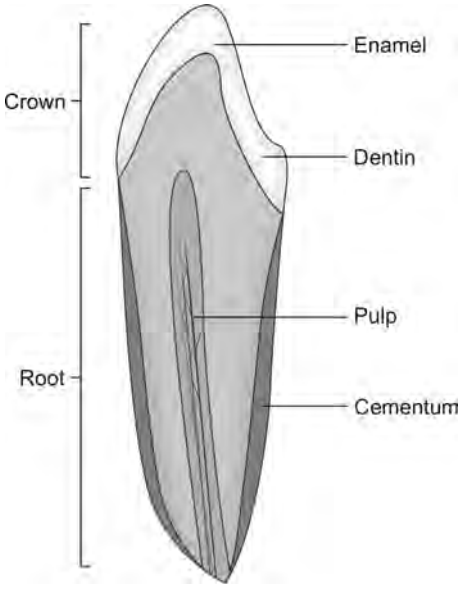


FIG. 2. Tooth diagram.

FIG. 3: Frenulum laceration. 18-month-old male that fell and sustained frenulum laceration. No intervention was required and he was discharged to home. ***(For color version, see plate 29)***

FIGS. 4A AND B: Tongue laceration. (A) 8 years of age male who sustained tongue laceration while jumping on a trampoline. (B) Laceration repaired with horizontal mattress sutures in the ED with procedural sedation. ***(For color version, see plate 29)***

- *Perforations*: These wounds are typically the result of a child falling with an object in their mouth. In these instances, the injury can be a small but deep perforation of the oral cavity or oropharynx. Careful inspection of the wound for any retained foreign body is important. When the perforation involves the posterolateral palate or a tonsillar pillar, one must also consider the possibility of damage to the large vessels residing in this region of the neck. A computed tomography scan of the region may be required to further evaluate the injury. In the majority of cases, no repair is needed for perforation injuries.

Pediatric Dental Trauma

Most hospitals do not have dental services available and thus the evaluation, diagnosis, and treatment of the patient fall on the providers in the ED. Most dental injuries that present do not require emergent intervention, however, to most parents any dental injury to their child seems emergent at the time. Providers that can adequately evaluate the patient with a dental injury can also provide reassurance to the parents. One resource that providers should have available in the ED is some form of dental splinting. This will allow them to stabilize an injured tooth initially until appropriate follow-up can be arranged. There are many commercial kits that involve acid etching of the tooth in conjunction with resin and/or soft arch wires that are available to splint the tooth until permanent repair. The specific management and treatment of the dental injury may differ depending on whether it involves the primary or permanent dentition.

CLASSIFICATION AND MANAGEMENT OF TRAUMATIC DENTAL INJURIES

- *Concussion*: It refers to minor traumatic injury to the tooth and supporting structures.
  - *Primary dentition*: No immediate intervention required, observation, soft diet × 1 week
  - *Permanent dentition*: No immediate intervention required, observation, soft diet × 1 week
- *Subluxation*: It refers to loosening of the tooth in its alveolar socket.
  - *Primary dentition*: No immediate intervention required, observation, soft diet × 1 week
  - *Permanent dentition*: No immediate intervention required, observation, soft diet × 1 week, consider dental radiograph to rule out fracture.
- *Lateral luxation*: It refers to loosening of the tooth in its alveolar socket with lateral displacement.
  - *Primary dentition*: Treatment by repositioning or extracting tooth, do not splint. Observation and soft diet × 1–2 weeks
  - *Permanent dentition*: Obtain dental radiograph, reposition, and splint tooth. Urgent dental consultation within 24–48 hours.
- *Extrusive luxation*: It refers to loosening of the tooth in its alveolar socket with vertical displacement.
  - *Primary dentition*: Treatment by repositioning or extracting tooth, do not splint. Observation and soft diet × 1–2 weeks
  - *Permanent dentition*: Obtain dental radiograph, reposition, and splint tooth. Urgent dental consultation within 24–48 hours
- *Intrusive luxation*: It refers to a tooth that has been forced up vertically into its alveolar socket. The tooth will appear shortened and in severe cases may appear as if it is missing.
  - *Primary dentition*: Obtain dental radiograph, observe, and allow to re-erupt. If alveolar plate is compromised, then tooth requires extraction. Routine dental follow-ups.
  - *Permanent dentition*: Obtain dental radiograph, urgent dental referral within 24–48 hours for surgical reduction. Permanent or secondary teeth do not re-erupt, thus reduction is indicated to prevent complications (i.e., root resorption).
- *Avulsion*: It refers to the complete displacement of the tooth from its alveolar socket. The periodontal ligament has been severed completely. The tooth may be completely removed or can remain attached to the gingival tissue.
  - *Primary dentition*: Do not replant, obtain dental radiograph if tooth is not located.
  - *Permanent dentition*: Tooth should be replaced in the socket as soon as possible. The root should not be handled or scrubbed. If tooth cannot be replaced within 30 minutes, it should be stored in a balanced salt solution or cold milk. In the ED you may obtain a dental radiograph to evaluate for alveolar fracture prior to reimplantation and splinting. Discharge home with soft diet, systemic antibiotics, and oral antiseptic rinse along with emergent dental referral within 24 hours.

CLASSIFICATION AND MANAGEMENT OF TOOTH FRACTURES

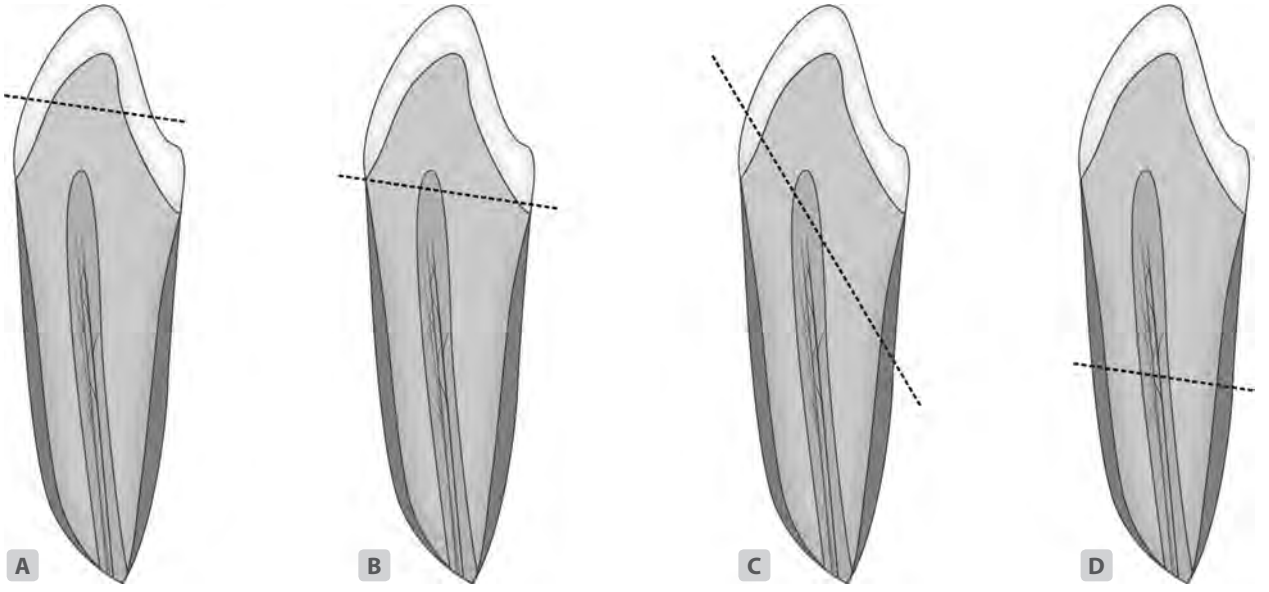
- *Uncomplicated crown fracture*: The fracture is limited to the enamel and dentin layers (**Fig. 5A**). Pain control is important to initiate as soon as possible. You may obtain a dental radiograph to rule out root fracture. These fractures may be associated with sharp edges thus dental referral within 24–48 hours is recommended for restoration or contouring to avoid further soft tissue injuries.
- *Complicated crown fracture*: The fracture involves the enamel and dentin layers along with exposure of the pulpal tissue (**Fig. 5B**). Initially, you may obtain dental radiograph to rule out root fracture. The exposed pulp is very sensitive to stimuli such as airflow and pressure. If available, calcium hydroxide can be used to place over the exposed pulp to ease the pain. Immediate dental referral within 24 hours is required. For younger children attempts to preserve the pulp vitality is important by pulp capping or partial pulpotomy. In older children, a root canal is commonly the treatment of choice.
- *Crown root fracture*: The fracture involves the enamel, dentin, and cementum. They may also include involvement of the pulpal tissue (**Fig. 5C**). Crown root fractures require dental referral within 24 hours. In the ED, radiographs to ascertain the fracture line and temporary stabilization of the tooth by splinting to the adjacent teeth can be performed.

- *Root fracture*: The fracture involves the cementum (**Fig. 5D**). The coronal segment of the tooth may be mobile and/or displaced and there is likely to be bleeding along the gingival sulcus. The initial ED treatment of root fracture involves repositioning of the tooth, if displaced and splinting to secure in place. These injuries require immediate referral to a dentist within 24 hours for a complete evaluation, treatment, and long-term follow-up/care.
- *Alveolar fracture*: The fracture involves the portion of the jawbone that carries the teeth. They are often combined with a luxation injury of the tooth. Alveolar fractures may cause malocclusion when the patient tries to close their mouth. These fractures result from significant facial trauma and thus one must consider possible injuries to other facial bones. A computed topography scan of the facial bones may be considered when there is concern for other injuries besides those to the dentition.

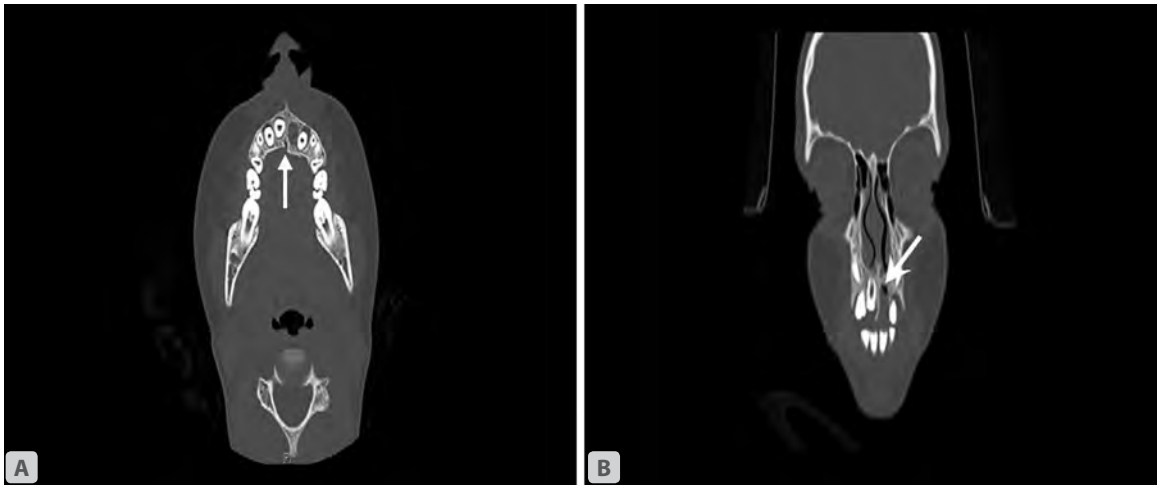
Figures 6A and **B** demonstrate a dental injury involving a tooth avulsion with an underlying alveolar fracture. Management of alveolar fractures is immediate referral to a dentist or oral surgeon following repositioning and splinting in the ED.

SUMMARY

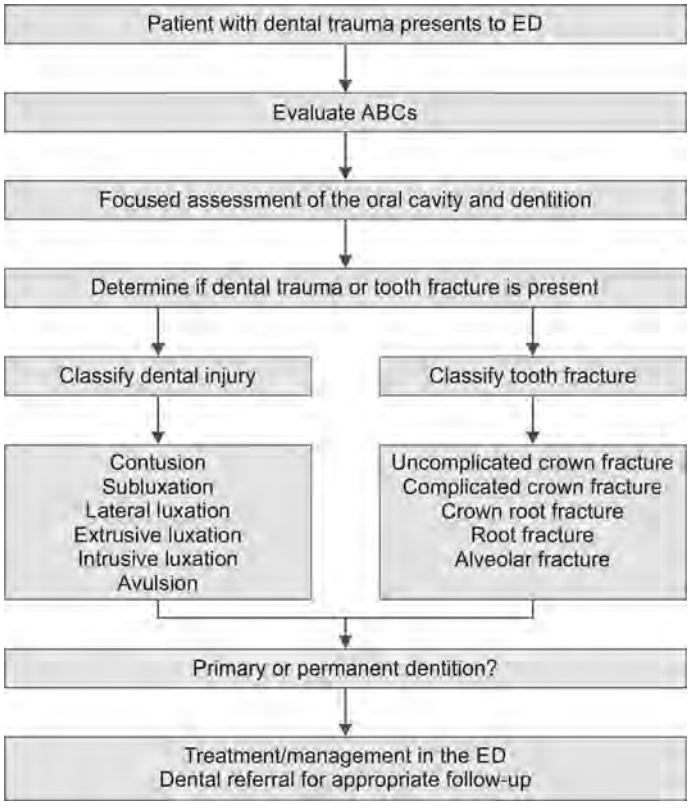
All healthcare providers need to be advocated for children in terms of good dental care. They can discuss proper dental hygiene as well as provide guidance to families about injury prevention and proper use of appropriate protective gear (i.e., mouth guards) during sports participation. However, when pediatric oral or dental injuries occur they can be very frightening to the patient and the parents. Having the knowledge to accurately diagnose and treat such injuries is essential to assure the best possible outcome for the patient (**Flowchart 1**).



FIGS. 5A TO D: Classification of tooth fractures. The solid black line represents the plane of the fracture.



FIGS. 6A AND B: Alveolar fracture. (A) 12 years of age female who fell while riding her bicycle and hit her face on the pavement. (A) Figure A shows the presence of an alveolar fracture (arrow). (B) Figure B shows the empty socket of an avulsed tooth (arrow) at the location of the alveolar fracture.



FLOWCHART 1: Approach to traumatic pediatric oral and dental injuries.

CHAPTER

Rashes in Newborn and Infant

Nadeem Uddin Qureshi, Irene Oriaifo, Rekha Gadiparthi, Mohammed Moiz Qureshi

INTRODUCTION

Skin disorders in children necessitate careful observation and thorough assessment of the child's history. During examination, consider the appearance of the rash and the site and pattern of its development. Skin rashes in children are a very common sign and often very difficult to diagnose, as more than one skin disease may be involved. **Table 1** illustrates various criteria involved in successfully diagnosing a rash. Skin rashes in children require careful history taking and assessment and examination of the skin (**Table 2**). With the urgent need for adjustment to the extrauterine environment that the newborn faces, many different adaptive changes occur across all organ systems, including the skin occurs. Many of skin lesion/rashes are benign, but some usually are a cause of considerable concern for parents.

This article reviews rashes in pediatrics, with a step-by-step approach to the classification and identification of the rash.

TABLE 1: Classification of skin lesion according to clinical presentation.

Vesiculobullous skin lesion	*Pustular skin lesion*	*Papular skin lesion*
• Impetigo • Scalded skin syndrome • Herpes simplex virus • Eczema herpeticum • Erythema multiforme • Stevens–Johnson syndrome and toxic epidermal necrolysis • Varicella (chickenpox) • Insect bites and stings (e.g., mosquitoes and bees), burn wounds (second degree)	• Infantile acne • Neonatal pustulosis • Secondarily infected vesiculobullous rash • Acute generalized exanthematous pustulosis	• Scabies urticaria/serum sickness • Keratosis pilaris • Papular acrodermatitis • Molluscum contagiosum • Plane warts • Streptococcal infection (scarlet fever), rubella (German measles) • Measles (rubella)

Skin lesions should be differentiated on the basis of various aspects whether red rashes are with epidermal breakage or not, whether they blanch with pressure or not (**Table 3**). Skin lesion can also be differentiated as hypopigmented or hyperpigmented lesions (**Table 4**).

TABLE 2: Pediatric patient assessment with skin lesions/skin rashes.

Initial assessment of the rash	Is there any fluid-filled vesicles? Is the rash raised (papular) or flat (macular)? Is the rash red? Is the rash scaly? Is the rash itchy? When did the rash start? Where did the rash start, and how did it spread?
History—what is the past medical and drug history?	Did the patient present with other symptoms (e.g., fever and headache)? Has the patient been exposed to new topical applications (e.g., soap and lotions)? Has the patient ingested any unfamiliar foods? Has the patient had close contact with someone else with the same symptoms? Has the patient traveled recently?
General examination	If a systemic illness is expected, refer to a medical practitioner for further management.
Examination of the skin	Examine the whole skin, even if the rash seems localized. Ensure that the patient is comfortable, with a close caregiver nearby. A rash resulting from a topical application will be present in a specific area (e.g., underarms and nappy area). A rash resulting from a systemic cause will be generalized and symmetrical. Systemic illness may also present in the mouth (e.g., syphilis, drug reactions like Stevens–Johnson syndrome).

TABLE 3: Differentiating red skin lesions/rashes.	
Red rashes with epidermal breakage	Eczematous rashes atopic dermatitis (eczema)
Red rashes with/without epidermal breakage	• Papulosquamous rashes (red and scaly) • Seborrheic dermatitis • Psoriasis • Tinea corporis • Pityriasis rosea
Red rashes with blanching	• Erythematous rashes (red and blanching) • Fever and exanthem • Erythema infectiosum • Roseola infantum • Kawasaki disease
Red rashes without blanching	• Purpuric rashes • Enterovirus infection • Septicemia • Leukemia • Henoch–Schönlein purpura • Idiopathic thrombocytopenic purpura (ITP) • Vasomotor straining • Child abuse • Trauma

TABLE 4: Differentiating skin lesions on the basis of pigmentation	
Blue/black rash	• Vascular malformations • Hemangiomas • Mongolian spots • Blue nevi • Melanoma
Hypopigmented lesions	• Pityriasis alba • Pityriasis versicolor • Vitiligo • Postinflammatory • Hypopigmentation
Hyperpigmented lesions	• Congenital pigmented nevi • Acquired pigmented nevi • Postinflammatory • Hyperpigmentation

TERMINOLOGY OF PRIMARY LESIONS

- Macules are nonpalpable lesions ≤1 cm, patches are nonpalpable lesions >1 cm.
- Papules are palpable lesions ≤5 mm, plaques are palpable lesions >5 mm.
- Nodules are palpable lesions >5 mm in both width and depth.
- Telangiectasias are dilated superficial blood vessels, vesicles are clear fluid-filled lesions ≤5 mm.
- Bullae are clear fluid-filled lesions >5 mm, pustules are pus-filled lesions ≤ 5mm.
- *Nevus flammeus*, *port-wine stains*, when presents in the area innervated by the ophthalmic branch of the facial nerve, is associated with Sturge–Weber syndrome, a neurocutaneous disorder with vascular malformations of the brain and intractable seizures.
- Multiple or clustered capillary hemangiomas may be associated with deep tissue and parenchymal involvement, and further evaluation is necessary.
- Dermal melanocytosis or *Mongolian spots* are dark blue–gray patches of melanocytes located in the dermis. Mongolian spots should not be confused with bruising.
- Seborrheic dermatitis can be recognized clinically by the presence of greasy scales and erythematous plaques.
- Diaper dermatitis is usually caused by irritation of the skin from prolonged contact with feces and urine. Sparing of the skin folds is diagnostic.
- Atopic dermatitis is usually caused by dry skin, can be recognized by distribution.
- *Candida* skin or oral infections may be secondary to excessive use of oral antibiotics. Treatment includes antifungal agents such as nystatin, ketoconazole, or clotrimazole as well as consideration of probiotics and hygiene.
- Multiple café-au-lait spots of neurofibromatosis increase the risk for auditory and central nervous system (CNS) tumors.
- Vascular malformations in a "beard distribution" on the face are associated with airway hemangiomas.

BENIGN NEONATAL SKIN LESIONS

- *Milia* are tiny white-yellow discrete pearly papules, 1–2 mm, frequently occurring on the face and scalp. They are superficial inclusion cysts of the pilosebaceous units that contain laminated keratinized material of sebaceous origin. They are firm and unlike pustules are not easily denuded by pressure. Cause is unknown. The lesions resolve spontaneously and no treatment is necessary.
- *Miliaria rubra,* prickly heat, is caused by sweat duct obstruction deeper in the epidermal or dermal layers. Erythematous small papules are noted over face, neck, and upper trunk. It is common in infants and children during hot, humid weather (**Fig. 1**).

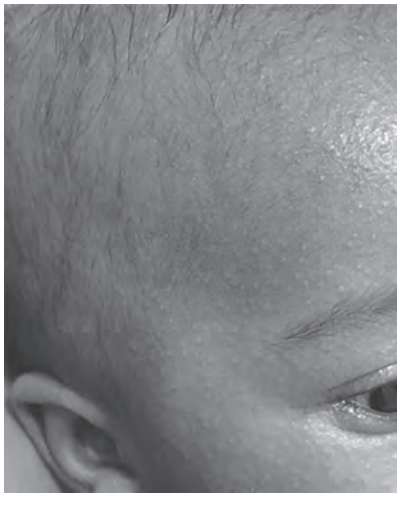

FIG. 1: Miliaria rubra. ***(For color version, see plate 30)***

- *Miliaria crystallina* is lesions caused by obstruction of eccrine sweat gland ducts located high in the outer layer of epidermis. Multiple thin-walled vesicles form over head, neck, and upper trunk.
- *Neonatal acne* is characterized by presence of open or closed comedones and papulopustules over cheeks and forehead. Thought to be due to placental transfer of maternal androgens, hyperactive neonatal adrenal glands or due to inflammatory response of skin to *Malassezia furfur* in severe cases. Treatment is not required as it is self-limiting, however, topical ketoconazole or hydrocortisone can be used in severe cases (**Fig. 2**).
- *Transient pustular melanosis* is a transient benign eruption seen in newborns at birth. It is more common in black infants. It presents as pustules which rupture to form fine scales and hyperpigmented macules. It may have all stages of lesions present anywhere on body but predominantly seen over forehead, neck, and lower back. A Wright stain of the contents will show a predominance of neutrophils, and absence of microorganisms **(Fig. 3)**.
- *Infantile acropustulosis* is a recurrent condition characterized by groups of pruritic vesiculopustular lesions on palms and soles. Lesions can occur on the dorsa of the feet, hand, fingers, ankles, and forearms. It can present from birth to 2 months of age. It resolves spontaneously by 2–3 years of age. Cause is unknown. Lesions start as tiny, red papules which evolve into vesicles and then pustules. Lesions appear similar to scabies. High-potency topical steroids and antihistamines may help relieve itching (**Fig. 4**).
- *Erythema toxicum* is a transient rash characterized by papules and pustules on an erythematous base. Usually, it is evident within first 48 hours of life and resolves spontaneously in 1–2 weeks without any sequelae. It can present as clumps of lesions in different areas or more diffuse, except palms and soles. Cause of this condition is unknown, thought to be secondary to an inflammatory reaction to microbial colonization at birth. Wright staining of the lesion contents will show collections of eosinophils with absence of infectious organisms (**Fig. 5**).
- *Seborrheic dermatitis* is common within the first 4 weeks of life. It is characterized by red scaling eruption predominantly over hair bearing areas and intertriginous areas such as scalp, eyebrows, eyelashes, perinasal, postauricular areas, neck, axilla, and groin. Scalp lesions consist of thick tenacious, salmon-colored scaly dermatitis, commonly known as "cradle cap" (**Fig. 6**). Pathogenesis is unknown although pityrosporum and *Candida* are

FIG. 2: Neonatal acne. ***(For color version, see plate 30)***

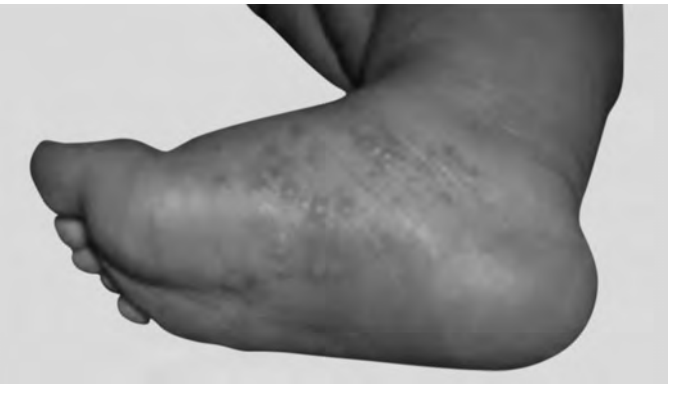

FIG. 4: Infantile acropustulosis. ***(For color version, see plate 30)***

FIG. 3: Transient pustular melanosis. ***(For color version, see plate 30)***

FIG. 5: Erythema toxicum. ***(For color version, see plate 30)***

implicated as causative agents. Seborrheic dermatitis is usually nonpruritic and responds well to low-potency topical corticosteroids and topical antifungal cream. Antiseborrheic shampoo and oatmeal baths often help.

- *Oral candidiasis* is also known as oral thrush or moniliasis. It is a superficial mucous membrane infection more common in premature infants. It can be seen in immunocompromised children or in those with underlying systemic diseases. *Candida albicans* is the most common cause. It is characterized by soft, creamy white plaques seen on tongue, palate, and buccal mucosa. Scrapping these lesions is difficult, and this differentiates from milk deposits. Scraping these lesions reveals erythematous base or punctate bleeding. Oral thrush can be asymptomatic but can cause pain, fussiness, and decreased feeding leading to dehydration and inadequate nutritional intake. Treatment includes topical application of nystatin over the affected sites. Recurrent infections can be treated with oral fluconazole for 10–14 days (**Fig. 7**).
- *Diaper dermatitis* encompasses all causes of skin irritation localized to the diaper area. Irritant dermatitis is the most common cause characterized by erythema, scaling, and excoriation sparing the intertriginous areas (**Fig. 8**). Failure to change diapers frequently and prolonged skin contact with urine and feces or from soaps and chemicals present in the diaper contribute to the rash. Absorbable disposable diapers have decreased the incidence of this problem. Secondary infection with *Candida* should be suspected when intertriginous areas are involved with the appearance of satellite lesions or diaper rash fails to respond to symptomatic treatment (**Fig. 9**). *Candida* skin or oral infections may also be secondary to excessive use of oral antibiotics. Treatment includes topical antifungal agents such as nystatin, ketoconazole, or clotrimazole as well as frequent change of diapers.
- *Drooling or spit-up rash* is common in newborn and infancy. Erythematous rash is seen on chin, cheeks, and neck creases. Usually it is caused due to prolonged contact with food or stomach acid that has been spit up. This rash comes and goes. It can be prevented by rinsing the face with water after all feedings or spit ups (**Fig. 10**).
- *Infantile scabies*: Scabies is highly contagious infestation caused by the mite *Acarus scabiei,* which burrows under the skin (**Figs. 11A** to **E**). The burrow which is produced by the female mite is pathognomonic sign for scabies. It consists of small scaly linear papule with pinpoint vesicles at the end. Infants are more likely to develop an intense and persistent nodular reaction to the mite. Lesions are characterized pruritic papules, pustules, and vesicles

FIG. 6: Seborrheic dermatitis. ***(For color version, see plate 30)***

FIG. 7: Oral candidiasis. ***(For color version, see plate 31)***

FIG. 8: Irritant diaper dermatitis. ***(For color version, see plate 31)***

FIG. 9: *Candida* diaper rash. ***(For color version, see plate 31)***

over the head, neck, trunk, palms, soles, lateral and instep portions of the feet, and lateral aspect of wrist. Eradication of scabies requires topical application of 5% permethrin cream to the patient, all household members, and close contacts. Thorough cleaning of all dirty clothing, towels, bedding, and car seat covers is essential. Two courses of treatment 1 week apart are necessary to kill the live mites and second to eliminate mites that had not hatched at the time of first application.

FIG. 10: Drool rash. ***(For color version, see plate 31)***

- *Infantile eczema* is also known as atopic dermatitis (**Fig. 12**). Usually, it begins between birth and 6 months of age and lasts about 2–3 years. Erythematous itchy papules and plaques that ooze and crust can occur over the cheeks, forehead, scalp, trunk, and extensor surfaces of the extremities. These patches are often symmetrical. Cause of atopic dermatitis remains elusive. Thought to be due to chronic elevation of IgE or aberrant cutaneous response to histamine and other mediators of inflammation. Atopic dermatitis can occur in families and in association with other atopic conditions such as asthma, allergic rhinitis, and food allergies. Children with eczema should be closely monitored for secondary bacterial and viral infections. Treatment includes adequate hydration and lubrication of skin, antipruritic agents to break itch-scratch cycle, and topical steroids to relieve itching and reduce inflammation.

FIGS. 11A TO E: Infantile scabies. ***(For color version, see plate 32)***

FIG. 12: Infantile eczema. ***(For color version, see plate 32)***

FIG. 13. Mongolian spot. ***(For color version, see plate 32)***

DISORDERS OF PIGMENTATION

- *Dermal melanosis, Mongolian spots* (**Fig. 13**), is single or multiple slate-gray or bluish-black irregular macules commonly seen over buttocks and lumbosacral area. It is more common in African- American and Asian infants. These are due to accumulation of melanocytes deep within dermis. Usually, self-resolve over years. Special variants of Mongolian spots, nevus of Ota (involving face and periocular area), and nevus of Ito (involving shoulder) may persist. Mongolian spots should not be confused with bruising.
- *Neurofibromatosis* is an autosomal dominant disorder characterized by multiple café-au-lait spots. Presence of six or more lesions measuring >5 mm in an infant, the presence of axillary freckling, optic glioma, iris hamartomas, or Lisch nodule is diagnostic (**Fig. 14**). These disorders are associated with a high incidence of optic gliomas, acoustic neuromas, and a variety of other CNS tumors. Neurofibromas are small, rubbery, and purplish lesions that usually appear during adolescence or pregnancy, but plexiform neurofibromas may be present at birth. The patient with neurofibromatosis who presents with headache or focal neurologic signs must be evaluated for an intracranial mass lesion. Other causes of café-au-lait spots include McCune–Albright syndrome, which is characterized by polyostotic fibrous dysplasia and multiple endocrine abnormalities.
- *Urticaria pigmentosa* can present at birth or first few months of life. It is characterized by multiple small reddish-brown papules or plaques over the trunk. These lesions are caused by vascular effects of histamine released from infiltrating mast cells in the cutaneous tissue. Development of a wheal and flare reaction after firm stroking of the lesion is a positive Darier sign (**Fig. 15**). Lesions are usually self-limited and resolve by adolescence. In infancy, these lesions can sometimes blister and widespread erosions can result in dehydration and sepsis. With temperature changes, metabolic insults, such as fever or viral illnesses, large numbers of degranulating lesions can produce flushing and systemic symptoms of histamine release. These patients should be counseled to avoid certain medications and iodinated contrast media.

FIG. 14: Neurofibromatosis with axillary freckling (Crowe sign). ***(For color version, see plate 33)***

FIG. 15: Darier sign for urticaria pigmentosa. ***(For color version, see plate 33)***

- *Incontinentia pigmenti* is an X-linked dominant disorder occurring in females and is usually present at birth (**Fig. 16**). It is a neurocutaneous syndrome characterized by four overlapping phases of skin presentation. The first stage usually within first 2 weeks of life manifested by inflammatory vesicles or bullae. The second stage presents usually before 6 months of age as the blisters evolve into

FIG. 16: Incontinentia pigmenti. ***(For color version, see plate 33)***

FIG. 17. Cutis marmorata. ***(For color version, see plate 33)***

warty plaques. As the plaques disappear, hyperpigmented whorls appear during stage 3. The final stage occurs later in adulthood with hypopigmentation and loss of hair and sweat glands. Approximately, 30% of patients will have seizures, CNS abnormalities, and mental retardation.

VASCULAR LESIONS OF INFANCY

- *Cutis marmorata* is a vascular phenomenon, characterized by reticulate reddish-blue mottling of the skin caused by transient vascular constriction and dilation (**Fig. 17**). It occurs symmetrically over trunk and extremities. It is a physiological response to cold temperature, and disappears on rewarming. When cutis marmorata is fixed, asymmetrical and does not disappear with rewarming, consider vascular malformation called cutis marmorata telangiectatica congenita.
- *Harlequin color change* is a benign transient color change, seen in approximately 10% of newborns (**Fig. 18**). Usually, it presents as well-demarcated color change with dependent half displaying erythema and the other half appears pale. It is thought to be due to temporary imbalance in the cutaneous blood vessel tone secondary to autonomic nervous system immaturity. It resolves spontaneously.
- *Vascular malformations* are common skin presentations at birth or in the first few months of life. They can be secondary to abnormalities of the capillary, venous, arterial, or lymphatic systems. Most are benign and self-limited, but a few may herald serious systemic consequences. The *salmon patch (nevus simplex or stork bite)* is a common capillary malformation may represent persistent fetal vessels, usually located on the forehead, upper eyelids, glabella, and posterior neck, and is present at birth. They become more apparent when baby cries or strains and usually resolve within 1–2 years, but if present on the back of the neck may persist for life.
- *Nevus flammeus*, *port-wine stains*, is persistent vascular malformations of deep dermal capillaries and postcapillary venules (**Fig. 19**). Mature capillaries infiltrate the deeper dermis and subcutaneous tissues causing purple red macules in newborn. They neither enlarge nor regress but become more hyperpigmented as the child grows.

FIG. 18: Harlequin color change. ***(For color version, see plate 33)***

FIG. 19: Nevus flammeus. ***(For color version, see plate 33)***

Most common over head and neck, when present in the distribution of ophthalmic branch of trigeminal nerve can be associated with Sturge–Weber syndrome, a neurocutaneous disorder with vascular malformations of the brain and intractable seizures.

FIG. 20: Strawberry hemangioma. ***(For color version, see plate 34)***

- *Simple capillary hemangiomas are* the most common vascular tumors in infancy. These are caused by proliferation of vascular endothelium and appear as small red telangiectasias that rapidly proliferate and protrude above skin to become the characteristic.
- *Strawberry hemangiomas* (**Fig. 20**) occur over the first year, then become stable, and involute by 5–9 years. Multiple or clustered capillary hemangiomas may be associated with deep tissue and parenchymal involvement, and further evaluation is necessary. Hemangiomas over the lower face, in an infant presenting with stridor or upper airway involvement suggest airway hemangiomas. Most of them will eventually involute; however, large lesions causing functional impairment may require steroids, pulsed-dye laser, or surgery. There are a number of hereditary and congenital conditions with vascular, hyper- and hypopigmented lesions, bulla, or ichthyotic scales that are beyond the scope of this text.

SUMMARY

Rashes are a very common occurrence in children, and often more than one skin condition may be present at the same time. The evaluation of skin conditions requires a systematic and holistic approach. A careful history is important to determine the origin of the rash. Referral is necessary if there are other systemic signs and symptoms.

175
CHAPTER

Pediatric Antibiotic Prophylaxis

Veena Raghunathan, Devendra Richhariya

INTRODUCTION

In acute pediatric emergencies, the focus is mainly on identifying the problem and instituting rapid measures and conducting procedures to counter the same. While this approach is essential for the acutely sick child, an important aspect of holistic care is also prevention of infections or its complications in such children. This is relevant in scenarios such as trauma akin to a perioperative setting where antimicrobial prophylaxis is required. While administration of an antibiotic prior to planned surgery is usually protocolized and scheduled, it is not so in the emergency room (ER) where the emergency physician is responsible for initiating appropriate antibiotic prophylaxis. Antibiotics are mainly prescribed for two purposes in ER—firstly, for treatment for presumed infection and secondly for prophylaxis which is the focus of this chapter. *Common indications for antibiotic prophylaxis* include wound/trauma, animal bites, surgical prophylaxis, endocarditis prophylaxis, and others (exposure to meningococcal disease, needle stick injuries, etc.).

TRAUMATIC WOUNDS

In trauma, when the skin barrier is compromised, microorganisms can enter to cause infection. Wounds caused by trauma can be classified into low or high risk based on chance of infection.

Pathophysiology

Trauma leads to damage of local tissue. This causes cytokine release leading to swelling and erythema at the site of wound. Cytokines direct neutrophils and neutrophils to clear bacteria at the wound. Fibroblasts signal new tissue regeneration, thereby healing process occurs. Clearance of bacteria by above processes depends on mechanism of injury (e.g., puncture wound vs. laceration) and type of object causing injury. Prevention of wound infection requires thorough wound cleansing and appropriate closure, however inspite of this wound infection can occur. Antibiotic prescription is required for the wound where the bacterial load is difficult to clear spontaneously. For example, deep wounds, contaminated object causing injury, open fractures, immunocompromised host, and injury in relatively hypoperfused area. Antibiotic prophylaxis is essential to prevent development of a wound infection in such circumstances, similar to a presurgical prophylaxis. It should be administered as quickly as possible in the ER. Prophylaxis can be achieved with a single dose; whereas treatment for an established infected wound (not complicated by osteomyelitis or retained foreign body) requires 7–10-day administration. For contaminated wounds, duration of 3 days would usually suffice as prophylaxis.

Classification

Traumatic wounds are classified into low-risk and high-risk wounds depending on injury and host factors. A low-risk wound is a clean and minor wound in a healthy host. Such wounds do not benefit from antibiotic prophylaxis. A high-risk wound has one or more of the following features: deep puncture/penetrating wounds, retained foreign body/contaminated wounds, open fractures, crush injuries, bites, and immunocompromised host (on steroids, chemotherapy, diabetes, renal disease, etc.); and wounds involving tendons, joints, and cartilage (relatively avascular areas). It is difficult to predict which high-risk wounds will progress to develop infection; however, generally experts opine that antibiotic prophylaxis to such wounds may be beneficial. A high-risk wound requires antibiotic prophylaxis for at least 3–5 days. The anatomic site of the wound may be related to the risk of infection. The presence of devitalized tissue or collected blood acts as a bacterial growth medium encouraging establishment and spread of infection. Wounds on the foot get infected more than those on the head. Regional blood flow variation and degree of contamination (from exogenous/endogenous sources) probably explain this variability.

General Principles of Traumatic Wound Management

Goal for management of a wound is to achieve skin healing and functioning, similar to pretrauma state. High-pressure irrigation with tap water/saline helps to decrease bacterial load and should be done in all wounds. Both timing and technique of closure also matter. Delayed closure up to 18 hours after injury of clean wounds does not appear to be

associated with increased infection rate. Primary closure is not advisable for high-risk wounds which initially need open wound management along with antibiotic prophylaxis. The risk of wound infection generally decreases after 4 days of above management. Hence after initial debridement, clean dressing is done for the wound, and decision for closure can be taken by day 3–5 depending on wound condition.

Role of Topical Antibiotics

The utility of topical antibiotics in ER is not well studied. Topical antibiotics like mupirocin, neomycin can eradicate colonization and even independently treat infections in minor wounds. Use of topical antibiotics in daily dressing change of wounds has been suggested by some studies whereas other studies have not shown any significant reduction in infection rates with the same.

Tetanus Immunization

Tetanus immunization status should be reviewed in all cases of traumatic injuries. If >5 years have lapsed since the last tetanus booster in case of high-risk wounds or >10-year lapse in case of low-risk wounds, tetanus prophylaxis is needed. DTaP (diphtheria, tetanus, and pertussis vaccine) is recommended in children 6 weeks–6 years, Td can be given in children 7–10 years, and TT can be given in children >10 years.

Open Fractures

Open fracture is an emergency and carries a risk of osteomyelitis. Any skin break that can allow bacteria up to the bone is considered as an open fracture. Bone could be jutting out from the wound, which is an obvious case; however, more subtle presentations can occur, e.g., wound proximal to a fracture. A Cochrane database review of seven studies concluded that antibiotics decrease incidence of early infections in open fractures of the limbs. Prophylactic intravenous antibiotic should be administered as soon as possible in the ER, definitely within 6 hours. Cultures at treatment initiation are not very useful. Risk of infection depends on severity of fracture and extent of accompanying soft tissue damage. Open fractures are stratified as follows—type 1: <1 cm laceration, no extensive soft tissue damage; type 2: >1 cm laceration, no extensive soft tissue damage; and type 3: extensive accompanying soft tissue damage (with >10 cm soft tissue injury/requiring vascular repair/open >8 hours/amputations). The Eastern Association for the Surgery of Trauma guidelines recommend that a first-generation cephalosporin, e.g., cefazolin + methicillin-resistant *Staphylococcus aureus* (MRSA) coverage clindamycin/vancomycin/linezolid should be given for type 1 and 2 fractures and continued for 72 hours or till 24 hours after wound closure. For type 3 fracture, additional gram-negative coverage (aminoglycoside) is recommended. High-dose penicillin should be added to wounds with fecal/possible clostridial contamination.

Plantar Puncture Wounds

Plantar puncture wounds deserve a special mention, as they have potential for development of delayed osteomyelitis, which can occur sometimes months following injury. A common form of injury is a child stepping on a nail. Cellulitis can develop late and further evolution to osteomyelitis, osteochondritis, or septic arthritis may occur in few cases. Incrimination bacteria in postplantar puncture osteomyelitis are usually *Pseudomonas* and *Staphylococcus aureus*/*Streptococcus* species. The role of prophylactic antibiotics in plantar puncture injuries is controversial, as it may not help to prevent infection occurring later. Hence, prophylactic prescription is generally restricted to wounds distal to metatarsophalangeal joints or having higher infection risk (diabetic/immunocompromised patient, retained foreign body, etc). Antibiotics such as ceftazidime/cefepime or ciprofloxacin are good choices in such cases. Such wounds should be reassessed after 2–3 days of injury to assess for cellulitis. Radiographs are useful to identify any radio-opaque foreign bodies in addition to the fractures in the foot.

Penetrating Abdominal Wounds

These carry a high risk of infection due to possibility of spillage of intestinal contents into the peritoneum. Such patients are benefitted from antibiotic prophylaxis prior to surgery. Broad-spectrum antibiotic therapy (active against aerobic and anaerobic organisms) should be used. A single beta-lactam antibiotic is sufficient and as effective as combined therapy with aminoglycoside. Prophylaxis for 24 hours is sufficient; it helps to lower rates of postoperative peritonitis.

To summarize, the main aspects of care of a traumatic wound include the following:

- Thorough cleaning and irritation
- Examination for retained foreign bodies
- Antibiotic prophylaxis for high-risk wounds
- Radiographs to evaluate fractures/foreign bodies
- Consider/defer wound closure as appropriate
- Tetanus immunization status
- Reexamination of wound within 24–48 hours to assess for healing/development of infections/wound closure

BITE WOUNDS

Bite wounds are a common reason for ER visit. Bites are commonly due to dogs, cats, or occasionally other animals. Probability of infection depends on location, type of bite wound, type of biting animal, and underlying medical condition of the patient. A dog's bite is potentially dangerous and can lead to bad lacerations, crush injuries, fractures, skull puncture, or penetration of body cavities. Cats' bite generally leads to puncture wounds, due to their pointed sharp teeth. Infants and toddlers are prone to bites in head and neck area. Older children, especially >15 years, in contrast usually have bite injuries in the extremities. Hand bite injuries are highly susceptible to infection. Clenched fist injuries are usually forceful and can cause fractures, joint, and tendon damage. It can lead to cellulitis and deep-seated infections sometimes requiring hand amputation. All bite wounds must be carefully examined as they but can extend into deeper tissue (bone, blood vessels, tendons, etc.). Human bites also pose some risk for infection. Usually, infection related to animal or human bites develops within 12–24 hours after the injury. Initial cultures from wound site do not predict which ones will subsequently develop infection.

Management of Bite Wounds

All bite wounds should be well irrigated with large amounts of pressurized saline. This is vital for reducing bacterial load.

Concentrated povidone-iodine, hydrogen peroxide, and alcohol should not be used as these may cause further damage to tissues. Foreign matter should be removed from the wound along with debridement of devitalized tissue. Role of primary wound closure and prophylactic antibiotics in bite wounds is not standardized and controversial. Decision regarding them should be individualized after weighing all pros and cons and discussion with the caregiver.

Selected wounds in areas with rich blood supply, which carry lower infection risk and where cosmetic result matters, e.g., head and face wounds, primary closure may be advocated after thorough cleaning. Puncture wounds or open large lacerations should not be closed by primary suturing. Contaminated wounds will have increased infection risk if closed early. On the other hand, exposed bone/tendons can undergo dessication in a wound left open. Scarring is more when wound heals by secondary intention. Delayed primary closure is another option. In this, wound is initially cleaned and debrided and then reassessed 3–5 days later. If wound is clean, it can be sutured. The cosmetic result of delayed primary closure is better than healing by secondary intention.

Role of Antibiotic Prophylaxis

It is recommended for high-risk wounds including dog and cat bite, puncture wound, bites involving hand, foot, face, joint, tendon, ligament and for immunocompromised, diabetics, and asplenic individuals (**Table 1**). A Cochrane review supports antibiotic prophylaxis for hand bite wounds. For lower risk wounds, role of prophylaxis is unclear. Bite wounds tend to be polymicrobial, unlike traumatic wounds. They contain bacteria from oral flora of the biting animal. Anaerobes such as fusobacterium and bacteroides are usually present in addition to *Streptococcus* species. Appropriate choice of antibiotic is amoxicillin-clavulanate or penicillin + cephalexin. If penicillin allergy is present, moxifloxacin/ciprofloxacin + clindamycin/metronidazole may be used. Azithromycin is also an alternative in such a circumstance; however, it is less effective against anaerobes. Coverage for MRSA is not required in bite wounds, as it is an unlikely colonizer of oral cavity of animals/humans. Rodents can cause rat bite fever (due to *Streptobacillus moniliformis* or *Spirillum minus*) which is characterized by fever and rash and needs treatment with penicillin. However, prophylactic antibiotics are probably unwarranted for as rat bites have low propensity for infection. Macaque monkey bite can lead to potentially lethal herpesvirus simiae infection. Prevention against this is best achieved by aggressive bite wound irrigation. Acyclovir prophylaxis may be considered.

There is weak evidence for routine prophylactic antibiotic use in human bite wounds. Human bites pose risk of spread of hepatitis B, HIV, and hepatitis C. Whenever suspected, prophylaxis against these viral diseases should also be additionally administered.

Persons bitten by potentially rabid animals or unknown animals who cannot be tested/observed for 10 days should be advised rabies immune globulin (RIG) and rabies vaccination series according to the National Center for Disease Control (NCDC) guidelines. Intradermal regimen for vaccine involves administration of 0.1 mL each at two different sites (deltoid areas) on days 0, 3, 7, and 28. Intramuscular regimen is the administration of 5 injections (1 mL each) on days 0, 3, 7, 14, and 28 in deltoid or anterolateral aspects of thigh (in infants and toddlers).

TABLE 1: Antimicrobial therapy in high-risk traumatic wound

Traumatic conditions	*Antimicrobial therapy*
Human bites; dog or cat bites (where indicated)	• Amoxicillin/clavulanate 40 mg/kg/d PO divided BID (maximum dose 875 mg PO BID) • In penicillin, allergic patients—clindamycin 30 mg/kg/d PO divided q6 or q8 h plus trimethoprim/sulfamethoxazole 5 mg/kg PO BID
Open fractures	• First-generation cephalosporin MRSA therapy • Additional therapy for type III open fractures is gentamicin or amikacin
Plantar foot wounds distal to metatarsophalangeal joint and through shoe sole	Ciprofloxacin, ceftazidime, or cefepime
All other high-risk wounds	First-generation cephalosporin or dicloxacillin MRSA therapy

Methicillin-resistant Staphylococcus aureus (MRSA) therapy can be achieved with either oral clindamycin 30 mg/kg/day PO divided q6 or q8h or trimethoprim-sulfamethoxazole 5 mg/kg PO BID, or intravenous clindamycin, vancomycin, or linezolid depending on local resistance patterns. Alternatives for MRSA coverage in children 8 years include doxycycline and tetracycline. Anti-MRSA therapy should be individualized based on previous history of MRSA infections, colonization, and/or household contacts with MRSA

ENDOCARDITIS PROPHYLAXIS

The American Heart Association (AHA) recommends preprocedure antibiotic prophylaxis to the high-risk cardiac lesions. High risk includes prosthetic valves, cyanotic congenital heart lesions (not repaired), transplants with valvulopathy, and previous history of endocarditis. The procedures for which antibiotic prophylaxis should be given include dental work, procedures involving infected skin, subcutaneous, and musculoskeletal tissue (e.g., abscess drainage). Antibiotic such as antistaphylococcal penicillin or cephalosporin should be used. If community acquired (CA)-MRSA is present in the community, vancomycin/clindamycin depending on local susceptibility patterns should be used. No prophylaxis is required for clean noncontaminated wounds.

For low-risk procedures, antibiotic prophylaxis is not required. Foley catheter insertion, endotracheal intubation, joint aspiration, arthroscopy, local anesthetic administration, etc., do not require prophylaxis.

Risk of infection from an ER procedure for patients with orthopedic implants is low. Only high-risk category, i.e., in first 2 years after joint replacement, previous implant infection, and patients on immunosuppression, prophylaxis is indicated for procedures such as abscess drainage.

CHEST TUBE INSERTION

Chest tubes insertion is performed in ER in trauma for hemo-/pneumothorax. This may become a port of infection occasionally, especially if placed in an emergency as compared to placement in a sterile field like operating room by a scrub-bed surgeon. However, evidence for role of prophylactic antibiotics is conflicting, and it does not appear to decrease

incidence of infection. Hence, at present, prophylactic antibiotic use cannot be recommended in such circumstances.

MENINGOCOCCAL EXPOSURE

Meningococcal disease is a potentially fatal condition which spreads rapidly by droplet route. It should be considered strongly in patients with clinical symptoms (fever and purpuric vasculitis rash) along with presence of gram-negative diplococci/positive culture from a usually sterile site [cerebrospinal fluid (CSF) and synovial fluid). As close contacts of an index case are highly likely to be colonized (nasopharyngeal) and develop disease, postexposure prophylaxis is extremely important, despite previous vaccination status. This is because serogroup B disease is not prevented by vaccination. It should be initiated at the earliest, delay of >14 days is considered nonbeneficial. In children, first-line antibiotic for prophylaxis includes rifampin/ceftriaxone. Ciprofloxacin is an alternative, used in adults. Droplet precautions can be stopped after 24 hours of antibiotic initiation. High-risk contacts which need antibiotic prophylaxis include childcare/preschool contact anytime during 1 week preillness, close social contact, sharing eating utensils, same household contact, flight passenger seated next to index case >8 hours, and unprotected contact during endotracheal intubation. Low-risk contacts (casual contact, no direct exposure, healthcare personnel with no direct exposure to patient secretions, etc.), do not require prophylaxis (**Box 1**). **Table 2** summarizes antimicrobial therapy for close contacts and persons with meningococcal disease.

BOX 1: Risk categories and recommendations of chemoprophylaxis in meningococcal disease.

High risk: Chemoprophylaxis recommended (close contacts)

- Household contact, especially children younger than 2 years
- Child care or preschool contact at any time during 7 days before onset of illness
- Direct exposure to index patient's secretions through kissing or through sharing toothbrushes or eating utensils, markers of close social contact, at any time during 7 days before onset of illness
- Mouth-to-mouth resuscitation, unprotected contact during endotracheal intubation at any time 7 days before onset of illness
- Frequently slept in same dwelling as index patient during 7 days before onset of illness
- Passengers seated directly next to the index case during airline flights lasting >8 hours

Low risk: Chemoprophylaxis not recommended

- *Casual contact*: No history of direct exposure to index patient's oral secretions (e.g., school or work)
- *Indirect contact*: Only contact is with a high-risk contact, no direct contact with the index patient
- Healthcare personnel without direct exposure to patient's oral secretions

In outbreak or cluster

Chemoprophylaxis for people other than people at high risk should be administered only after consultation with local public health authorities

PERTUSSIS EXPOSURES

Pertussis is one of the most highly communicable diseases, with attack rates of 100% recorded in susceptible individuals. It is also known as "whooping cough," because of the pronounced inhalational whoop that is classically heard after a series of coughs. Infants and young children have the highest rates of acquisition, and young infants experience the most serious manifestations of illness. Although better vaccines and vaccine strategies are being pursued, physicians should remain vigilant to recognize, diagnose, and treat pertussis cases and their contacts. 2013 Advisory Committee on Immunization Practices (ACIP) recommends three doses of acellular pertussis vaccine at 2, 4, and 6 months of age, with a booster at 15–18 months, and a second booster at 4–6 years. An additional booster is recommended at 11–12 years. For adults, a one-time booster of acellular pertussis is recommended, but some experts argue that this should be repeated every 10 years, as protection is not lifelong. In October 2012, the ACIP recommended that all pregnant women receive one booster dose of tetanus/diphtheria/acellular pertussis (Tdap) for every pregnancy at 27–36 weeks' gestation regardless of previous Tdap history to maximize maternal antibody response and passive antibody transfer to the infant.

Pathophysiology

Pertussis disease is caused by *Bordetella pertussis* (95%) and less commonly by *Bordetella parapertussis*. A related organism, *Bordetella bronchiseptica,* is normally enzootic in animals and has been isolated from humans with cough-like illnesses. *Bordetella* is fimbriated gram-negative rod that expresses virulence factors, including filamentous hemagglutinin, periactin, and pertussis toxin, which cause a lymphocytic leukocytosis in unimmunized individuals. Transmission is presumably via droplets from a coughing patient that reach the upper respiratory tract of susceptible individuals.

Classification

Cases of pertussis fall into two categories—(1) Classic illness and (2) Mild illness. Pertussis that occurs as a primary infection in a previously unimmunized child is referred to as classic illness, whereas mild illness can occur in a previously vaccinated or unvaccinated host. Classic illness presents in three stages—(1) An initial stage with rhinorrhea, tearing, and mild cough; (2) A paroxysmal stage where cough increases

TABLE 2: Antimicrobial regimens for close contacts and persons with meningococcal disease.

Antimicrobials	*Age*	*Does*	*Duration*
Rifampin	<1 month	5 mg/kg PO q12h	2 days
	>1 month	10 mg/kg PO q12h (maximum 600 mg)	
Ceftriaxone	<15 years	125 mg IM	Single dose
	>15 years	250 mg IM	
Ciprofloxacin		20 mg/kg PO (maximum 500 mg)	Single dose

Rifampin is not recommended for use in pregnant women.

in frequency and number and when paroxysms of cough are interspersed with a significant inspiratory whoop that may be associated with post-tussive vomiting; and (3) A convalescent stage when coughing decreases in frequency and severity. Mild illness typically manifests as an indolent infection, and usually comes to medical attention because of chronic cough lasting 2 or more weeks in duration. Testing and presumptive treatment should be considered in infants with evidence of severe pertussis (e.g., white blood cell count >30,000/mL, tachycardia, and hyperventilation) and in those with a history of recent exposure to an index case. In adults, most have either been previously vaccinated and/or exposed to pertussis illness and thus may have some degree of immunity that can alter the initial clinical presentation to include only serial coughing, air hunger, and headaches.

Diagnosis

Laboratory testing to confirm pertussis disease includes culture on appropriate media, direct fluorescent antibody testing (DFA), or polymerase chain reaction (PCR). Nasopharyngeal specimens (swab, washing, or aspiration) are best for testing and are more likely to isolate the organism within the first 3 weeks of cough. DFA testing of secretions may be helpful in patients with symptoms for >3 weeks who may have negative culture or PCR testing, but these tests may cross-react with other antibodies to yield false-positive results or false-negative results in infants with pertussis disease due to limited antibody production.

Treatment

Treatment of those exposed to cases of pertussis includes a two-pronged approach of vaccination and chemoprophylaxis. Pertussis exposures should be evaluated for pertussis immunization status. Those not immunized or under-immunized should be vaccinated according to the recommended schedule. Special efforts should be made to give chemoprophylaxis to those at high risk for severe pertussis, including infants, pregnant women, and those in regular contact with these groups. First-line medications used for chemoprophylaxis include macrolide antibiotics—azithromycin, clarithromycin, and erythromycin. Azithromycin should be given to infants <6 months because of increased risk of hypertrophic pyloric stenosis associated with erythromycin use in this age-group. Alternative treatment can be given with trimethoprim-sulfamethoxazole in case of drug allergy or resistance to macrolides. A summary of chemoprophylactic regimens is outlined in **Table 3**. Side effects of macrolide antibiotics are typically related to the gastrointestinal system, including diarrhea, nausea, abdominal pain, and loose stool. Disposition all persons exposed to pertussis should be observed for 21 days after exposure to ensure they do not display signs or symptoms of pertussis. Those with symptoms or with confirmed pertussis should be excluded from day care, school, work, and other public settings until they have completed at least 5 days of antimicrobial therapy.

TABLE 3: Recommended antimicrobial therapy and postexposure prophylaxis for pertussis in infants, children, adolescents, and adults.

Azithromycin	<1 month	10 mg/kg/day as a single dose for 5 days
	1–5 month	10 mg/kg/day as a single dose for 5 days
	>6 month and children	10 mg/kg as a single dose on day 1 (maximum 500 mg), then 5 mg/kg as a single dose on days 2 through 5 (maximum 250 mg/day)
	Adolescents and adults	500 mg as a single dose on day 1, then 250 mg as a single dose on days 2 through 5
Erythromycin	<1 month	Only give if azithromycin is not available because of risk of pyloric stenosis: 40 mg/kg/day divided q6 h for 14 days
	1–5 month	40 mg/kg/day divided q6h for 14 days
	>6 month and children	40 mg/kg/day divided q6 h for 7–14 days (maximum 1–2 g/day)
	Adolescents and adults	2 g/day divided q6 h for 7–14 days
Clarithromycin	<1 month	Not recommended
	1–5 month	15 mg/kg/day divided BID for 7 days
	>6 month and children	15 mg/kg/day divided BID for 7 days (maximum 1 g/day)
	Adolescents and adults	1 g/day divided BID for 7 days
TMP-SMP	<1 month	Contraindicated in <2 months of age
	1–5 month	*>2 months of age*: TMP, 8 mg/kg/day; SMX, 40 mg/kg/day divided BID for 14 days
	>6 month and children	TMP, 8 mg/kg/day; SMX, 40 mg/kg/day divided BID for 14 days
	Adolescents and adults	TMP, 320 mg/day; SMX, 1,600 mg/day divided BID for 14 days

Complications

Complications of pertussis include pneumonia, apnea, seizures, encephalopathy, and cardiorespiratory failure. The death rate in young children who acquire disease is 1–2%. Pertussis can present with nonspecific signs of rhinitis and mild cough that fail to improve after 7–14 days. Other clinical signs include cough with or without paroxysms, whoop, and vomiting. Diagnosis relies on clinical suspicion, but disease manifestations can be elusive. Prompt diagnosis and antibiotic treatment limits spread to contacts and to the community. Transmission can be blocked if vaccine coverage rates are high and booster vaccines are given, but new vaccines with higher efficacy and additional control strategies are warranted. Acquisition of pertussis disease confers immunity, but similar to vaccine-induced immunity, this wanes over the time.

INFLUENZA EXPOSURES

Influenza viruses are RNA viruses and classified into three types—A, B, and C. Type A is the most common and is further subdivided based on surface antigens hemagglutinin and neuraminidase. Type B displays less genetic diversity compared with type A, and type C causes only mild disease in children. Influenza is spread by the respiratory route when large, virus-laden droplets are coughed or sneezed into the environment, or other contact with respiratory secretions. Transmission requires close contact, as large droplets can travel approximately 1 m and rapidly fall from the air after being expelled. The incubation period is from 1 to 4 days, with most cases occurring on day 2 postexposure. Although adults are deemed infectious from the day before symptom onset for the next 6–11 days, children transmit virus from several days before symptoms develop until up to 10 days after onset. Host immunity depends on underlying immune status and previous exposure to either naturally circulating virus or vaccine strains. As a result of limited host immunity, influenza disproportionately affects children <2 years, with the highest rates of hospitalization in children <6 months.

Diagnosis

Influenza is diagnosed using viral culture, PCR, or immunofluorescent or rapid diagnostic testing and is easiest to detect during the first 3 days of clinical symptoms when viral shedding is highest. Nasopharyngeal testing, using a swab, aspirate, or washing, is preferred. Influenza virus can be grown in culture within 2–6 days, a period after which antiviral medications may not provide maximal benefit reverse-transcriptase PCR (RT-PCR) testing is available in some settings, with more rapid results than culture while maintaining high sensitivity and specificity. Direct fluorescent and immunofluorescent testing can yield results in 3–6 hours, and can be used as a basis for treatment and prophylaxis of high-risk contacts. Both viral culture and RT-PCR methods are considered the gold standard for influenza testing.

A common influenza test used is rapid influenza diagnostic testing (RIDT). RIDTs are based on immunochromatographic lateral flow and membrane-based assays that are advantageous in their quick turnaround time and ease of use. Disadvantages include high false-negative rates during high influenza activity, high false-positive rates during low influenza activity, and some tests do not distinguish between influenza A and B or pandemic strains.

Chemoprophylaxis following influenza exposures should be considered in the following scenarios involving high-risk children; protection of unimmunized high-risk children or children who were immunized <2 weeks before influenza circulation, because adequate immune response develops 2 weeks after immunization; protection of children at increased risk of severe infection or complications, such as high-risk children for whom the vaccine is contraindicated; protection of unimmunized close contacts of high-risk children; protection of immunocompromised children who may not respond to vaccine; control of influenza outbreaks in a closed setting, such as an institution with unimmunized high-risk children; and protection of immunized high-risk children if the vaccine strain poorly matches circulating influenza strains.

TABLE 4: Recommended oseltamivir dose for influenza in pediatric age and adults.

Drug	*Age*	*Dose*
Oseltamivir	Neonate	1 mg/kg/dose BID (prophylactic dose—single dose)
	Infants (8–11 months)	3 mg/kg/dose BID for 5 days (prophylactic dose—single dose)
	≥12 months	• *<15 kg*: 30 mg BID • *15–23 kg*: 45 mg BID • 23–40 kg: 60 mg BID • *>40 kg*: 75 mg BID • Prophylactic dose—single dose
	Adults	75 mg BID (prophylactic dose—single dose)

Treatment

Drugs available in the United States for treatment or chemoprophylaxis of influenza exposures include the neuraminidase inhibitors oseltamivir and zanamivir, and the adamantanes amantadine and rimantadine. Neuraminidase inhibitors are active against both A and B strains, whereas the adamantanes are active only against A strains. Because of resistance of circulating A strains against the adamantanes, use of this class of drugs has not been recommended for use since 2005. Dosing of the neuraminidase inhibitors varies by age and weight and is summarized in **Table 4**. The duration of antiviral prophylaxis is for 7 days after exposure.

Optimal timing of initiation of antiviral therapy is as soon as possible after exposure has occurred for prophylaxis and within 48 hours of symptom onset for treatment. For those with compromised renal function, oseltamivir, amantadine, and rimantadine dosing should be adjusted. Only zanamivir does not require adjustment in renal insufficiency.

Complication

Potential complications of influenza illness include respiratory failure requiring mechanical ventilation and bacterial superinfection. Rare complications include encephalopathy, myocarditis, myositis, pericarditis, Reye syndrome, and transverse myelitis. Potential complications of antiviral medications used for treatment and prophylaxis include nausea and vomiting associated with oseltamivir and bronchospasm associated with zanamivir. Because of potential exacerbation of underlying conditions, such as asthma, zanamivir is contraindicated in people with underlying respiratory disease. Disposition education of patients and their caregivers regarding the need for prophylaxis and compliance with the prophylactic regimen is essential. For those who are not at increased risk or who refuse prophylaxis, physicians should offer anticipatory guidance to return for care and treatment should symptoms develop.

SUMMARY

To conclude, antibiotic prescribing in the ER for prophylaxis has specific indications. Broad usage should be avoided in ER to decrease unnecessary antibiotic usage. Overprescribing antibiotics carries the risk of increasing antibiotic resistance and adverse infections such as *Clostridium difficile*. Majority of antibiotics prescribed in ER are usually continued without any change after admission for 48 hours or so. Hence appropriate prescribing practices are very important in the ER setting.

176 CHAPTER

Pediatric Gastrosurgical Emergencies

Meera Luthra, Apurva Arora

INTRODUCTION

This chapter covers common abdominal surgical emergencies in children that are often mistaken for benign self-limiting diseases. Most of the abdominal surgical emergencies in children present with pain abdomen, vomiting, distension, fever, and poor feeding. Due to the inherent difficulties involved in pediatric history taking and examination, the recognition of the urgency is often delayed. In 21.66% cases, cause of acute abdomen is congenital and acquired in 78.33%. A long list of pathologies presenting with broadly the same symptoms can confuse and/or delay the physician from ordering the ideal singular diagnostic investigation and making a timely diagnosis (**Table 1**). Morbidity and mortality in children vary by age and the condition.

TABLE 1: Nontraumatic cause of pediatric surgical abdomen.

Newborns: 0–1 months	• Duodenal Obstruction • NNEC • Intestinal malrotation • Volvulus • Anorectal malformation • Hirschsprung's disease
Infants and toddler: 1 month–2 years	• IHPS • Intussusception • Obstructed hernia • Foreign Body ingestion
Young children: 2–5 years	• Appendicitis • Meckel's causing • Intussusception • Foreign body ingestion • Intestinal obstruction? Band
Older children: 3 years and older	• Appendicitis • Cholecystitis • Pancreatitis • Abdominal cyst • Gonadal (ovarian/testicular torsion)

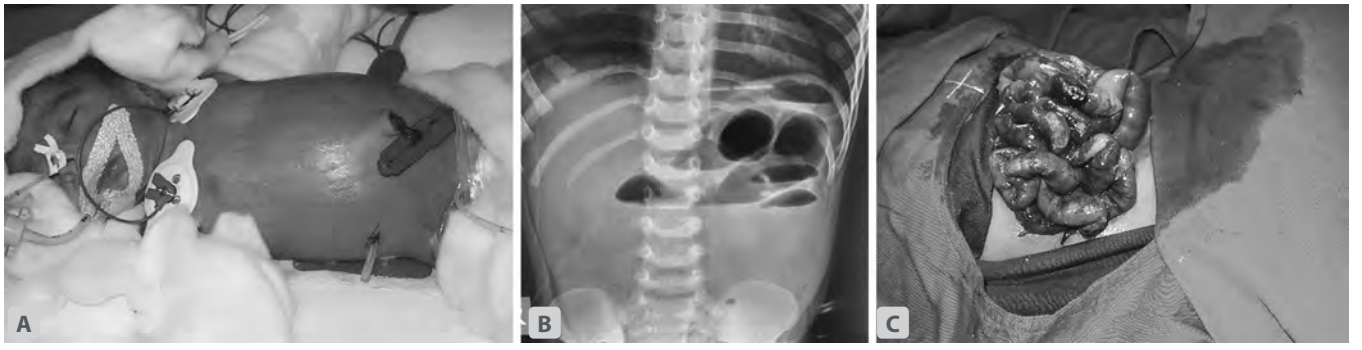
(IHPS: infantile hypertrophic pyloric stenosis; NNEC: neonatal necrotizing enterocolitis)

GENERAL APPROACH TO A SICK CHILD WITH ABDOMINAL SYMPTOMS

- Observe the child's behavior before you approach the patient directly wherever possible, because sometimes children can get scared or intimidated by the white coat. A child sitting or playing comfortably on the ER gurney can be quite reassuring.
- Rule out shock/dehydration/signs of sepsis apart from checking vitals and doing routine primary survey for airway and breathing.
- Due to lesser body weight and blood volume, children are more liable to dehydration—wide-bore intraosseous IV access is quite reliable in children.
- Consider surgical pathology early in the history and examination.
- Resuscitate while you evaluate/investigate.
- Have a low threshold for early imaging/specialist consult in children, especially for newborns and infants. Serial examinations are valuable if the diagnosis is not clear in the first instance.

NEONATAL NECROTIZING ENTEROCOLITIS

Typically, the baby is an NICU graduate, initially, there will be a mild abdominal distension, bilious vomiting, and lethargy. There is a drop in the mean blood pressure and often a drop in the platelet count. More often than not, these babies recover uneventfully on conservative management and antibiotics. A localized area of tenderness and a discoloration of the abdominal wall is a harbinger of intestinal gangrene. However, neonatal necrotizing enterocolitis (NNEC) is very deceiving and babies can deteriorate suddenly. Signs of sudden deterioration are sudden increase in the abdominal girth (**Fig. 1A**), suggestive of intestinal obstruction or perforation. A plain X-ray may show multiple air fluid levels (**Fig. 1B**). Surgical approach can vary from making a stoma with drainage of intraperitoneal collection to a resection and anastomosis (**Fig. 1C**).



FIGS. 1A TO C: (A) Clinical picture of neonatal necrotizing enterocolitis (NNEC); (B) X-ray abdomen showing multiple air fluid levels; (C) intestinal gangrene. ***(For color version, see plate 34)***

DUODENAL OBSTRUCTION

Congenital duodenal obstruction is amongst the most common anomaly in newborn. It affects one in 2,500–10,000 low births. Duodenal obstruction constitutes half of the cases of neonatal intestinal obstruction. They include duodenal atresia/stenosis (intrinsic) or malrotation and annular pancreas (extrinsic) obstruction. One-third of babies with duodenal obstruction have trisomy 21 or Down's syndrome. The baby presents with vomiting and later dehydration. The plain X-ray shows a double bubble appearance (**Fig. 2**). Resuscitation surgery is required and standard operation is a Kimura diamond-shaped duodenoduodenostomy.

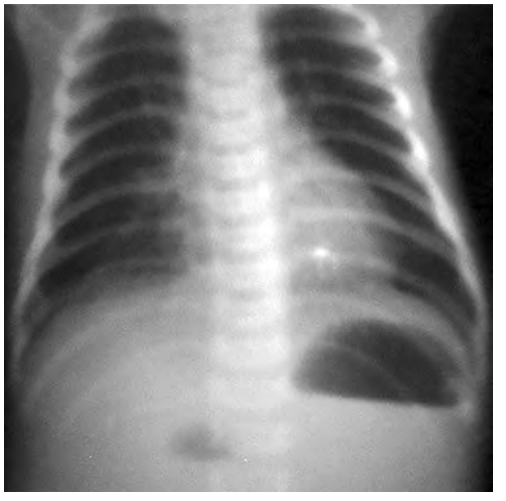


FIG. 2: Duodenal obstruction with double bubble appearance.

INTESTINAL MALROTATION AND VOLVULUS

Malrotation occurs due to incomplete rotation of the bowel with an abnormal fixation of the mesentery of the bowel. It is within this abnormal fixation that a volvulus occurs. Plain X-ray and ultrasound may be normal or show signs of obstruction. Barium upper GI series show that the gastroduodenal junction is to the right of the midline instead of the left. Ultrasound may show a "whirlpool sign" when the superior mesenteric vein (SMV) and mesentery wrap around the superior mesenteric artery (SMA) in a clock-wise direction. A baby with a malrotation presents with mild abdominal distention and failure to accept feeds. Usually, the baby is well on nasogastric aspiration and IV fluids, but as soon as baby is fed, the baby has obstructive symptoms.

It often takes a week after birth to diagnose a baby with the help of X-rays and a contrast study. Sometimes the baby with malrotation can go to puberty and adulthood without being diagnosed. Surgery is straightforward and these babies recover soon. The babies who have a volvulus have a very aggressive presentation. The neonates present with sudden onset of biliary emesis. Bleeding per rectum is another presentation and indicates a poor prognosis. Early surgery is the only choice of treatment in volvulus. At the same time, resuscitation before surgical intervention is mandatory. The outcome of babies with volvulus depends on a timely diagnosis, good preoperative preparation, and early surgery. It can vary from complete recovery to a disastrous outcome and/or intestinal failure in the event there is a volvulus with gangrene.

ANORECTAL MALFORMATION

The baby presents with an absent anal opening or a vestibular anus in the case of a female baby. A baby with anorectal malformation (ARM) may have a missed diagnosis, if the attending physician has not looked at the perineum. At times, in girls there is a vestibular anus and the absent anal opening goes unnoticed as the baby passes meconium after birth. Depending on the tightness of the anal opening in newborn, a stoma may be required for a high ARM or an anoplasty for a low ARM (**Fig. 3**).

HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease is named after Harold Hirschsprung. It is also known as aganglionic megacolon due to the absence of parasympathetic ganglion cells of Auerbach's plexus in a variable portion of the distal intestine. The incidence 1: 15,000, it may be associated with other congenital anomalies. Babies with Hirschsprung's disease present at birth with delayed passage of meconium, abdominal distention, and vomiting. They may present later in childhood with milder symptoms. Rarely, a patient comes to emergency with abdominal distention and intestinal obstruction. Newborn with Hirschsprung's may present with intestinal perforation and is

very sick, lethargic, and has a tender abdomen. If the patient is stable, then a barium enema should be done the next day (**Fig. 4A**). However, an acute obstruction which fails to respond to nasogastric aspiration requires early surgery (**Fig. 4B**) and a stoma.

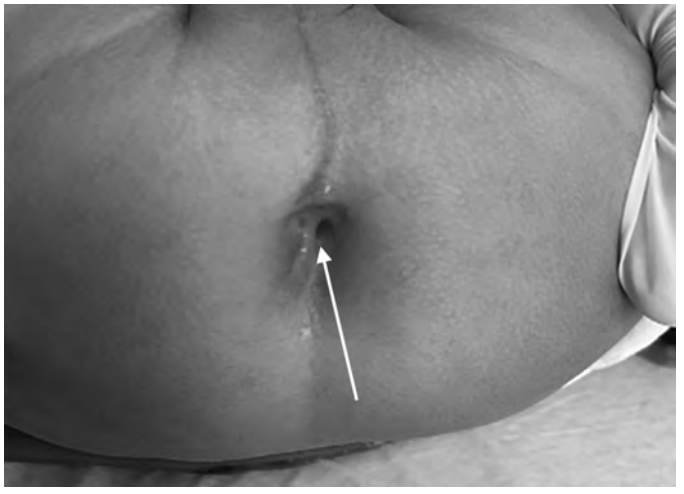

FIG. 3: Anal dimple—anorectal malformation (ARM). ***(For color version, see plate 34)***

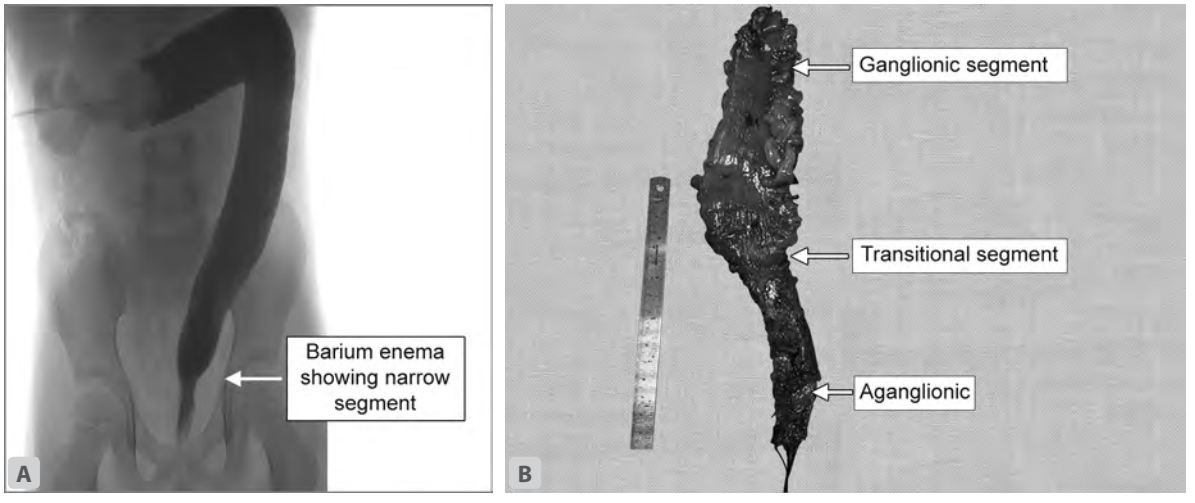
INFANTILE HYPERTROPHIC PYLORIC STENOSIS

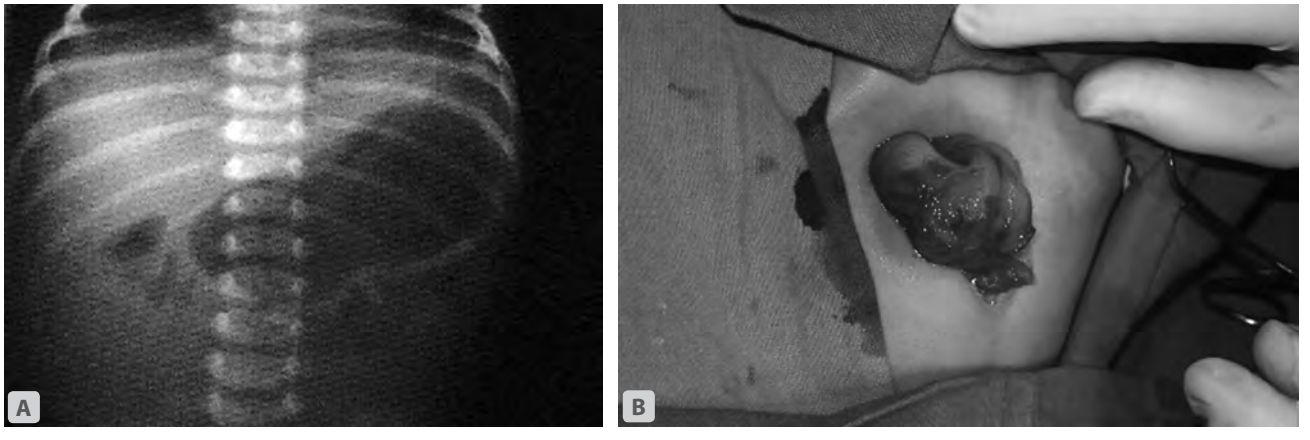
Classically, this is a first-born male baby. The incidence is 2–1,000 live births and male female ratio is 4:1. Early exposure to erythromycin in young infants has also be noted in babies with infantile hypertrophic pyloric stenosis (IHPS). Typically, the baby presents at 3 weeks of age with projectile, forceful vomiting, and an epigastric lump. The baby occasionally is dehydrated and sick due to excessive vomiting. A good clinical examination will reveal a pyloric tumor or an "olive". A plain X-ray abdomen is mostly nonspecific, but gastric dilatation with paucity of distal bowel gas is suggestive of IHPS (**Figs. 5A** and **B**). Gastric peristalsis may be seen as the "caterpillar sign". The baby has hypochloremic alkalosis due to loss of hydrochloric acid. Ultrasound shows >15 mm length and >3 mm width of the pyloric muscle. The surgery that follows is Ramstedt's pyloromyotomy which is the gold standard for this condition.

INTUSSUSCEPTION

The baby with intussusception is 3–9-month-old who is being weaned off from mother's milk and presents with incessant intermittent cry, with folding up of the legs, and



FIGS. 4A AND B: (A) Barium study in Hirschsprung's disease; (B) intraoperative Hirschsprung's specimen. ***(For color version, see plate 34)***



FIGS. 5A AND B: (A) X-ray pyloric stenosis; **(B)** intraoperative specimen pyloric stenosis. ***(For color version, see plate 35)***

bleeding per rectum. The baby with intussusception is usually a well-fed baby but gets sicker with increasing time. The baby starts to vomit and develops abdominal distention with current jelly stool. The intussusception is usually ileocolic and 90–95% are presumed to be the result of lymphoid hyperplasia. Diagnosis is made on a typical history and clinically an abdomen lump is felt. Early intussusceptions can be diagnosed and treated with ultrasound or fluoroscopic reduction. Ultrasound shows a target or "doughnut" sign. Fluoroscopy shows a typical meniscus sign or a filling defect. As time advances, the child becomes sicker lethargic and has altered sensorium. Adequate resuscitation, the baby requires surgical intervention. Surgical intervention varies from reduction of the intussusception with hydrostatic or fluoroscopic means to resection and anastomosis of the intussuscepted bowel which is gangrenous (**Figs. 6A** and **B**).

CONSTIPATION

A child with constipation presents with mild-to-severe abdominal pain sometimes mimicking appendicitis. A careful history and clinical examination will give the clue to the diagnosis. The child is typically one who has bottle feed through the day or someone who has junk food predominantly. A plain X-ray often shows impacted stools.

MESENTERIC LYMPHADENITIS

This condition can also mimic appendicitis. The pain is generalized and the white cell count is enlarged normal. The ultrasound shows multiple enlarged mesenteric lymph nodes. Most babies settle with pain killers but some require admission and IV fluids to give rest to the bowel.

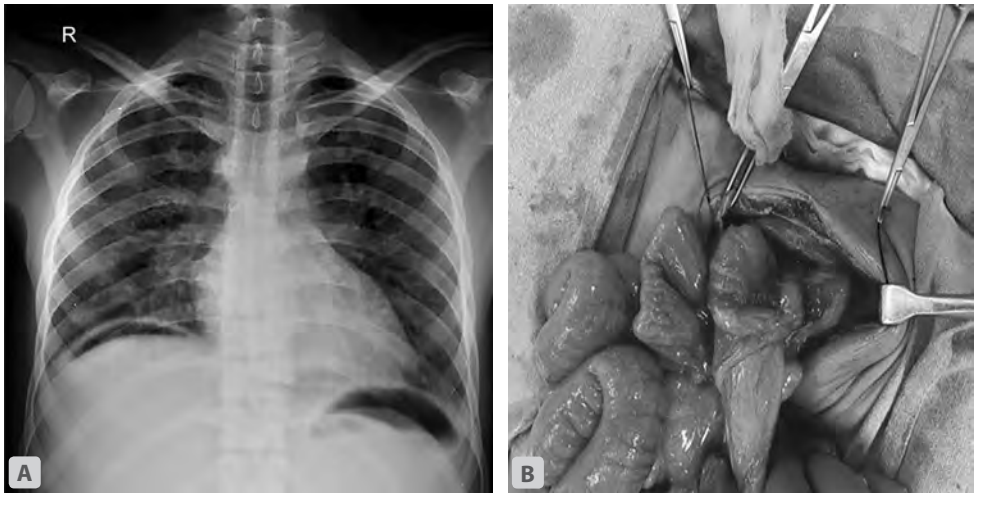
ABDOMINAL TRAUMA

Blunt trauma abdomen can present with an intestinal perforation (**Figs. 7A** and **B**) or mesenteric tear or omental torsion. Children sometimes hide the history of trauma when they present in emergency for fear that their parents may scold then. Any child with abdominal pain should be asked for history of trauma. Splenic and liver trauma may present with abdomen pain or distention. The child is pale and an ultrasound is diagnostic management of lower and splenic trauma response to conservative management along with blood transfusion, very few babies require surgery.

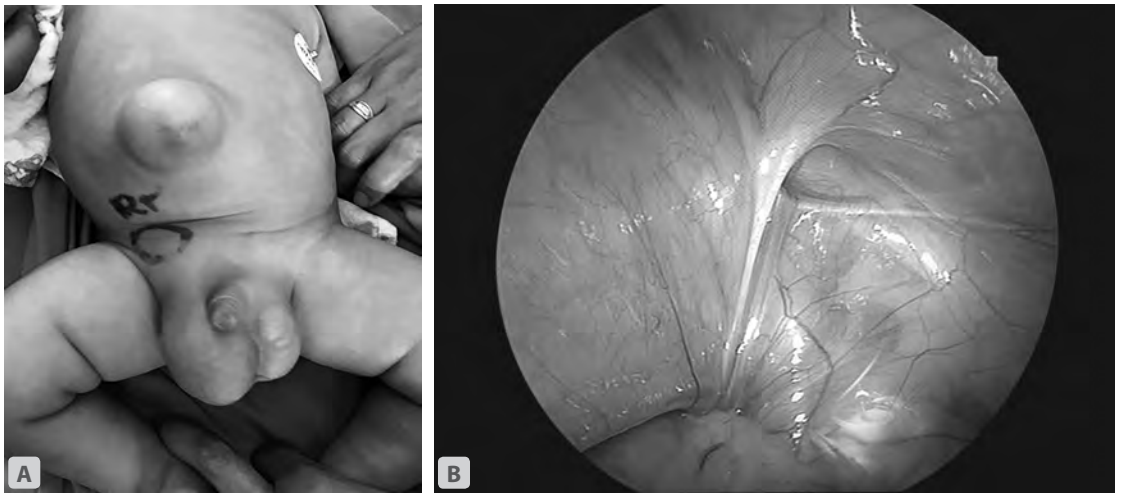
OBSTRUCTED HERNIA

The most common emergency is a child who presents with a swelling in the inguinal region which does not reduce. If

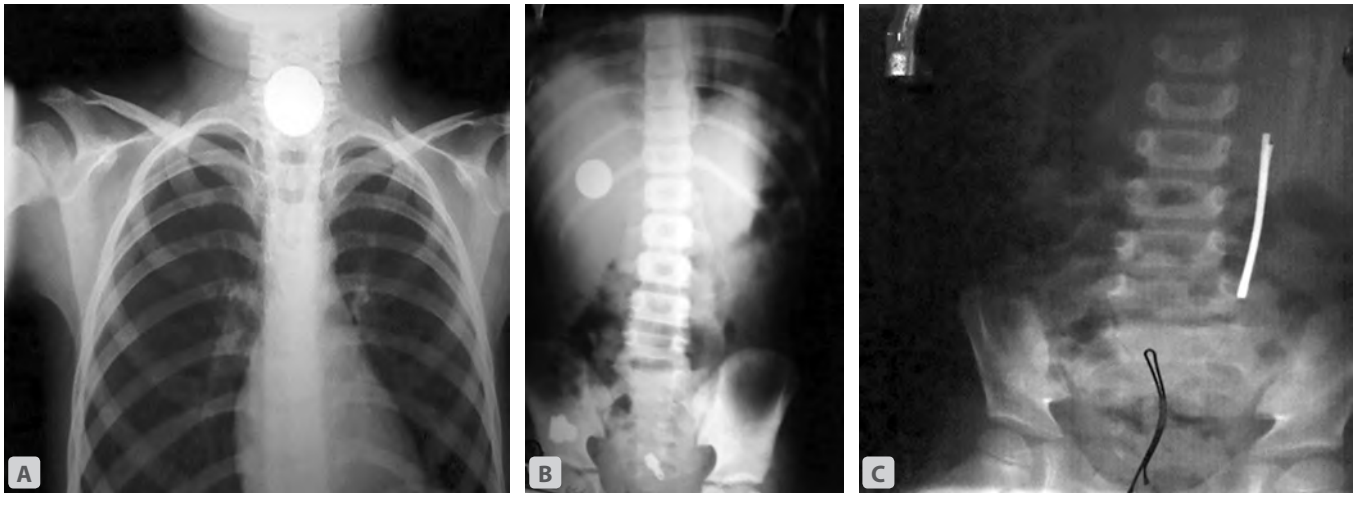
FIGS. 6A AND B: (A) Intussusception; (B) resected specimen. ***(For color version, see plate 35)***



FIGS. 7A AND B: (A) X-ray showing air under the diaphragm; (B) Intestinal perforation. ***(For color version, see plate 35)***



FIGS. 8A AND B: (A) Irreducible swelling right inguinal and umbilical hernia; (B) laparoscopic correction. ***(For color version, see plate 36)***



FIGS. 9A TO C: Foreign body ingestion—(A) coin in esophagus; (B) coin in abdomen; and (C) clip abdomen.

this swelling is irreducible (**Figs. 8A** and **B**), the child starts to vomit and develops distention of the abdomen. It cannot be overemphasized that any child who comes with abdominal pain must be examined with the pants pulled down to look for an obstructed hernia or a torsion testis. Occasionally, it could be an obstructed umbilical hernia. Early diagnosis is the way to early recovery. An attempt can be made to reduce the hernia and operate next morning. If it remains irreducible, then an emergency surgery must be carried out or else the bowel will become gangrenous.

FOREIGN BODY INGESTION

The average age of a baby who swallows a coin or aspirates a peanut is 1–2 years. The baby who swallows a coin is usually comfortable and has no physical finding except the history. A plain X-ray can be performed to locate the foreign body in cricopharyngeus or in the stomach (**Figs. 9A** to **C**). It can be taken out by a Magill forceps in the child in ER itself. However, button batteries are notorious. If history of button battery is present, and the X-ray confirms the battery, then emergency endoscopy must be done to extract the foreign body. Foreign bodies in the laryngotracheal tree are dangerous as the baby comes with mild-to-severe respiratory symptoms of sudden duration. The culprit is usually a vegetable foreign body such as a peanut, a screw, a whistle, or a pen tip. A good history and clinical will clinch the diagnosis. Unilateral decreased breath sound or noisy breathing may be present. The patient may be admitted to the ward or pediatric intensive care unit (PICU) depending on his clinical condition. Rigid bronchoscopy is the way forward. The reason we mention it here is that it is sometimes difficult to differentiate a foreign body in the esophagus versus the trachea.

APPENDICITIS

Appendicitis is common after 5 years of age and the child usually presents with central abdominal pain and right iliac fossa tenderness with rebound tenderness. The male-to-female ratio is 1.4:1. The child may be dehydrated with poor appetite for a day or so. The white cell count is raised with neutrophilia and the clinical diagnosis is confirmed by ultrasound. If the history is longer than the child is sicker and the abdomen may be tense and tender all over suggestive of a perforated appendix with peritonitis. There are various clinical prediction rules (CPRS) and various scores such as Alvarado score/MANTRELS

(Migration, Anorexia, Nausea/vomiting tenderness, relend pain, Elongation of temperature, Leukocytosis), and pediatric appendicitis score (PAS). Treatment consists of stabilizing the child followed by appendectomy; open/laparoscopy (**Fig. 10**). Computed tomography (CT) scan is only done in case of a diagnostic dilemma. Sensitivity and specificity for CT are 94% and 95%, respectively, over USG, 88% and 94% (Doria 2006).

MECKEL'S DIVERTICULUM

Meckel's diverticulum presents with painless bleeding per rectum. Meckel's diverticulum can also cause intussusceptions and intestinal obstruction. Painless bleeding from the heterotrophic gastric mucosa of a Meckel's is diagnosed by a technetium scan. If the diagnosis is still in doubt, an ultrasound and CT should be done. The choice of treatment is surgical resection of the Meckel's and an anastomosis of the small bowel (**Figs. 11A** and **B**).

CHOLECYSTITIS

The child presents with epigastric pain which later shifts to the right hypochondrium. The child may have fever, symptoms of dyspepsia, and tenderness in the right hypochondrium. The white cell count is raised and an ultrasound shows a thickened gallbladder (GB) wall or GB calculus (**Fig. 12**). An acalculous cholecystitis can occur in a child with enteric fever. Although, rare such patients are sicker and may need surgical intervention. Management consists of conservative management with an elective cholecystectomy 6 weeks later. If there is evidence, if perforation, then an emergency cholecystectomy is warranted.

PANCREATITIS

Pancreatitis is rare in children, although seen from time to time. The child presents with acute epigastric or central abdominal pain which is radiating to the back. On examination, there may be tenderness in the epigastric region. Serum amylase and serum lipase are often raised. An ultrasound may show GB stones. The pancreas is best seen on the CT scan (**Fig. 13**). Pancreatitis responds to rest to the GI tract by inserting a nasogastric tube and IV fluids. Once the child has recovered, a magnetic resonance cholangiopancreatography (MRCP) is done to evaluation the biliary tract, surgery is only indicated in cases of pseudocyst of the pancreas or an anatomical anomaly in the biliary or pancreatic duct.

FIG. 13: Pancreatitis on computed tomography.

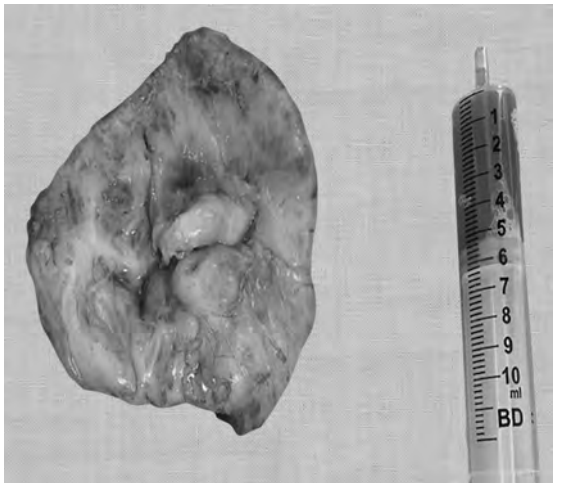

FIG. 14: Mesenteric cyst. ***(For color version, see plate 37)***

ABDOMINAL CYST

Abdomen or mesenteric cyst is often congenital acute abdominal pain occurs usually when the cyst is twisted. The child may present with increasing abdomen girth. Ultrasound is diagnostic and, in some cases, CT scan may be required. Management consists of surgical intervention (**Fig. 14**).

FEATURES OF CONCERN

Signs, symptoms, or radiological findings that prompt urgent surgical intervention.

- *Red flag symptoms*: Bilious vomiting/persistent nonbilious vomiting, inability to tolerate feeds, incessant cry, abdominal distension with vomiting, and bleeding per rectal with unstable vital signs
- *Red flag signs*: A lethargic child with pallor/dehydration, labored shallow fast breathing or grunting, abdominal distension visible loops/visible peristalsis, distended abdomen with tenderness/rebound tenderness, and hypothermia (in neonates). Radiology features which are suggestive of serious pathology are X-ray abdomen—pneumoperitoneum, multiple air fluid levels, fixed localized dilatation of loops, paucity of bowel gas in abdomen, paucity of bowel gas in pelvis and dilated proximal loops, pneumatosis intestinalis, and portal venous gas. Ultrasound abdomen findings suggestive of serious pathology are free fluid, target sign of intussusception and acute appendicitis. Color Doppler finding which suggestive of serious pathology are superior mesentric artery (SMA) and superior mesentric vein (SMV) axis reversal, decreased or absent flow to a gonad.

POSTOPERATIVE COMPLICATIONS

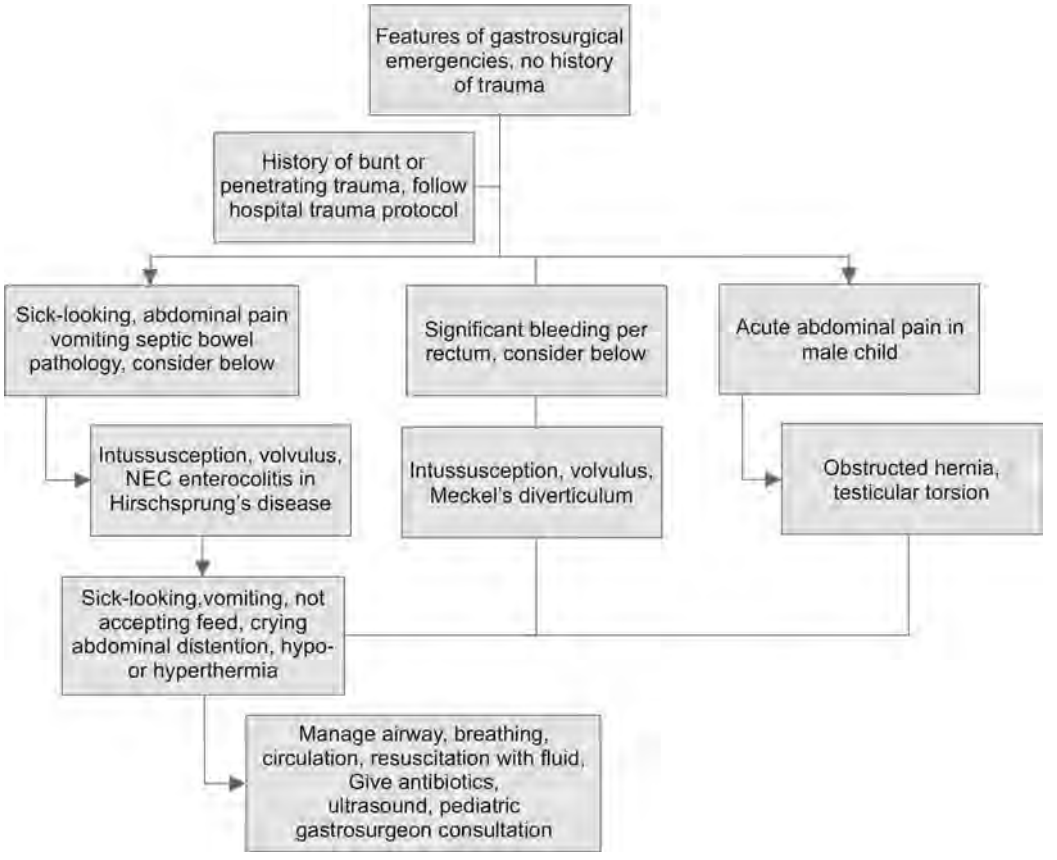
Patients operated for pediatric gastrointestinal emergencies may develop the various complications in postoperative periods, e.g., mild-to-moderate wound infections, leak from intestinal anastomosis, residual abscess and bleeding and postoperative adhesive obstruction. All these complications can be anticipated and addressed from the time the patient enters the emergency by a vigilant emergency physician. Early antibiotics and early diagnosis followed by good resuscitations will warrant early surgery. Intestinal perforation and severe abdomen pain with grossly distended abdomen which do not respond to nasogastric aspiration demand early surgery.

MANAGEMENT

Management consists of fluid resuscitation, placement of appropriate size nasogastric tube and continuous drainage, hospitalization, serial examination, and treatment of underlying cause. If pediatric patient with acute abdominal symptoms rule out any history of blunt or penetrating trauma (follow hospital trauma protocol if trauma). Sick looking children with abdominal pain and vomiting have septic bowel pathology unless proven otherwise, e.g., volvulus, intussusception, NEC, and enterocolitis in Hirschsprung's disease. Bilious vomiting is an indication of a high bowel obstruction, warrants immediate surgical consultation. Significant bleeding per rectum with unstable vital signs can be seen in intussusception, Meckel's diverticulum, and volvulus. Examination of genitalia is imperative in children with acute abdominal signs, especially boys, to pick up obstructed hernias and testicular torsions. On examination, if child is sick appearance, lethargic, inability to accept feeds orally, vomiting, hyper-/hypothermia, abdominal distension, and low urine output incessant cry; start the resuscitative measures: Perform primary survey, check oxygen saturation, temperature, and dehydration signs, start resuscitation with intravenous fluid, start broad spectrum antibiotics, warm the babies if hypothermic, place the nasogastric tube and aspirate if indicated. Perform initial investigations, e.g., venous blood gas, blood glucose, blood group and typing, X-ray chest and ultrasound abdomen if indicated and arrange early neonatologist and pediatric surgeon consult. Management approach of gastrosurgical emergencies is summarized in **Flowchart 1**.

SUMMARY

Abdominal pain is one of the most common presenting complaints in the pediatric emergency department. Early recognition of any life-threatening conditions requires high indices of suspicion and also rewarding. The diagnosis of pediatric abdominal emergencies remains challenging despite advances in research and treatment and can be associated with high cost and morbidity. Management often includes appropriate fluid resuscitation, electrolyte repletion, obtaining advanced imaging, and prompt surgical consultation.



Features of gastrosurgical emergencies, no history of trauma
History of bunt or penetrating trauma, follow hospital trauma protocol
Sick-looking, abdominal pain vomiting septic bowel pathology, consider below
Significant bleeding per rectum, consider below
Acute abdominal pain in male child
Intussusception, volvulus, NEC enterocolitis in Hirschsprung's disease
Intussusception, volvulus, Meckel's diverticulum
Obstructed hernia, testicular torsion
Sick-looking,vomiting, not accepting feed, crying abdominal distention, hypo- or hyperthermia
Manage airway, breathing, circulation, resuscitation with fluid, Give antibiotics, ultrasound, pediatric gastrosurgeon consultation

FLOWCHART 1: Management approach for gastrosurgical emergencies.

177
CHAPTER

Geriatric Emergency Department

Don Melady, Thom Ringer

INTRODUCTION

Most medical specialties define themselves by the organ system in which they are an expert. By contrast, Dr Judith Tintinalli, a preeminent emergency physician leader, has described emergency medicine (EM) as "a population-based specialty." By this, she means a group of clinicians who must provide every form of care—preventive, primary, urgent, and critical—to anyone and everyone in the community they serve, particularly its most vulnerable members. More so than any other specialty, every aspect of EM practice is heavily determined by the characteristics of that population.

There is no more universal and striking feature of the world's population than its rapid aging. Worldwide, the number of persons aged 80 years or over is expected to triple between 2017 and 2050. In India, a comparatively young nation by global standards, the number of adults aged 65 years or older is expected to rise from 83 million in 2019 to 227 million by 2050. Moreover, in much of the world, the increase in emergency department (ED) visits by older adults outpaces the rate of growth of this population.

These trends have enormous implications for the vast majority of EDs that already struggle with funding, staffing, and space. American data reveal that on an average, an older patient stays in the ED for 20% longer and uses 50% more laboratory and imaging services than younger counterparts. Moreover, frail (medically and psychosocially vulnerable) older adults are at a high risk of prolonged hospitalization, functional dependence after discharge, healthcare-related harm, and death.

Equally, though, care of older adults is uniquely rewarding and an opportunity to return to the compassionate heart of medicine. Harkening back to Tintinalli's paradigm of a *population-based specialty*, the International Federation of Emergency Medicine has challenged EM practitioners and institutions to "recognize that older people are *a core population of service users,* not defined merely by chronological age but by the complex interactions of physical, psychological and social frailty, disease, and access to care."

Despite a tendency among EM clinicians and bodies to see care of older adults as resting outside of the specialty's core responsibilities, geriatric EM (GEM) advocates have been successful in:

- Creating and promoting best practices for the design and operation of geriatric EDs
- Developing robust research to support evidence-based care of older adults
- Advocating for more attention to geriatric topics in medical education

In this chapter, we focus on creating and promoting best practices in the geriatric ED.

WHAT IS A GERIATRIC EMERGENCY DEPARTMENT?

Creating a geriatric ED does *not* require a purpose-built space, radical redesign, or even changes apparent to the naked eye. Rather, the GEM pioneer Dr Ula Hwang and her colleagues simply *define a geriatric ED as one that provides:*

- Better education in GEM care for all clinicians, including physicians, nurses, and allied health professionals
- Evidence-based protocols for common geriatric syndromes
- Appropriate structural modifications

In 2013, the American College of Emergency Physicians (ACEP), the Society for Academic Emergency Medicine, the American Geriatrics Society (AGS), and the Emergency Nurses Association developed and published practice guidelines designed to "effectively improve the care of the geriatric population and which [are] feasible to implement in the ED." In 2018, on the basis of these guidelines, the ACEP began accrediting geriatric EDs. In the culmination of nearly a decade of innovative work, the ACEP Geriatric ED Accreditation Criteria (GEDA Criteria) are a structured and rigorous framework to help put into practice the tenets articulated by Hwang et al. By 2020, 166 EDs, including international ones, had achieved one of the three levels of accreditation.

Formal accreditation may not be the goal of all EDs which want to improve the care of older ED patients. They may simply

want a framework to organize those changes. As such, we offer a practical, minimalist approach to *three key elements of the geriatric ED*:

1. People
2. Education
3. Processes

A PRACTICAL APPROACH TO GERIATRIC EMERGENCY DEPARTMENT OPTIMIZATION

People

Creating Leadership

Ideally, a geriatric ED will have one physician and one nurse manager with joint responsibility for the oversight of the geriatric ED initiatives and processes. These professionals should have some minimal geriatrics training and/or experience—or strong interest in cultivating such expertise—and continually develop their geriatrics knowledge and skill base. The ACEP GEDA Standards, for instance, recommend 8 hours of geriatric-appropriate continuing education every 2 years.

Involving Multiple Disciplines

Geriatrics-informed ED care requires attention to the interplay of medical, physical, psychological, and social vulnerabilities. While EM physicians can and should recognize the presence of these last three factors in their patients, they are not trained or best positioned to evaluate and address all of them. As such, it is essential to involve nursing staff as well as physiotherapists, social workers, occupational therapists, and other allied health professionals from the outset of any geriatric ED initiative. Most EDs do not have those professionals as a regular part of the ED team. It is helpful to establish a process with them that allows for targeted assessments of the selected older patients in a timely manner.

In departments without allied health support, other options include focused training for nurses in gait and falls risk assessment and creating a binder (real or electronic) of information about community resources available for older adults. In their advocacy at the departmental and institutional levels, the geriatric leads should prioritize an access to an interdisciplinary team ahead of education and supplies. Nothing has shown more positive impact on patient outcomes for older adults than multidisciplinary care.

Engaging Patients and Caregivers

In most societies, family members provide a substantial amount of care for older adults. In many cases, particularly where the older adult is cognitively impaired or does not speak the language in which medical care is provided, caregivers are responsible for carrying out discharge instructions, following up on referrals and results, and managing medication changes. This experience offers them invaluable insights into the practical aspects of care, both within the ED and after discharge. Involving patients and caregivers in the development and governance of geriatric ED initiatives helps to capture those perspectives and use them to improve care.

Education

The GEDA Criteria observe that "the success of (a geriatric ED program) rests largely on the education of a multidisciplinary staff directed toward the needs of the geriatric population." Molnar and colleagues' *"5M" model* summarizes the care issues that clinicians need to address to provide optimal care to older adults in any setting (**Table 1**).

Effective Interdisciplinary Education

Given that geriatric ED care is a team sport, it follows that the teams that provide care together should learn together. While the design of effective educational programs is beyond the scope of this chapter, a comprehensive review by Hammick and colleagues of the evidence around interprofessional education highlights certain key principles which are as follows:

- Staff should fully participate in the development and delivery of educational programs.
- Programs should be continuously improved based on the learner reactions.
- Curricula must reflect as much as possible the actual practice environment, including its limitations, rather than an abstract ideal state.
- Teaching should be structured with an understanding that staff are adult learners in professional practice with little dedicated educational time, as opposed to preclinical students whose main focus is didactic learning.
- Like any change program, education should be evaluated in real and simulated practice settings for its impact on attitudes and behavior.

Ways of Delivering Education

The GEDA Criteria recommend considering a broad range of educational methods, including didactic lectures, case

TABLE 1: 5M model for geriatric patient care in an emergency department.

Mind	• Mentation • Dementia • Delirium • Depression
Mobility	• Impaired gait and balance • Fall injury prevention
Medications	• Polypharmacy • Optimal prescribing • Adverse medication effects and medication burden
Multicomplexity	• Multimorbidity (the presence of multiple overlapping and interacting medical conditions) • Complex biopsychosocial situations
Matters most	Each individual's own meaningful health outcome goals and care preferences, going well beyond the most basic issue of so-called code status

conferences, simulations, journal clubs, coaching, and online modules. Simulation and case-based learning, though resource-intensive, are preferred by learners. In addition, studies demonstrate that they are particularly well suited to promoting interdisciplinary collaboration and teaching learners to untangle the complexity of geriatric ED scenarios using a variety of perspectives.

It is also important to provide training to all staff whose work involves providing care to the older ED patient. In most systems, EM physicians and nurses play a large role in educating prehospital ambulance and emergency medical services (EMSs) personnel. Despite having the direct contact with older adults in the community, prehospital clinicians consistently receive limited geriatric training. Community paramedicine, which gives EMS an expanded role in delivering public health, primary and preventive care to older adults where they live, is one of the most promising geriatric ED innovations.

Processes

Patient's Journey

Depending on their acuity, all ED patients go through certain steps in their journey through the department, e.g., transport/arrival, triage, transfer to another area of the department, initial assessment by a nurse, physician assessment, treatment, reassessment or consultation, and disposition. The geriatric ED is the one in which all of these steps have been examined and improved using geriatric principles. Physician leaders have a natural tendency to pay the most attention to what they know best and focus exclusively on medical decision-making (e.g., simply encouraging physicians to broaden their differentials or consider the harms of treatment). However, this approach neglects all the other interactions that affect care.

One simple exercise, common to all quality improvement initiatives, is to collaborate with ED staff to draw a map of the typical patient journey and then consider what unique challenges older adults face at each stage. Examples include:

- *The waiting room*: Is the "front door" of the ED accessible to older adults who use canes or walkers? Are signs readable to people with visual impairment? Can people with cognitive impairment understand where they are supposed to go?
- *Triage*: Are caregivers encouraged to participate, even if by phone, in the triage process so that ED personnel can get the whole story? Is there an opportunity for triage personnel to look for signs that a patient might be physically or socially frail? Can they flag older adults whose chronological age does not match up with their "medical age" (level of morbidity or functional impairment)? Might they screen for cognitive impairment and ask about and document living situation and medications?
- *Discharge*: Does preparation for discharge involve more than simply establishing a diagnosis? Is safety for discharge assessed? Are caregivers notified when an older adult is being discharged home? If a discharge prescription is provided, does someone ask how the patient will fill it and know how to take it? If there are concerns about cognitive impairment, are follow-up and return-to-care instructions clearly documented and communicated to someone who can ensure that they are followed?

Medical Directives and Preprinted Order Sets

In many geriatric EDs, triage and/or nursing personnel are permitted by medical directive to initiate certain orders before the patient is seen by a physician. These include measures to prevent falls, and delirium prevention orders through effective management of factors, such as pain, disorientation, and constipation. Many EDs also have preprinted order sets that allow physicians to quickly and conveniently activate these measures even when they are not extensively trained in taking care of older adults.

Policies and Protocols

Though labor- and time-intensive, the GEDA Criteria strongly recommend a full review of all the departmental and institutional policies and procedures with the potential to affect care *of* older adults. These should be analyzed using a 5M lens to optimize them for geriatric patients. Examples of pertinent policies include:

- Standardized screening for delirium and cognitive impairment using validated tools
- A medication review by a pharmacist as part of the ED process
- Screening of an elder for abuse and neglect
- A standardized approach to fall assessment to identify the cause and modifiable risk factors and modifications for safe discharge
- Pain assessment and control
- Goals of care (e.g., do not resuscitate/allow natural death, palliative care)
- Clear evidence-based guidelines for urinary catheter placement

SUMMARY

Populations of older people are increasing globally. They are among the core users of ED services. A successful ED in the 21st century will acknowledge that reality and will start making changes—large and small—to its structure and processes. This may involve a long-planned and expensive complete change of the physical environment if time and resources are unlimited. But more importantly, it should involve small incremental changes, implemented one at a time—enhanced education of caregivers about issues specific to older patients, creating opportunities for enhanced assessment beyond those that are purely medical, or changing the workflow to permit screening for important geriatric conditions, such as delirium and cognitive impairment and abuse/neglect.

Early research suggests that implementing these changes has a beneficial return on investment. While hiring a new geriatric nurse case manager may be expensive, it may well lead to a significant decrease in ED length of stay, in avoidable admissions, and in unnecessary early ED returns. Similarly, implementing a process that ensures early identification or prevention of a delirium can pay substantial human and financial dividends in decreased morbidity and hospital expenses. Building a system that allows ED physicians and nurses to provide the best possible care to older patients will create conditions for better recruitment and retention and instill a sense of pride that they are fulfilling the EM mission, best articulated by Dr Tintinalli, of being an essential resource to all members of the community they serve.

178 CHAPTER

Comprehensive Geriatric Assessment

Lorraine Lau, Rebecca Schonnop

INTRODUCTION

Older people often have multiple comorbidities, polypharmacy, and atypical presentations. Unlike younger patients, they rarely present to the emergency department (ED) with an isolated medical issue. They require a comprehensive approach for evaluation, management, and disposition planning. Multiple domains need to be considered including medical, psychological, functional, and social and environmental factors. Physicians often focus on the medical assessment, but other domains are equally important to care of in the ED and will largely influence the assessment and disposition plans. To capture these multiple important domains in the geriatric care, a comprehensive geriatric assessment (CGA) was developed by geriatricians. A CGA is a multidimensional interdisciplinary approach toward older persons to help develop a complete holistic care plan. Completion of a CGA in the ED has been associated with reduced functional decline and a decrease in repeat ED visits. However, it is time consuming and is not intended to be used by emergency physicians for episodic assessment of patients with acute presentations. In this chapter, the CGA framework (**Fig. 1**) will be used to outline how to apply an acute comprehensive assessment for older patients in the ED setting, categorizing these components within the medical, psychological, functional, and social and environmental domains.

MEDICAL ASSESSMENT

Older people often present to the ED with atypical clinical presentations, physical findings, and investigation results due to age-related physiologic and anatomic changes. These changes can result in vague or delayed complaints with absence of typical findings, confounded by polymorbidity and polypharmacy with drugs that may cause or mask disease symptoms.

Generalized symptoms—such as weakness, dizziness, fatigue, and malaise—are easy to dismiss, but these may be due to multiple serious causes. They require cautious evaluation as these patients are at increased risk for bad outcomes. Falls are a common ED presentation for older patients; they should be thought of, not as an event, but as a symptom. They may be the presenting complaint for underlying illness and pathology, such as acute coronary syndrome, sepsis, adverse drug effects, and intra-abdominal pathology. Older people often lack the typical presentation of illnesses, such as pain or fever. A review of past medical history, medications, and a thorough physical examination are components of this medical assessment. This section will highlight some principal differences in the clinical presentation and physical examination that should be considered for older patients.

Vital Signs

Due to age-associated changes, interpreting vital signs in older patients requires enhanced knowledge and skills of physicians. These changes lead to loss of regulatory and adaptive mechanisms. Older people also have a lower core body temperature and altered thermoregulatory responses.

FIG. 1: Comprehensive geriatric assessment framework.

Compensatory tachycardia may not be observed as maximal heart rate decreases and the cardiovascular system is less adrenergically responsive with age. Hypotension can be a later clinical sign due to stiff peripheral vasculature and loss of responsiveness to sympathetic stimuli. Furthermore, dysregulation of autonomic sensitivity can lead to orthostatic hypotension. Assessing orthostatic vitals can be helpful in patients presenting with dizziness or syncope.

Neurologic System

A complete neurologic exam may sometimes be difficult because of cognitive or sensory impairment. On physical exam, look for signs of head injury, neurologic deficits, impaired speech, and impaired cognition. As part of the neurological assessment, physicians should also screen older people for delirium. Delirium is reported in 7–20% of older patients in the ED, and older ED patients are at the highest risk for delirium. Delirium is associated with increased morbidity and mortality, reinforcing the need for routine screening and early recognition. Numerous screening tools have been validated or tested for diagnostic accuracy for use in the ED, including variations of the confusion assessment method (CAM), such as brief confusion assessment method for the (bCAM), modified confusion assessment method for the emergency department (mCAM-ED), and confusion assessment method for the intensive care unit (CAM-ICU). The fundamental components of delirium guided by CAM are outlined in **Figure 2**. To accurately complete a delirium screen, one must know the patient's baseline status, acquired through collateral history.

Cardiovascular System

With age, a weakening cardiovascular system leads to increased risk of diseases including coronary artery disease, dissection, heart failure, valvulopathies, and other comorbidities. Silent or unrecognized infarctions account for 25% of all myocardial infarctions (MIs) but account for up to 60% in patients over the age of 85 years. For acute coronary syndrome patients, those over the age of 85 years are more likely to present with heart failure and have different symptoms, such as dyspnea, diaphoresis, nausea and vomiting, and syncope compared to younger patients. On physical examination, evaluate for existing or new murmurs, irregular and nonequal pulses, and signs of heart failure.

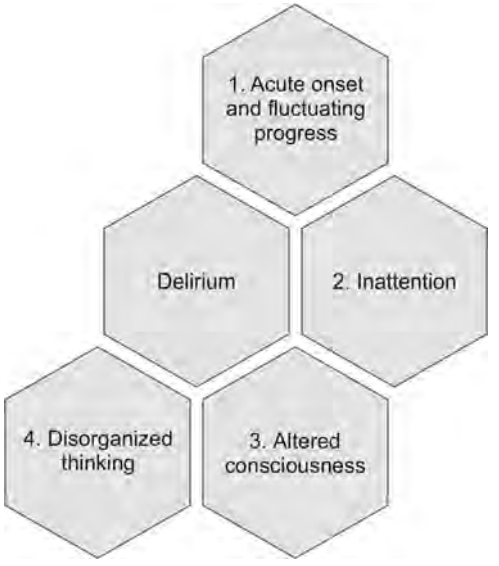

FIG. 2: Components of delirium based on confusion assessment method: Delirium = 1 + 2 + either 3 or 4.

Respiratory System

Pulmonary function decreases with age, and cardiopulmonary disease can further decrease respiratory reserve. On exam, assess for respiratory distress, auscultate for adventitious sounds, and take into consideration baseline respiratory function [e.g., history of chronic obstructive pulmonary disease (COPD)]. For ambulating older patients, consider performing a walk test in the ED while monitoring oxygen saturation to look for desaturation with exertion.

Gastrointestinal System

Compared to younger patients, older patients with intra-abdominal infections tend to present atypically or delayed which are associated with increased likelihood of surgical intervention, morbidity, and mortality. The abdomen should be examined fully, noting previous scars, pain, distension, organomegaly, masses, or ecchymoses. In older patients, abdominal musculature is often thin, which may lead to limited guarding and rigidity in the presence of peritonitis. Localization of pain is also impaired due to fewer peripheral sensory nerve cells.

Genitourinary System

Urinary tract infections (UTIs) are commonly overdiagnosed, largely due to the high prevalence of asymptomatic bacteriuria in older people (up to 19% in community-dwelling older people). According to Canadian and American guidelines, urinary symptoms include urinary frequency, urgency, dysuria, suprapubic tenderness, costovertebral tenderness, changed urinary incontinence, and gross hematuria. New confusion, decreased appetite, falls, wandering, or aggression alone are not indications for investigations of a UTI.

Musculoskeletal System

Given the increased prevalence of osteoporosis in older patients, even minor trauma such as a fall from standing height can lead to fractures. Approximately 10% of falls among older adults result in a fracture. Hip fractures, for example, are associated with a significant increased risk of mortality and morbidity. In geriatric trauma, special considerations include spine fractures, rib fractures, pelvic fractures, and long bone fractures. Assess for neurological deficits, respiratory distress in cases of associated pneumothorax, hip pain, and bone deformities.

Integumentary Examination

Aging skin loses elastin and collagen, the epidermis becomes thin, and there is decreased subcutaneous support. As such, older adults have fragile skin and are more prone to soft-tissue injuries. With immobilization, pressure ulcers may develop in as little as 4–6 hours and become a potential source of infection. On exam, it is important to assess the patient's back and sacral region and look thoroughly for ulcers, skin breakdown, and cellulitis.

Medications

Polypharmacy increases with advanced age. Due to physiological changes with aging, pharmacokinetics (what the body does to a drug) and pharmacodynamics (what a drug does to the body) are different in older patients. A thorough review of a patient's medications is important, including both prescription and over-the-counter drugs. In addition to obtaining an accurate list, physicians should inquire about how the patient manages his/her medications. Identify if the patient requires observation and assistance with medication administration, and if the medications are stored in bottles, pill organizers, or blister packs. A habit history of recreational substances including cigarettes, alcohol, and cannabis consumption should also be documented. This accurate and complete medication history is imperative to prescribe safely in the ED, to discern if presenting symptoms may be attributable to adverse medication effects, and to continue important home medications while the patient is in the ED.

PSYCHOLOGICAL ASSESSMENT

Older adults can present to the ED with cognitive impairment, agitation, and behavioral changes. This can include acute delirium, behavioral and psychological symptoms of dementia, and mood disorders. Delirium should be assessed as part of the acute neurological examination, described above. Cognitive and mood assessments should be considered for older people in the ED as indicated by their presenting issues.

Cognitive Assessment in the Emergency Department

The ED visit is a unique opportunity to identify underlying neurocognitive disorders which may have a significant impact on the patient's ability to function in the community and may have an impact on the ED assessment. A patient with underlying cognitive impairment may not be able to give an accurate history, to participate in the entire physical examination, or to understand and follow through with disposition planning. While there are several validated cognitive assessments available, such as the Mini-Mental State Examination (MMSE), Montreal Cognitive Assessment (MoCA), and Rowland Universal Dementia Assessment Scale (RUDAS), they have limited applicability in the ED because of time constraints. The three step Mini-Cog instrument is a screening tool that can be completed quickly in the ED to aid in identifying cognitive impairment. This short test involves a three-item recall component for memory and a clock drawing test. A score of 3 or greater indicates a lower likelihood of dementia but does not rule out mild cognitive impairment. Collateral information from family, friends, or caregivers can aid in understanding the patient's baseline cognitive status prior to ED presentation. If a cognitive disorder is suspected, this may alter your assessment and disposition instructions in the ED. It should certainly be communicated to the primary care provider in the community for follow-up.

Assessment of Mood Disorders

Major depression is a prevalent health disorder in older adults. Compared to younger patients who may present with primarily low mood, older people with depression more commonly have irritability, anxiety, and physical/somatic symptoms. There are short, validated tools that can be used in older persons, including the ED Depression Screening Instrument (ED-DSI) and the Patient Health Questionnaire-2 (PHQ-2). If a patient screens positive for depression, this should prompt a safety assessment to inquire about suicidality, including protective and risk factors. It is important to arrange follow-up in the community and communicate mood or safety concerns with the primary care provider when the patient is safe for discharge.

FUNCTIONAL ASSESSMENT

Beyond diagnosing and treating older patients' medical issues in the ED, it is especially important to evaluate their functional status. This includes their ability to perform activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs refer to self-care tasks: transferring (i.e., between a bed and chair), toileting, bathing, dressing, feeding, and continence. IADLs refer to activities that are needed to live independently: shopping, preparing meals, housekeeping, managing medications, driving or using public transportation, managing finances, and using a telephone/technology. Identifying in the ED the patient's baseline function can clarify the clinical presentation and guide disposition planning. Inquiring about current help and services at home (i.e., primary caregiver, personal support worker, community services) is important for a safety assessment. It may prompt a suggestion for additional home support.

Gait assessment is a vital component of the functional assessment. Provide patients with an appropriate mobility aid for evaluation. The timed up and go (TUG) test is a simple test that can be used in the ED for assessing mobility, static, and dynamic balance. The patient stands up from sitting position on a chair, walks for 3 meters, turns around, walks back, and sits back down. If the test takes longer than 20 seconds, it indicates that the person may need assistance and further evaluation. If it takes 30 seconds or more, it suggests that the person is prone to falls. However, it is important to note that no single screening method used in isolation, including the TUG, has been demonstrated to be accurate for predicting the risk of falls.

Allied healthcare professionals play an essential role in the functional assessment of patients. If available in the ED, interdisciplinary team members can help with more detailed evaluations that can help optimize discharge planning. These professionals include occupational therapists, physical therapists, social workers, and dedicated geriatric ED nurse case managers.

SOCIAL AND ENVIRONMENTAL ASSESSMENT

Assessing the patient's socioenvironmental circumstances is vital in organizing an appropriate discharge plan. This domain includes understanding the patient's social support network (i.e., spouse, family, caregiver, roommate), available support resources (i.e., family, community services), and environmental/home safety (i.e., ability to perform usual ADLs/IADLs in the physical environment). Home safety also encompasses the physical and social environment. Screening for elder abuse and/or neglect is an important part of the

assessment. Correcting a patient's acute medical illness without considering social and environmental factors can quickly break down a discharge plan, resulting in an unsafe discharge, or a prompt return ED visit. For example, discharging a patient home with a wrist fracture splinted in a cast may not be appropriate if the patient lives alone, has limited social support, and uses a walker for ambulation. If available, use your allied health workers, including social workers and geriatric ED nurse case managers, to help facilitate this assessment and liaise with community support services. Occupational therapists in the community can also help with assessing the patient's home environment, identifying safety risks, and recommending assistive devices or environmental modifications.

Advanced Care Planning

In the face of potentially life-threatening circumstances, early goals of care discussion in the ED ensure patient-centered care. Have the discussion with the patient if they are competent and the situation is appropriate, identify the person who has the power of attorney, and look for official documents such as a Do Not Resuscitate Confirmation Form. Online tools are available for physicians interested in developing skills for discussion on advanced care planning and end of life, such as the Center to Advance Palliative Care (CAPC) website (https://www.capc.org/).

SUMMARY

Older people present to the ED with complex clinical presentations that can make the diagnosis, management, and safe disposition challenging. An ED-based CGA, similar to a formal CGA, enhances care of the older patient by considering the medical, psychological, functional, and social and environmental domains of the patient's presentation. It is essential to factor these contributing aspects into disposition planning and to utilize an interdisciplinary team approach to deliver high-quality care to older patients in the ED.

179
CHAPTER

Geriatric Syndromes

Devendra Richhariya

INTRODUCTION

With increasing age, physiological degeneration of various organs occurs as a normal biological process and requires no treatment, termed physical aging. With improvement in the accessibility of the healthcare system to most, people are living longer; the prevention of disability in elderly is the basis of healthy aging. A geriatric syndrome is a condition of "multifactorial health conditions with impairment of multiple systems in an older person vulnerable to situational changes." The geriatric syndrome is a unique feature of common health problems in older people with multifactorial and multiorgan systems involvement. These syndromes do not limit to one organ system or discipline-based boundaries, because of their multifactorial nature. For example, an elderly patient may present to the emergency room with delirium and altered cognitive and neural functions if they have urinary tract infection (UTI). The geriatric syndrome-defining criteria include: (1) disorders related to age, (2) age-related functional decline, (3) multiple systems involvement, (4) complex multifactorial etiology, (5) usually poor outcome if not diagnosed early and treated, and (6) usually treatable.

Five major geriatric syndromes are as follows: (1) falls, (2) urinary incontinence (UI), (3) pressure ulcers, (4) delirium, and (5) functional decline. The common risk factors of these giants of the geriatric syndromes include age, cognitive impairment, functional impairment, and impaired mobility. Frailty is the common entity of these geriatric syndromes. The main feature of frailty—after a stressful and destabilizing event—is the reduced ability to regain physiological homeostasis. With the decline in physiological reserve and function of multiple organ systems with increasing age, elderly are often unable to cope up with the acute stresses. Frailty in turn may further intensify the shared risk factors and the geriatric syndromes.

FALLS

A fall is considered as an unintentional event when a person attempts to rest on the lower surface. Falls can be divided into three phases. The first phase includes initiating events which involve extrinsic risk factors, such as environmental hazards, and intrinsic risk factors, such as joints problems, weakness of muscles, and slow postural reflexes. The second phase is considered when systems which maintain upright posture fail to detect and correct any displacement in time to avoid a fall. These are individual and intrinsic factors related to body, such as loss of sensory function, impaired central processing, and muscle weakness. The third phase includes body impact on environmental surfaces, usually the floor or ground, which results in the transmission of forces to body tissue and organs. This is followed by sequelae phases, with disabling prospects which may be physical, psychological, or social. Falls are extremely common among older adults. Each year, about one out of three elderly people who live in the community falls; this rate increases with advanced age and is higher among people who live in institutional settings. Falls cause considerable mortality and morbidity. The risk factors for falls include: (1) *Intrinsic risk factors*: gait and balance impairment, peripheral neuropathy, vestibular dysfunction, muscle weakness, vision impairment, medical illness, advanced age, impaired activities of daily living (ADLs), orthostasis, dementia, and drugs and (2) *Extrinsic risk factors*: Environmental hazards, poor footwear, and restraints.

Assessment for Falls

The most important predictors of falls can be assessed by taking the history of previous falls, gait/balance impairment, use of psychoactive medication, and decreased muscle strength. The assessment of fall includes detailed history of fall to find out a specific etiology or to narrow down the differential diagnosis. This includes history of orthostatic hypotension or slip gait, balance or vision disturbance, vertebrobasilar insufficiency, arterial or carotid sinus compression, and loss of consciousness (history of syncope or seizure). History should also be taken for assessment of risk factors including polypharmacy and functional and environmental assessments. Physical examination should include assessment of gait, assessment of hearing and vision (sensory assessment), measurement of orthostatic vital signs, and neurologic and musculoskeletal assessment, as well as depression and cognitive impairment screening. The examination should also include an appropriateness of footwear and gait aid. Depending on the results of this risk assessment, appropriate multifactorial interventions may be undertaken for preventing ambulatory falls, such as home assessment and modification

for high-risk individuals; exercise programs that include strength, gait, and balance exercises, such as physiotherapy; vitamin D supplementation in doses greater than 700 IU/d; review medications, minimizing psychoactive medications and reducing the total number of medications; management of postural hypotension; expedition of cataract surgery on the first affected eye; and considering pacing in cardioinhibitory carotid sinus hypersensitivity and recurrent falls. Manage foot problems and recommend use of antislip shoe devices for the outdoors. The patient and the caregiver should be educated regarding specific environmental improvement.

URINARY INCONTINENCE

Urinary incontinence is a troublesome and common disorder among geriatric patients that leads to a social or hygienic problem. UI is an involuntary loss of urine that is objectively demonstrable and many older frail persons require assistance by a caregiver. The urinary continence is maintained due to the integrity of the lower urinary tract (LUT), the nervous system, the visceral supporting mechanism (pelvic floor), and the urine production mechanism. With aging, the LUT undergoes a series of morphological and functional changes, which alter the functions, such as bladder overactivity and urgency, impaired bladder contractility, increased residual urine, and decreased functional bladder capacity. UI and LUT symptoms may be caused by prostatic hypertrophy—benign or malignant. In women, an increased incidence of atrophic vaginitis and related symptoms occurs due to estrogen deficiency, which increases the incidence of recurrent UTIs, and also UI. A practical approach to incontinence in an elderly patient depends on its duration (acute or chronic).

Acute or transient incontinence: This includes cases of short-duration incontinence (lasting <4 weeks), including functional, without any associated structural disorder. The causes for these include: *D*—delirium, dementia, diabetes; *R*—restricted mobility, retention; *I*—infection, inflammation, impaction of stool; *P*—pharmaceutical agents and psychological causes.

Chronic or established incontinence: These cases are commonly associated with structural disorders, either in the urinary tract or outside of it (e.g., nervous system). The incontinence lasts longer than 4 weeks. This established incontinence might be further classified depending on the etiopathogenesis. Urge incontinence presents as urgency, frequency, and nocturia. Elderly may present with strong urge to void, caused by an overactive detrusor muscle causing excessive involuntary bladder contraction. Various neurological conditions including stroke, spinal cord lesions, dementias, and Parkinson's disease are associated with UI. Coughing, sneezing, bending, lifting, or laughing increase intra-abdominal pressure which gives rise to conditions known as stress incontinence. The cause is pelvic muscular weakness causing urethral hypermobility, multiparity, hypoestrogenism, obesity, and pelvic surgical procedures, such as prostatic resection. Overflow incontinence occurs when the bladder muscle is overdistended. The patient may present with stress or urge symptoms. Functional incontinence is considered when in spite of a competent urinary system, physical or psychological impairment impedes continence status. A mixed type of incontinence, including features of more than one aforementioned type, may also occur.

Assessment for Urinary Incontinence

History-taking should include the questions about UI onset, frequency, volume, timing, and associated factors or events. Cognitive and functional assessments along with potential comorbid conditions associated with UI should be evaluated under physical examination. Perform rectal examination to assess masses, tone, and prostate nodules or firmness in men (not size). The neurologic assessment should be done to evaluate sacral cord integrity with perineal sensation. Examination of vaginal mucosa should be done for severe atrophy, and the pelvic examination should include evaluation for pelvic organ prolapse (cystocele, rectocele, uterine prolapse) with straining. Urine analysis is important for hematuria, pyuria and/or bacteriuria, dysuria, associated with fever, or other signs of UTI, especially if UI is not acute. Ultrasound or catheterization is used to look for postvoid retention, especially in frail elderly with recurrent UTIs and neurological concerns. A clinical stress test (single vigorous cough relaxed patient) may be helpful in documenting stress UI. When etiology is questionable and intervention is required, cystoscopy and urodynamic studies may be used.

Treatment

Correction of contributing factors and reversible causes is an important part of treatment. Nonmedical interventions, such as lifestyle and behavioral changes, are beneficial; these include avoiding excess of fluid intake, especially in the evening to avoid nocturia, less intake of caffeinated beverages, and alcohol; and smoking cessation. Bladder training and pelvic muscle exercises, both of which are effective for urge, mixed, and stress UI and are often used in combination, are two main behavioral therapies for UI. Pharmacologic treatment is largely limited to antimuscarinic agents for urge UI, overactive bladder, and mixed UI. Of these, oxybutynin (immediate and extended release, and topical patch), tolterodine (immediate and extended release), solifenacin, darifenacin, and trospium have been used widely. Women who have stress or urge UI are exacerbated by bladder or uterine prolapse, and pessaries may benefit them. Duloxetine is used for moderate-to-severe stress UI, especially in women. Alpha-blockers are beneficial in men with LUT symptoms, use cautiously due to hemodynamic effects. Desmopressin should be avoided in elderly UI because it can precipitate hyponatremia. In the cases of chronic urinary retention or bladder-impaired contractility, in which the patient keeps high postvoid residual urine, catheterization may be required. Minimally invasive therapies helpful for patient with urge UI refractory to antimuscarinics include botulinum toxin injection into the bladder wall and sacral neuromodulation. In refractory cases, especially in women with stress incontinence, surgery may be beneficial.

PRESSURE ULCERS

Pressure ulcers are developed when an area of skin and the tissues which get placed under pressure result in impairment of their blood supply and leads to their damage. Pressure sores, bedsores, and decubitus ulcers are the other different names of the pressure ulcers. Pressure ulcers exert deep impact on both patients and the healthcare system. These lead to severe or intolerable pain, are prone to infection, and are associated with high mortality rates.

National Pressure Ulcer Advisory Panel (NPUAP)/European Pressure Ulcer Advisory Panel (EPUAP) international classification of pressure ulcers:

Stage I: Intact skin and nonblanchable erythema.

Stage II: Partial-thickness skin, loss of the epidermis or dermis, presentation of lesions as an abrasion, blister, or superficial ulcer.

Stage III: Full-thickness skin loss that may extend up to the fascia but does not penetrate the fascia; the ulcer may be undermined.

Stage IV: Full-thickness skin loss with involvement of deeper structures, such as muscle, bone, or joint structures.

Unstageable ulcer (depth unknown): Full-thickness tissue loss in which the base of the ulcer is covered by slough and/or eschar in the wound bed.

Suspected deep tissue injury (depth unknown): Discolored intact skin, with purple or maroon localized area, or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear.

Risk factors for pressure ulcers' development are either intrinsic or extrinsic. The intrinsic risk factors responsible for pressure ulcers are reduced mobility and poor nutrition. Less subcutaneous fat, decreased dermal thickness, and decreased sensory perception in elderly persons make them prone to more rapid tissue injury and delayed healing. In some studies, incontinence, diabetes mellitus, stroke, white race, skin abnormalities, and male sex are also documented as rick factors for pressure sore. The extrinsic factors responsible for pressure ulcers are pressure, friction, shear stress, and moisture. Out of these, pressure is the most significant predictor of pressure sores. Sacrum, heels, ischial tuberosities, greater trochanters, and lateral malleoli are the most common sites for pressure ulcers. Friction can damage superficial skin, as well as deeper vessels, leading to increased ischemia. Moisture is also the independent risk factor for pressure ulcer and associated infections as well.

Assessment for Pressure Ulcers

Thorough clinical examination is critical to the identification of pressure ulcers that may serve as an occult focus for infection. Look for signs of soft-tissue involvement, such as warmth, erythema, local tenderness, purulent discharge, and presence of foul odor. Systemic signs, such as fever and leukocytosis, may be minimal or absent, and even local signs of inflammation may not be obvious because of associated comorbidities and advanced age. One should assess for the presence of exudate, odor, sinus tracts, necrosis or eschar formation, tunneling, undermining, infection, healing (granulation and epithelialization), and wound margins. As patients who are malnourished have more bony prominences and are therefore at a greater risk for pressure ulcers, nutritional assessment is important. Microbiological evaluation should be done with an aim to distinguish between bacterial invasion and colonization. Blood cultures or cultures of deep tissue biopsy specimens are more clinically important than the cultures of superficial swab or aspiration of the pressure ulcer. Imaging studies in cases of pressure ulcer are helpful in the assessment and determination of the presence of osteomyelitis and to find out the extent of deep-tissue involvement. It includes plain radiography, CT and MRI, and radionuclide scintigraphy.

Management of Pressure Ulcers

Reduction of extrinsic factors—in particular, pressure relief—is a cornerstone of therapy. This may be done with the use of pressure-reducing devices, such as low-air loss or air-fluidized bed, or static devices, such as foam or fluid-filled mattresses or supports, in patients who can change positions independently. Debriding of necrotic tissue, cleansing the wound, managing bacterial load and colonization, and selecting a wound dressing are other important components of ulcer management. Appropriate antibiotic therapy is instituted in infected pressure ulcers. In an elderly frail patient who is susceptible to develop pressure ulcers, prevention is the most important aspect. Risk factor assessment on hospital visit and application of appropriate preventive measures, such as improving general health, minimizing external forces, and promoting educational programs about pressure ulcers to caregivers, are the keystones. The emphasis on quality nursing care is important in this regard.

DELIRIUM

Delirium is considered as an acute, fluctuating syndrome of altered mental status, unawareness to surroundings, and cognition precipitated by an underlying condition or event, in vulnerable persons. It is frequently described by using terms, such as altered mental status, acute confusional state, sundowning, encephalopathy, and acute organic brain syndrome. An episode of delirium can initiate a cascade of deleterious clinical events, in older adults and serious complications including prolonged hospitalization, loss of functional independence, reduced cognitive function, and death. History from various sources (family members, caregivers, etc.) and bedside observations are helpful in diagnosing the delirium. *Diagnostic and Statistical Manual of Mental Disorders (DSM-5) criteria for delirium include:*

A. A disturbance in attention (i.e., inability to direct, difficulties in focus, unable to sustain, and shift attention) and unawareness (reduced orientation to the environment).
B. The delirium develops over a short period of time (usually hours to a few days); baseline attention and awareness changes and fluctuation of severity occur during the course of a day.
C. Cognition disturbance (e.g., memory deficit, disorientation, language, visuospatial ability, or perception).
D. Criteria A and C changes are not explained by another preexisting, neurocognitive disorder and not explained in the context of a severely reduced level of arousal, such as coma.
E. History, physical examination, or laboratory findings confirm that the disturbances are due to multiple etiologies and as a result of direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e., due to a drug of abuse or a medication), or exposure to a toxin.

Multiple risk factors give rise to development of delirium. The risk factors are of two types: (1) predisposing factors (patient arrives with) and (2) precipitating factors (iatrogenic factors). In older people, dementia is the most prominent risk

factor and present in up to two-thirds of all cases of delirium. Severe medical illnesses; comorbid psychiatric disorder; such as depression, alcoholism, poor functional status, inactivity, malnutrition, male gender, hearing or vision impairment; and social isolation are the other predisposing factors. Common drugs which precipitate delirium are sedative hypnotics, narcotics, anticholinergic drugs, corticosteroids, and other psychoactive medications. Besides infection (urinary tract, lungs, skin, blood), metabolic disturbances (fluid, electrolytes, nutrition), polypharmacy, structural upsets (surgery, trauma, cardiac ischemia, central nervous system and pulmonary insults), and retention problems (fecal impaction, constipation) may be involved.

Assessment for Delirium

Clinically, in delirium, patients may be hyperactive (agitation, restlessness, hypervigilance), or hypoactive (apathetic, lethargic) or mixed. Delirium in the geriatric age group presents with subtle manifestations, such as incontinence (new onset), falls, immobilization, dysphagia, dysarthria, mild disorientation, and slowing in the speed of mental processing. The detailed history is important in assessing the delirium which should include the mental status change and search for potential predisposing, precipitating, or perpetuating factors, e.g., recent medication changes or signs of medical illnesses. For identifying the delirium the *confusion assessment method* is the most effective tool. A comprehensive physical examination of cardiorespiratory and neurologic systems is required to find out infectious diseases.

Treatment

Diagnosis and treatment of the underlying conditions remain the mainstay of managing the delirium in elderly. Whenever possible, medications, such as psychotropic, narcotic, and anticholinergic medications, should be reduced or discontinued. Physical illnesses should be treated on an urgent basis. Nonpharmacological measures are of great help in managing the delirium in older people, measures such as noise reduction; provision of soft lighting, clocks, and calendars; orienting the patient to time and place; appropriate powered eyeglasses and hearing aids are helpful in correcting sensory deficits and increasing the patient's sense of control which may reduce symptoms.

FUNCTIONAL DECLINE

The functional status of an elderly is determined by the ability to perform ADLs—self-care activities that a person performs daily, such as eating, dressing, bathing, ambulating, and toileting—and instrumental activities of daily living, which a person performs to live independently, such as shopping for groceries, meal preparation, housework, getting to places beyond walking distance, managing medications, managing finances, and using a telephone. Cardiopulmonary diseases, neurologic conditions, diabetes mellitus, cancer, obesity, dementia, affective disorders, ophthalmologic and auditory disorders, and fractures are the common health problems in the elderly, which cause a functional decline. In geriatric population, the active presence of various health issues (e.g., arthritis, stroke, heart disease) may have a more disabling effect than predicted in the day-to-day life and hampers the self-care also. An elderly patient commonly experiences reduced mobility and activity levels during hospitalization. Functional decline, including changes in physical status and mobility, has been identified as the leading complication of hospitalization for the elderly.

Assessment of Functional Status

History taking, with the emphasis on characterization of the functional disability itself and focusing on the course of functional decline, associated symptoms, and specific tasks that have been affected by the disability, including basic ADLs is important. An assessment of the existing comorbid conditions should be done, such as cognition, mood disorders, pain, poor nutrition, adverse medication reactions, sensory impairments, and muscular weakness. Contextual factors, including social support, financial resources, and environmental factors, should be assessed by the physician.

Treatment

Medical and surgical interventions should be undertaken promptly, if needed. These interventions typically increase the capacity and improve the quality-of-life (e.g., cataract surgery, hip replacement, oxygen supplementation, medications to improve cardiac output). Also, exercise, nutritional supplements, and prosthetic devices (e.g., hearing aids) greatly improve the overall functional status. Early mobilization protocols, timely removal of catheters, and reorientation programs should be undertaken during hospital stay itself before discharging the patient.

SUMMARY

With improvement in accessibility of healthcare to most of the population, people have started living longer; the prevention of disability in the elderly is the basis of healthy aging. Geriatric syndrome is a condition of "multifactorial health conditions with impairment of multiple systems in an older person vulnerable to situational changes." A geriatric syndrome comprises unique features of common health problems in older people with multifactorial and multiorgan systems involvement. These syndromes do not limit to one organ system or discipline-based boundaries, along with their multifactorial nature. Good history-taking, comprehensive physical examination, and specific management are necessary for assessing geriatric syndrome.

180 CHAPTER

Abuse or Neglect in Geriatric Population

M Sai Surendar

INTRODUCTION

Is there elder abuse in India? Elder abuse is not a problem in India. Our culture is respectful and supportive toward elders, hence protecting elders against the scourge of abuse. Old age has never been a problem for India as a value-based family system prevails in our country. *Role of elderly in society*: *Elderly* people have substantive experience throughout their lives. They play an important role in contributing to the knowledge capital of the society, emotional-spiritual guidance to a community. *What has sidelined the elderly*? The wisdom of elderly has been sidelined in the age of digital world. Techno smarts have eclipsed the wisdom of age and experience of the elderly population. Now it seems that the information held by most experienced members of the society is now uploaded into the cloud, easily googled with a few strokes on the keyboard. We need to understand the risk factors of mistreatment with the elderly (**Table 1**). The risk factors for the abuse can be divided into victims related, perpetrators related, relation based, and community based. The risk factors can be high or low. Understanding the risk factors of abuse will be helpful in taking preventing measures.

DEFINITION: ELDER ABUSE

The World Health Organization, 2002, defines elder abuse as "A single, or repeated act, or lack of an appropriate action occurring within any relationship where there is an expectation of trust, which causes harm or distress to an older person." This broader definition includes abuse by any person, including strangers.

Action: Harming a person or his/her property or assets—*abuse.*

Not acting: Not providing care or assistance when a person should have—also called *neglect.*

Mistreatment can be a single one-time action or continuous and repeated acts over a period of time. The issue is always the impact on the older person. Ask yourself, was the older adult hurt in some way? Elder abuse comes various forms, such as psychological, chemical, financial, sexual, spiritual, confinement, and neglect (**Fig. 1**).

TABLE 1: Risk factors for abuse.

	Risk factors	***Risk level***
Individual (victim)	• Functional dependence/disability	High
	• Poor physical health	High
	• Cognitive impairment	High
	• Poor mental health	High
	• Low income/financial dependence	High
Individual (perpetrator)	• Mental illness	High
	• Abuser dependency	High
	• Substance abuse	High
	• Victim–perpetrator relationship	Potential
	• Marital status	Potential

Physical Abuse

Inflicting physical pain or injury by hitting, slapping, shoving, burning, and forceful restrain comprise physical abuse. We may not often witness an elderly person get hit. What we are more likely to notice is the injury (bruises, broken bones, physical pain), or an older adult's fear of an abusive person. In a caregiving context, being unnecessarily rough or forceful is physical abuse. For example, shoving or pulling a person into a room, dressing a person by yanking his/her limbs into clothes, or roughly transferring a person from a bed to a chair or toilet. In each of these instances, the caregiver could be gentle with the person.

Chemical Abuse

Overmedicating a person, denying needed medication, or making medication decisions without consulting a doctor comprise chemical abuse. Chemical abuse is medication abuse. Too much or not enough medication can cause harm. When medication decisions are not for the well-being of an older person or when medication decisions are made without the consent of the person who needs the medicine or the legal substitute-decision-maker, then that is abuse. Medication abuse is most common when older adults have health problems that make it impossible or difficult for them to take care of themselves, fill prescriptions, or understand medical information. For example, denying an expensive medication to save money for inheritance could be mistreatment. On the

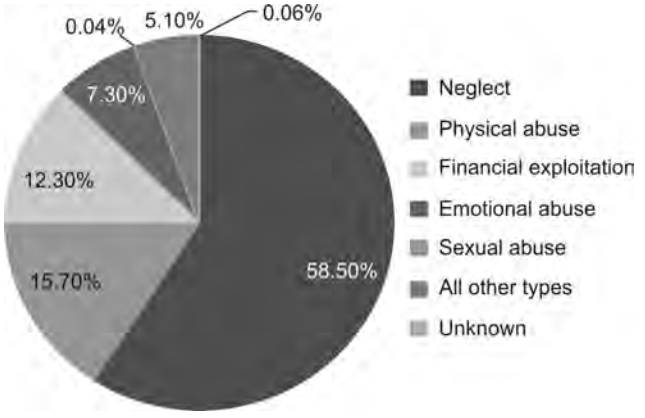

FIG. 1: Types of elder abuse.

flip side, giving them a higher dose of the medicine so that they become more docile and make fewer demands is also abuse.

Spiritual Abuse

Preventing a person from practicing his or her faith or forcing a person to participate in a spiritual ritual or to practice a religion comprises spiritual abuse. Our faith is an important part of who we are as people. When someone prevents an older person from practicing his or her faith and seeing people in a chosen faith community, then it is mistreatment. Prohibiting a person from going to church, mosque, or any other place of worship or from being involved in spiritual or religious practices of choice or forcing to practice a different religion or forcing a nonbeliever to follow a faith and its institutions can also be abusive. Forcing a person to participate in any religious or spiritual ceremony, event, or ritual could be elder abuse. Requiring a person to receive any form of spiritual-based healing would be abuse. Spiritual abuse is mentioned in very few laws, but it can go hand in hand with psychological abuse and can have a devastating effect on an older person.

Combinations

Emotional abuse often accompanies physical abuse or financial exploitation. Physical abuse often accompanies financial abuse.

NEGLECT

Neglect means failure to carry out a care-giving responsibility. *Passive neglect*: Unintentional failure. *Active neglect*: Intentional failure to provide care. Neglect is a complex idea. Basically, if a person depends on another person for care or assistance, and that person does not take proper care of the older person, that could be neglect. Assistance could be with food and nutrition, mobility, medication and medical appointments, and intimate activities, such as bathing and toileting. In some cases, assistance can mean finding a different helper if providing help is too difficult or time consuming for an individual.

STATISTICS OF GROUND REALITY

103.84 million people out of India's 1.21 billion population (census 2011) are senior citizens. Elder abuse is a silent pandemic. One in nine Americans over 60 years of age has experienced abuse, but only 1 in 23 cases of elder abuse in the US is reported. Most nations report that they still do not have a formal action plan to address elder abuse. A recent survey of 133 countries found that only 40% had national plans and only 17% had a national survey.

Reporting of abuse (WHO): Only 4% of elder abuse is reported. Elderly fear retaliation or worry about getting the abuser into trouble. Most of the elderly are mentally incapable and feel ashamed and embarrassed. Also, many countries do not have a proper system or have limited system where older people can turn for help. Most cases involve more than one form of abuse—79% involve psychological abuse, 54% financial abuse, 19% physical abuse, 17% neglect, and 1% sexual abuse. Major contributors of elder abuse are son (32.39%), relative (23%), daughter (14.5%), spouse (13.5%), stranger (7.04%), friend (5.16%), and neighbor (4.69). The perpetrators are often a family member—adult child or grandchild who is unemployed, addicted to alcohol and drugs and is mentally ill, or a socially irresponsible citizen. 67.3% of elder abuse victims are females as per the National Centre on Elder Abuse, Bureau of Justice.

Status in India: According to a rough estimate, nearly 40% of older population living with their families are reportedly facing abuse of one of the kind or other, but only 1 in 6 cases are reported. *Forms of abuse*: Disrespect—55%, verbal abuse—39%, economic exploitation—23%. Maintaining confidentiality of family matters is the main reason behind 45% of elders not reporting the abuse. Up to 23% of elders did not report abuse as they did not know how to deal with the problem. Up to 58% of elders experienced abuse in Madurai. 61% of them lived with family (HelpAge India report).

IDENTIFY ELEDR ABUSE IN THE EMERGENCY DEPARTMENT

A victim may be unable or unwilling to tell you that abuse is occurring in view of relationship to, or fear of, the abuser, which may affect the victim's willingness to pursue arrest. It is very important that an emergency physician recognizes signs of abuse in the victim. Inadequately explained bruises, cuts, burns, dehydration, and malnutrition could be some of the signs.

Overly medicated or sedated, unusual confinement, lack of grooming, fear of speaking for oneself, shame, fear, embarrassment, inadequate medical supplies leads to worsening health despite a treatment plan. Behavioral signs of abuse or neglect also need to be looked for. During the physical examination, note the size, shape, and location of all injuries. Photographing the injuries is helpful for forensic documentation.

PREVENTION OF ELDER ABUSE

Avoid living with a person with a history of abuse or violence. Beware of financial motifs of the family members. Elder should take appropriate measures (**Fig. 2**). They should stay social, expand their friend network, invite friends and relatives at home, and try new activities to make new friends. They should keep in touch with old friends and neighbors if a case of relocation is involved. They should be careful while signing any documents and take the help of a trusted one. They should not interfere with the lives of the younger generation and unnecessarily instruct them.

Caregiver interventions: This is a promising approach to prevent elder abuse, thus assisting them in housekeeping, meal preparation, education, and day care, which should be promoted as abuse-prevention strategies.

Stay social and expand friend circle
Do not interfere in lives of younger. Do not instruct or complain unnecessarily
Invite friend and relatives at home. Try new activities
What the elderly should do?
Do not sign any paper unless reviewed by trusted one
Keep in touch with old friends and neighbors

FIG. 2: Measures to prevent abuse.

Emergency shelter: Providing emergency shelter to battered elderly especially women is a hallmark intervention. However, shelter homes are not designed to accommodate older women with physical health problems or dementia. These shelter homes offer temporary relocation for victims, providing not only a safe environment but also a medically appropriate one.

Money management program: This is offered to individuals with financial exploitation. Assistance is given in paying bills, making bank deposits, and paying home care personnel. This intervention is promising, as the preventive potential is high and targeted to groups at high risk for financial exploitation and in particular individuals with some degree of cognitive impairment and who are socially isolated. Since this program is carried out by well-trained and accredited money managers, the risks of adverse outcomes are low.

Helplines

Telephonic helplines is one of the most widely effective interventions, which allow individuals to seek advice and assistance regarding elder abuse. Helplines are typically staffed by trained volunteers or professionals and facilitate early intervention that can prevent mistreatment.

Helplines have the advantage of in that that callers remain anonymous if they choose to because many elders experience shame about the abusive situation.

Multidisciplinary Teams

Multidisciplinary teams, including criminal justice, healthcare, mental healthcare, victim services, civil legal services, adult protective services, financial services, and long-term care, are helpful in proxy decision-making, coordinating care and reducing fragmentation, leveraging resources, increasing professional knowledge, and improving outcomes.

LEGAL FRAMEWORK

Hindu Personal Law: "The statutory provision for maintenance of parents under Hindu personal law is contained in Sec 20 of the Hindu Adoption and Maintenance Act, 1956."

Muslim Personal Law: "Children in easy circumstances are bound to maintain their parents even if they are able to earn."

The Code of Criminal Procedure (CrPC): "CrPC 1973 is a secular law and governs persons belonging to all religions and communities." "Daughters, including married daughters, also have a duty to maintain their parents." "Maintenance and Welfare of Parents and Senior Citizens Act, 2007, has also been there to provide legal assistance and help to senior citizens of our country."

SUMMARY

Older persons should be able to live with dignity and security and should be free from exploitation and mental and physical abuse. Every geriatric patient gives us an opportunity to look for abuse and to create awareness in the patient and his/her family about abuse. Resuscitation studies document no difference in the percentage of successful outcomes across the age spectrum. Elderly patients who survive are no more likely to sustain irreversible brain injury than younger patients. Unless there is a well-defined advance directive, there should be no discrimination based on age in resuscitating elderly patients in cardiac arrest.

181 CHAPTER

Drug Therapy in a Geriatric Patient

Phraewa Thatphet

INTRODUCTION

The progression of medical technology and innovation makes human lives longer. The global proportion of the aging group of people increases every year as well as in the emergency department (ED). Geriatric patients account for up to one fourth of emergency patients. Unfortunately, research reveals that physicians still cannot treat this group of patients appropriately. Using drugs with potential adverse effects, polypharmacy, and adverse drug events (ADEs) are common problems in the elderly. These misconceptions of drug use in the elderly have caused many adverse effects and complications. This chapter aims to provide the principle of appropriate drug use in the elderly to enhance their good care taking. This chapter will highlight common and preventable clinical issues, which are prescribing inappropriate medication, polypharmacy, and ADE.

PHYSIOLOGIC CHANGES

Physiological changes due to aging affect both pharmacokinetics and pharmacodynamics. Understanding these processes will help physicians to optimize the choice of drugs, route, and dose in elderly patients.

Pharmacokinetics

The pharmacokinetic of drugs is divided into four main categories: (1) Absorption, (2) Distribution, (3) Metabolization, and (4) Excretion.

Absorption

The older adult will have decreasing gastrointestinal blood flow and motility, increasing gastric pH, and decreasing gastric acid secretion. But overall absorption function is not significantly changed in the elderly.

Distribution

The elderly has less lean body mass compared to the younger adult. This may affect the drug that binds to the muscle, for example, digoxin which can enhance toxicity even in a dose lower than expected. Older people also increase total body fat and decrease total body water. These affect the distribution of the drug. The hydrophilic drugs, for example, lithium, digoxin, and aminoglycosides, may decrease the volume of distribution and have higher initial serum concentration. On the other hand, lipophilic drugs, for instance, benzodiazepines, phenytoin, and propranolol may increase the volume of distribution and increase accumulation and prolong half-life. Aging people also decrease in plasma protein binding which leads to increase in free fractions of protein-binding drugs, for example, warfarin, diazepam, and furosemide. Older adults with malnutrition or having liver disease may affect albumin levels leading to decreased volume distribution and higher serum concentration in drugs with high protein binding. For example, ceftriaxone, furosemide, phenytoin, diazepam, ibuprofen, digoxin, and warfarin can lead to toxicity.

Metabolization

The liver is the main organ for metabolization in many drugs. Advanced age associated with decrease hepatic mass and blood flow. Decreasing blood flow affects metabolization with the first-pass mechanism and leads to increased bioavailability of the drug. Some of the drugs in this group that are commonly used in the elderly are calcium channel blockers, beta-blockers, nitrates, a tricyclic antidepressant, and hydralazine. Decreasing hepatic mass and number of functional hepatocytes slow down the metabolization of drugs and increase half-lives, for instance, acetaminophen, diazepam, nifedipine, and theophylline. The hepatic function of enzymes usually does not significantly change, but it can be affected with the co-congestion of multiple drugs that are metabolized with the same enzymes or with the consumption of a large amount of one type of drug. Cytochrome P450 is one of the enzymes that has a major role in drug metabolization, and it changes in the oxidative phase in an older adult which affect many drugs, for example, diazepam, amitriptyline, and alprazolam.

Excretion

The renal system is responsible for the excretion function. Unfortunately, renal function decreases with age even in the normal adult. The glomerular filtration rate (GFR) declines by about 8 mL/min/1.73 m^2 per decade after 40 years of age. Using serum creatinine alone is not reliable to estimate renal function

in older adults since it was affected by decreased muscle mass and muscle wasting. The Cockcroft–Gault formula is a useful tool to calculate GFR in an older adult as it uses the age, weight, and gender of the patient in the calculation. Even if a study showed that the Cockcroft–Gault equation overestimated GFR by 16%, it still remains handy and is a useful tool to use in the ED. In older age group, decrease in renal functions and clearance ability resulting the drug accumulation and toxicity of many drugs, e.g., aminoglycoside, lithium, morphine and ketorolac. Many drugs should be avoided in the elderly patients who have declined creatinine clearance, for example, ciprofloxacin, apixaban, dabigatran, enoxaparin, fondaparinux, rivaroxaban, gabapentin, pregabalin, tramadol, ranitidine, and colchicine.

Pharmacodynamics

The change in pharmacodynamics in an older adult can be explained from the decrease in the number of receptors or affinity or changes in postreceptor response which leads to a decrease or increase in sensitivity; another reason behind the change in pharmacodynamics is that physiologic and homeostatic mechanisms impairment with age. Patient can develop increase or decrease in sensitivity for a partcular drug. For beta-agonists, beta-blockers, furosemide, and various vaccines, the sensitivity decreases with advance age; on the other hand, benzodiazepines, dopaminergic agents, H1 antihistamines, metoclopramide, neuroleptics drugs, opioids, and warfarin have more sensitivity with aging.

Moreover, older people with malnutrition have some chance to alter the absorption and bioavailability of drugs as well as increase the toxicity of some drugs from dehydration and electrolyte imbalance.

COMMON PROBLEMS OF DRUG USE IN AN OLDER ADULT

Since there are many changes in the older adult, it leads to problems associated with aging change. There are many problems or ADEs related to medication use in the elderly, for example, polypharmacy, adverse drug reaction (ADR), medication nonadherence, over-the-counter drug, herb and remedies usage, drug treatment failure, medication error, prescribing inappropriate drug, inappropriate dosage, inappropriate medical handling, adverse drug withdrawal event, drug–drug interaction, drug–food interaction, untreated indication, and treatment without indication. The problems can be categorized into problems due to medical provider–related factors, drug-related factors, and patient-related factors. Some problem related to these factors are shown in **Figure 1**.

PRESCRIBING INAPPROPRIATE MEDICATIONS

Prescribing inappropriate medication (PIM) is a crucial issue for geriatric care. There was an estimate that half of the elderly patients were prescribed at least one potentially inappropriate medication with increasing prevalence during the past decade. Due to physiological changes listed above, the physician should bear in mind that the effect of medications used in a younger adult might not have the same effect as in the older people and sometimes can cause the risks. Using inappropriate medication in an elderly adult is associated with higher costs, ADEs, poorer health-related quality-of-life, falling, readmission to the ED, hospitalization, and even death. *Many tools are being used to assess inappropriate medications. Two of the most validated and practical tools for use in the ED are Beers and STOPP/START (Screening Tool of Older Persons' Prescriptions/ Screening Tool to Alert to Right Treatment) criteria, respectively.*

Beers Criteria

Beers criteria were developed by the American Geriatrics Society. The latest version was revised and launched in 2019. It contains the information about medications that are potentially inappropriate in most older adults, those that should typically be avoided in older adults with certain conditions, drugs to use with caution, drug–drug interactions, and drug–dose adjustment based on kidney function. **Table 1** lists some of the potentially inappropriate medication use in older adults that are frequently used in the ED.

Moreover, some medications have drug–disease or drug–syndrome interactions which should be avoided in patients with specific underlying conditions. Commonly used drugs have been listed in **Table 2**.

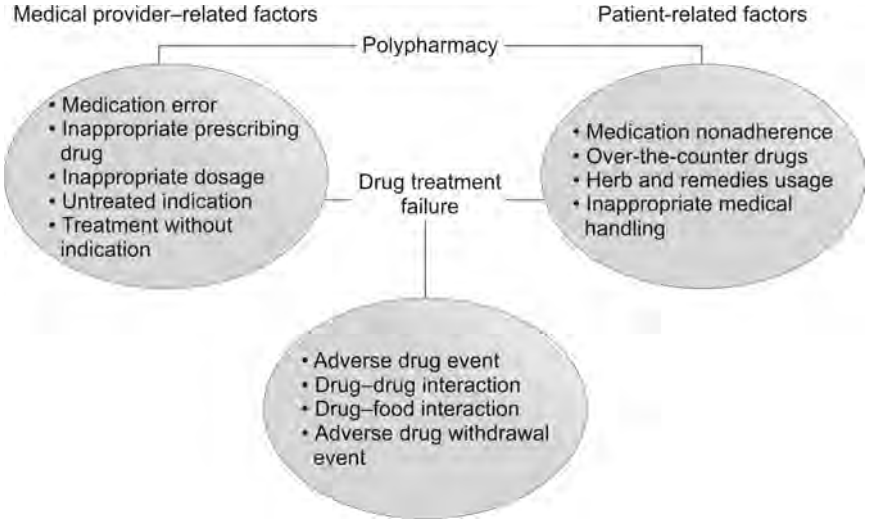

FIG: 1: Problems related to medication use in the elderly.

TABLE 1: Potentially inappropriate medications commonly used in older adults which should be avoided.

Drugs	*Recommendation*
• Anticholinergics First-generation antihistamines: ○ Chlorpheniramine ○ Cyproheptadine ○ Dimenhydrinate ○ Diphenhydramine (oral)	Avoid
Antiparkinsonian agents: Benztropine (oral)	Avoid
Antispasmodics: Hyoscyamine	Avoid
Cardiovascular: Digoxin	Avoid this rate control agent as first-line therapy for AF and HF
Amiodarone	Avoid as first-line therapy for AF unless the patient has HF or substantial LVH
• Central nervous system Antidepressants, alone or in combination: ○ Amitriptyline ○ Nortriptyline	Avoid
Antipsychotics, first (conventional) and second (atypical) generations	Avoid, except in schizophrenia or bipolar disorder, or for short-term use as antiemetic during chemotherapy
Barbiturates: Phenobarbital	Avoid
• *Benzodiazepines* • *Short and intermediate acting:* ○ Alprazolam ○ Lorazepam • *Long acting:* ○ Clonazepam ○ Diazepam	Avoid
Endocrine: Insulin, sliding scale	Avoid
Sulfonylureas, long-acting: Glyburide (Glibenclamide)	Avoid
Gastrointestinal: Metoclopramide	Avoid, unless for gastroparesis with the duration of use not to exceed 12 weeks
Proton-pump inhibitors	Avoid scheduled use for >8 weeks unless for high-risk patients
Pain medications: Meperidine	Avoid
• *Noncyclooxygenase-selective NSAIDs, oral:* ○ Aspirin > 325 mg/day ○ Diclofenac ○ Ibuprofen ○ Mefenamic acid ○ Naproxen	Avoid chronic use, unless other alternatives are not effective and the patient can take gastroprotective agent (proton-pump inhibitor or misoprostol)
Indomethacin *Ketorolac*	Avoid
Skeletal muscle relaxants: Orphenadrine	Avoid

(AF: atrial fibrillation; HF: heart failure; LVH: left ventricular hypertrophy; NSAIDs: nonsteroidal anti-inflammatory drug)

Besides the previous list of drugs, some medications should be used with caution in the older adult, for instance, aspirin (for primary prevention of cardiovascular disease and colorectal cancer), dabigatran, rivaroxaban, prasugrel antipsychotics, carbamazepine, diuretics, SNRIs, SSRIs, TCAs, tramadol, dextromethorphan/quinidine, and trimethoprim-sulfamethoxazole.

Elderly people tend to have more diseases and need more medication groups of treatment. BEERS criteria also list potentially clinically important drug–drug interactions that should be avoided in older adults. Some of the common drugs are listed in **Table 3**.

Avoid using drugs in the same class because most of the ADEs are dose dependent.

Beers criteria also pay attention to drugs with strong anticholinergic properties that can cause serious adverse effects in the elderly, for example, delirium, falls, hospitalization, and death. Common uses of drugs in this group are amitriptyline, nortriptyline, promethazine, antihistamines (first generation), hyoscyamine, benztropine, chlorpromazine, and orphenadrine.

STOPP/START Criteria

STOPP/START criteria were developed by the European multidisciplinary specialists. These were adapted from the Beers criteria by aiming at avoidance of medications that cause or contribute to adverse effects and hospitalization in older adults. The criteria updated the medications commonly used in Europe and have been last revised in 2015. STOPP contains the list of medications that have drug–drug and drug–disease interactions, drugs that increase the risk of falls, and drugs which duplicate therapy. Some examples of drugs listed in STOPP criteria which are frequently prescribed in the ED are listed in **Box 1**.

STOPP criteria also describe drugs that affect elderly people who are prone to fall. These drugs are benzodiazepines, neuroleptic drugs, and vasodilator drugs with persistent postural hypotension.

Opioid usage is one of the most concerned points in the general population as well as in the elderly. STOPP criteria give the suggestion not to use long-term powerful opiates, e.g., morphine or fentanyl as first-line therapy for mild-to-moderate pain, and regular opiates for >2 weeks in those with chronic constipation without a concurrent laxative.

STOPP criteria also suggest to avoid using drugs in the same class (duplicate drug classes).

There is some intersection between BEERS and STOPP criteria. Anyway, the physician should use both tools as a guide to correlate with the patient's clinical condition and judge for the risk–benefit of the patients.

START criteria are criteria about medications that should be considered in patients aged 65 years old or more with a specific condition and no contraindication. Example of the medications which can be started in the ED are listed in **Box 2**.

POLYPHARMACY

There are various definitions of polypharmacy, both from using unnecessary medication or from using too many medications. In general, polypharmacy is defined as using 5 or more medications and hyperpolypharmacy is using 10 or more medications.

TABLE 2: Medications should be avoided in older adults with certain medical conditions.

Disease or syndrome	*Drug(s)*	*Recommendation*
Heart failure	Avoid in heart failure with reduced ejection fraction: Nondihydropyridine CCBs (diltiazem, verapamil)	As noted, avoid or use with caution
	Use with caution in patients with heart failure who are asymptomatic; avoid in patients with symptomatic heart failure: NSAIDs and COX-2 inhibitors	
Syncope	• AChEIs • Nonselective peripheral alpha-1 blockers (i.e., doxazosin, prazosin) • Tertiary TCAs • Antipsychotics: ○ Chlorpromazine ○ Olanzapine	Avoid
Delirium	• Anticholinergics • Antipsychotics • Benzodiazepines • Corticosteroids (oral and parenteral) H2-receptor antagonists: ○ Cimetidine ○ Ranitidine • Meperidine	Avoid
Dementia or cognitive impairment	• Anticholinergics • Benzodiazepines • Antipsychotics	Avoid
History of falls or fractures	• Antiepileptics • Antipsychotics • Antidepressants: ○ TCAs ○ SSRIs ○ SNRIs • Opioids	• Avoid unless safer alternatives are not available; avoid antiepileptics except for seizure and mood disorders • *Opioids:* Avoid except for pain management in severe acute pain
Parkinson disease	• Antiemetics: ○ Metoclopramide ○ Promethazine • All antipsychotics (except quetiapine, clozapine, pimavanserin)	Avoid
History of gastric or duodenal ulcers	• Aspirin > 325 mg/day • Non-COX-2-selective NSAIDs	Avoid unless other alternatives are not effective and the patient can take a gastroprotective agent (i.e., proton-pump inhibitor or misoprostol)
Chronic kidney disease stage 4 or higher (creatinine clearance <30 mL/min)	NSAIDs (non-COX and COX selective, oral and parenteral, nonacetylated salicylates)	Avoid

(AChEIs: acetylcholinesterase inhibitors; CCBs: calcium channel blockers; COX: cyclooxygenase; NSAIDs: nonsteroidal anti-inflammatory drug; SNRIs: serotonin-norepinephrine reuptake inhibitors; SSRIs: selective serotonin reuptake inhibitors; TCAs: tricyclic antidepressants)

About 30% of adults older than 65 years of age take five or more medications.

Polypharmacy can be caused due to many reasons, ranging from necessary reasons, such as multiple comorbidities of the patients, to unnecessary and preventable reasons, such as prescribing cascade and uncoordinated care. Prescribing cascade happens when the physician misinterprets the adverse effect of one medication as new symptom and adds a new medication to treat the symptom which leads to new more adverse effects. For example, the doctor starts treatment for gout after the patients have hyperuricemia from thiazide diuretics or misinterpret extrapyramidal effects from metoclopramide to Parkinson's disease and start the treatment with levodopa. This can happen due to an incomplete review of the previous drug list (medical discrepancies) or unawareness of the potential adverse effects of prescribed drugs. Medical

TABLE 3: Potentially clinically important drug–drug interactions that should be avoided in older adults.

Object drug and class	*Interacting drug and class*	*Risk rationale*	*Recommendation*
Opioids	Benzodiazepines	Increased risk of overdose	Avoid
Opioids	Gabapentin, pregabalin	Increased risk of severe sedation-related adverse events, including respiratory depression and death	Avoid
Corticosteroids (oral or parenteral)	NSAIDs	Increased risk of peptic ulcer disease or gastrointestinal bleeding	Avoid; if not possible, provide gastrointestinal protection
Lithium	ACEIs or loop diuretics	Increased risk of lithium toxicity	Avoid; monitor lithium concentrations
Phenytoin	Trimethoprim-sulfamethoxazole	Increased risk of phenytoin toxicity	Avoid
Theophylline	Cimetidine or ciprofloxacin	Increased risk of theophylline toxicity	Avoid
Warfarin	Amiodarone, ciprofloxacin, macrolides (excluding azithromycin), trimethoprim-sulfamethoxazole, NSAIDs	Increased risk of bleeding	Avoid when possible; if used together, monitor INR and bleeding closely

(NSAIDs: nonsteroidal anti-inflammatory drug; ACEI: angiotensin-converting-enzyme inhibitors; INR: international normalized ratio)

BOX 1: Potentially inappropriate prescription in older adults.

- *Cardiovascular system:*
  - Digoxin at a long-term dose >125 μg/day with impaired renal function (eGFR < 50 mL/min)
  - Loop diuretic for dependent ankle edema or as first-line monotherapy for hypertension
  - Beta-blocker in combination with verapamil
  - Aspirin with a past history of peptic ulcer disease without histamine H2 receptor antagonist or proton-pump inhibitor
  - Aspirin at dose >150 mg/day
  - Warfarin for first, uncomplicated deep venous thrombosis for >6 months or for first uncomplicated pulmonary embolus for >12 months
- *Central nervous system and psychotropic drugs:*
  - TCA with dementia/glaucoma/cardiac conductive abnormalities/constipation/an opiate or calcium channel blocker/prostatism or prior history of urinary retention
  - Long-term (i.e., >1 month), long-acting benzodiazepines and benzodiazepines with long-acting metabolites
  - Long-term (i.e., >1 month) neuroleptics as long-term hypnotics or in those with parkinsonism
- *Gastrointestinal system:*
  - PPI for peptic ulcer disease at full therapeutic dosage for >8 weeks
  - Anticholinergic antispasmodic drugs with chronic constipation
- *Respiratory system:* Theophylline as monotherapy for COPD
- *Musculoskeletal system:* NSAID with history of a peptic ulcer disease or GI bleeding, unless with concurrent H2 receptor antagonist, PPI or misoprostol/moderate-severe hypertension/heart failure/chronic renal failure/with warfarin/or long-term use (>3 months) for symptom relief of mild osteoarthritis
- *Urogenital system:* Bladder antimuscarinic drugs with dementia/chronic glaucoma/chronic constipation/chronic prostatism
- *Endocrine system:*
  - Glibenclamide or chlorpropamide with type 2 diabetes mellitus
  - Beta-blockers in those with DM and frequent hypoglycemic episodes

(COPD: chronic obstructive pulmonary disease; NSAIDs: nonsteroidal anti-inflammatory drug; PPI: proton-pump inhibitor; TCAs: tricyclic antidepressants)

discrepancies occurred in 71% of patients transferred to a skilled nursing facility. The unawareness of potential adverse effects of prescribing drugs is another cause of prescribing cascade. The doctor should be familiar with the adverse effects of common drug use in the elderly to prevent the prescribing cascade.

UNCORDINATED CARE

With advanced age, people tend to have more comorbidities. People aged 65 years old or more have three or more underlying diseases and one fifth have five or more. With more diseases, patients visit more specialists. Sometimes, patients seek for

BOX 2: Medications that should be considered in older adults with specific conditions.

- *Cardiovascular system:*
  - Warfarin in the presence of chronic AF or aspirin when warfarin is contraindicated
  - Aspirin or clopidogrel with a history of atherosclerotic coronary, cerebral or peripheral vascular disease in patients with sinus rhythm
  - Antihypertensive therapy where systolic BP consistently >160 mm Hg
  - Statin therapy with a history of coronary, cerebral, or peripheral vascular disease, where functional status remains independent for activities of daily living and life expectancy is > 5 years
  - ACE inhibitor with chronic heart failure
  - ACE inhibitor following acute myocardial infarction
- *Respiratory system:* Regular inhaled beta 2 agonist or anticholinergic for mild-to-moderate asthma or COPD
- *Central nervous system:* Antidepressant with moderate-severe depressive symptoms
- *Gastrointestinal system:* Proton pump inhibitor with severe GORD or peptic stricture requiring dilatation
- *Musculoskeletal system:* Calcium/vitamin D supplement in patients with osteoporosis (fragility fracture, dorsal kyphosis)

(ACE: angiotensin converting enzyme; AF: atrial fibrillation; GORD: gastroesophageal reflux disease)

a second opinion (doctor shopping) or get over-the-counter drugs when they are not satisfied with the treatment or when a new/uncontrolled symptom emerges. All of these reasons can lead to getting the same group of drugs or even the same drug if the medical personnel fail to explore a thorough list of the patient's current medication. This issue can occur with the patient who has been transferred to a different level of care or a different healthcare facility.

ADVERSE DRUG EVENT

Adverse drug event or adverse drug reaction is an unintentional unwanted effect from drug use. More than one -third of community-dwelling older adults experienced ADR. In the decade from 2004 to 2014, the incidence of ADR increased from 20,000 to 450,000 ED visits per year. 28% of hospital admissions of older people in the United States are a result of drug-related problems, up to 70% of which are attributed to adverse reactions to drugs. These can be varied from mild to lethal. There are multiple risk factors of ADR in the elderly, for example, age more than 85 years old, frailty, low body weight or body mass index, six or more chronic health conditions, memory problems, estimated creatinine clearance (CrCl) <50 mL/min, nine or more medications (including prescribed and over-the-counter drugs), 12 or more doses of medication, prior ADR, multiple prescribers, multiple pharmacies, no regular review of patient's medication list, poor communication among providers, and prescription of a complex medical regimen. Common drugs associated with ADE in the older adult are anticoagulants, antipsychotics, nonsteroidal anti-inflammatory drugs, cardiovascular medications, diuretics, anticonvulsants, benzodiazepines, and hypoglycemic medications. From 2013 to 2014, an estimated 34.5% of ED visits related to ADEs occurred among older adults, with anticoagulants, antibiotics, and diabetic agents being responsible for an estimated 46.9% of these visits.

PRINCIPLES OF GERIATRIC DRUG USE

As described above, there are many problems due to medication usage in the elderly and most of them are preventable. These principles will help the physician to decrease adverse events from drug use and also save the cost of unnecessary medication usage and complications of treatment.

- *Start the medication only when having proper indication*: The physician should consider before starting any new medication and make sure that there is a proper indication to start a new drug. Always check for the current medication(s) to avoid "prescribing cascade." Consider if there are other nonpharmacologic treatments for that condition which can delay or lower the dose of medication and decide how long to use the medication; also consider if the medication will be used only for relief of an acute symptom or will be used for treating the chronic disease.
  On the other hand, the physician should not withhold starting medication when there is a proper indication and should not be under treatment because of the fear of adverse effects. Elderly patients tend to get undertreatment as compared with an adult and it can lead to adverse events too. For example, undertreatment of pain can affect activities of daily living, functional impairment, falls, depression, decreased appetite, impaired sleep, and social isolation. Delay in starting preventive medication leads to disease progression or adverse events may occur. Therefore, the physician should use the best evidence from history taking, physical examination, investigation results, combination with life-expectancy, and goal of the life of patient and caregiver.
- *Explore for contraindication*: Before starting any new medication, the doctor should check for all possible contraindications, look for drug–drug or drug–disease interaction, and advise patients and/or caregivers about relative contraindications compared to risk–benefit together. Not only before starting new drugs, but the physician should also consider discontinuing medication if there is any change in the patient's conditions, e.g., change in renal function or worsening of comorbidity.
- *Discontinue unnecessary therapy*: Elderly patients are prone to have more comorbidities; due to this condition, attending more than one specialist is not uncommon in the elderly. Sometimes, the physician feels uncomfortable to discontinue the drugs prescribed by other doctors, especially from another specialist. The necessity of the current drugs should be understood and the physician should consider to stop these when there is no further indication to use them in the patients which include the data of age group, comorbidity, life expectancy, goal of the life of the patients, possible adverse effect outweighing the benefit of the drug, the patient developing adverse effect sign or symptom that may be related to the drug, or if there is another drug that may be superior to the current one. Moreover, the physician should check if the dose

can be reduced, for example, when the drug reaches the ceiling effect or when the renal function is deteriorated. With thorough consideration, more than half of the drug can be discontinued without significant adverse outcomes or death. Over-the-counter drugs are easy for patients to access drugs. Some patients use over-the-counter drugs concurrent with prescribing drugs without knowing that they are the same drugs because of the different trade names. Sometimes, the patient seeks further medication because the prescribing drug has delayed onset to effect the symptom he/she wants to relieve. Patient education about medication onset and schedule for follow-up after prescribing can decrease risk from inappropriate over-the-counter drugs.

Discontinuation of unnecessary drugs can be done in hospitalization, care transition (hospital to home, home to the nursing facility, referral to another level of care), or follow-up period. The primary doctor who has a long relationship with patients and caregivers has a higher chance to talk and explore the patients' drugs. In the setting of the ED, the physician does not usually have enough time to approach all the medications of the patients. Help from multidisciplinary, for example, registered nurse or pharmacist, proves to be helpful in such a case.

- *Herbal remedies and dietary*: Herbal remedies and dietary supplements are not uncommon in older adults. One study found that almost three fourths of patients aged 75 years old and older use at least one of the prescribed drugs and one dietary supplement. Most of the times physician rarely asks the patient about these supplements, some of these supplements can cause durg interactions as well. An example of common drug interaction with a dietary supplement is taking warfarin with ginkgo biloba which can increase the risk of bleeding while taking warfarin with St John's wort can decrease the efficacy of anticoagulation. St John's wort can also increase the risk of serotonin syndrome if the patient takes it with serotonin-reuptake inhibitors. The physician should ask the patients about the current use of herbal remedies or dietary supplement or use brown-bag methods by asking them to bring all of their current medications including over-the-counter drugs and herbal agents to healthcare visits to check for unnecessary and potentially harmful drugs.
- *Start low and go slow*: Due to changes in the patient's physiology, geriatric patients are sensitive to the bioavailability of drug and adverse effects. The physician should consider starting a new drug with a lower dose compared to younger adults and use a shorter follow-up period to adjust the dose. Anyway, the initial dose should reach the therapeutic goal of the symptom or disease that requires treatment.
- *Patient education*: This can help in drug adherence, decrease adverse effects from seeking further over-the-counter drug, and increase the efficacy of the drug. Patient education should include discussion of dosing, scheduling, expected results of the medication, risks, interactions, and an assessment of patient understanding of proper use of the medications.
- *Follow-up*: The physician should schedule a follow-up for the patient to assess the efficacy of the drug, adverse effect of the drug, adherence of the drug, and time point to discontinue the medication.

SUMMARY

Medication usage in the patients is complicated due to changes in physiology with advanced age. The physician should be familiar with the changing processes and concerns about proper prescription and follow-up to decrease the risk of adverse events and to increase the efficacy of the treatment.

182 CHAPTER

Pain Management in a Geriatric Patient

Elif Dilek Cakal, Mohammad Anzal Rehman, Arif Alper Cevik

INTRODUCTION

The world's population is aging. The global life expectancy at birth has reached 72.3 years. The total number of people aged 65 years or above was 703 million in 2019 and is projected to double to 1.5 billion in 2050. The portion of older adults in the global population will increase from 9 to 16% in the same time frame. Furthermore, people over 80 years of age will proceed from 20–28% of the geriatric population. These estimations suggest that older patients will become an increasing part of medical practice in the upcoming decades.

Emergency departments (EDs) play a significant role in providing health care to older adults. 12–21% of all ED visits are geriatric patients. 32–51% of these ED visits result in hospital admission. In 2017, 22.1% of people aged 65 years or older and 27.6% of people aged 75 years or older had at least one visit to an ED in the United States of America (USA). In 2003, per 100 population, people aged 75 years or older visited EDs approximately 64 times in the USA and 73 times in Ontario, Canada. The widespread use of EDs among older adults warrants that emergency physicians must be prepared to manage geriatric care.

Overall, pain is shown to be the most frequent geriatric chief complaint on presentation to the ED in various series. In one study, while abdominal pain, chest pain, and headache were the most frequent disease-related types of pain, headache, hip pain, and back pain were more prominent in older adults who presented with an injury. In addition to acute complaints, older patients with persistent pain often seek relief in the ED. The considerable need for pain control in daily practice makes it an essential skill of geriatric care in the ED.

UNDERTREATMENT OF PAIN

Studies show that pain is undertreated in all age groups in the ED, but older adults face a higher risk of oligoanalgesia. Compared to younger adults, older adults tend to report less severe pain, get discharged with more severe pain, and have a lower pain reduction in the ED. Also, older adults are less likely to receive analgesics in the ED and at discharge. Overcrowding seems to further increase time to pain assessment and treatment, the portion of patients who received no analgesia, treatment with inappropriate analgesics, and inadequate documentation. Despite pain being among the top chief complaints in older adults, the quality of pain management in the ED remains problematic.

Untreated and undertreated pain in older adults is a multifaceted problem and has an impact on patients, caregivers, the healthcare system system, and the society as a whole. Older adults with chronic pain suffer from adverse functional, physiological, and psychological consequences. Persistent pain in an older adult is associated with increased frailty, social isolation, dependency, neuropsychiatric disorders, sleep disturbances, and decreased functional capacity and quality-of-life. In addition to patients, caregivers of geriatric patients with chronic pain are also susceptible to physical morbidity and physiological distress. Inadequate pain management decreases patient satisfaction in the ED and increases return visits and health care costs. Therefore, managing pain adequately is essential in this age group.

UNDERSTANDING PAIN IN ELDERLY

Pain is a common but sophisticated complaint. It has been traditionally defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." Pain may be defined as acute or chronic based on its duration. Acute pain is transient, reversible, and considered useful for survival as it is generally provoked by a threat to the organism, such as a disease or injury. In contrast, chronic or persistent pain is deemed to be a multidimensional syndrome and refers to pain that lasts longer than three months. However, more importantly, chronic pain outlasts the normal healing process, even if it was initially associated with a lesion.

The pain process starts with mechanical, chemical, and thermal irritations to nociceptive fibers; emotional, social, and cultural experiences affect how this sensory is processed in the brain and result in an individual emotional and behavioral response. The fact that pain is inherently subjective and multifactorial poses challenges with the assessment of pain. Physicians have to assess what the patient is experiencing by observing his/her verbal or nonverbal expressions or via self-report or non-self-report measures. Especially in older adults with limited communication, the need for caregiver's interpretation adds to this complexity.

DIFFERENCES OF PAIN MANAGEMENT IN THE ELDERLY

The perception and expression of pain are greatly altered in older adults due to physiological, mental, and social differences. An altered pain process in the peripheral and central nervous systems with normal aging makes pain severity and localization less accurate. In practice, it frequently translates to a lower intensity and atypical abdominal and chest pain of potentially life-threatening origins. In addition to physiological changes, cultural background and personal misconceptions and fears related to pain alter how the pain is perceived and communicated. A common misconception among older adults is that pain is an integral part of aging or chronic diseases. Some may see pain medication as the last resort and avoid asking for treatment for fear of adverse effects or addiction. Training physicians about geriatric pain, institutional strategies, and creating an accessible healthcare system will help to overcome these challenges.

Pharmacologic treatment of pain is also altered due to physiological changes with normal aging. As a general rule, older adults are more sensitive to both the therapeutic and the toxic effects of drugs. The aging-related physiologic changes and their impact on pharmacokinetics are summarized in **Table 1**.

Also, comorbidities increase with age and affect pain management on many levels. Many comorbidities such as hepatic, renal, neurodegenerative, and cardiovascular diseases warrant a careful choice of drugs, dosing, and route of administration. Diseases that alter mental capacity and disabilities, including visual, hearing, and speech impairments, further complicate the assessment of pain and compliance to therapy. Lastly, aging and comorbidities are associated with polypharmacy, which increases the likelihood of adverse reactions and must be taken into consideration when prescribing drug therapies to older adults with comorbidities.

PAIN ASSESSMENT

Elderly patients presenting with pain to the ED are at an increased risk of receiving suboptimal pain management. The disparities in management for these patients stem largely from the unique difficulties in the assessment of pain in this population. In order to ensure the best pain control and patient-oriented outcomes, the provider responsible for older adults in the EDs should attempt to overcome the following barriers during pain assessment:

- *Misconceptions*: Elderly patients, and indeed even some of their healthcare providers, tend to adhere to the traditional belief that pain is a normal consequence of aging. However, despite the increased prevalence of chronic pain in older adults, recent evidence revealed the belief of pain being secondary to advanced age as unfounded. Therefore, all levels of pain should be addressed appropriately and patients counseled regarding the importance of recognizing pain regardless of age.
- *Communication:* The ideal approach to pain assessment involves obtaining the patient's self-report of pain. The patient's self-described account has been found in several studies to be more accurate compared to standard healthcare provider pain assessments. Older patients, however, frequently deny or underreport their pain. Often, their unwillingness to express pain is a consequence of cultural beliefs, with stoicism implicated in many behavioral studies.
- *Cognitive status:* Many elderly individuals have an associated cognitive and/or functional impairment that may impede their ability to adequately express pain. Pain

TABLE 1: Aging-related physiologic changes and their impact on pharmacokinetics.

	Major changes with normal aging	*Pharmacokinetics*	*Clinical impact*

Absorption	• *Transdermal:*
	  ○ Atrophy of the dermis and epidermis
	  ○ Reduced tissue perfusion
	• *Sublingual*: Decreased saliva production
	• *Oral*: Contradictory evidence, including changes in gastric pH and gastric emptying time
		• Significant individual variability in transdermal, sublingual, and oral routes
		• No difference with normal aging in intramuscular and intravenous routes
			Alterations in absorption unlikely to have a significant clinical impact

Distribution	• Increased body fat • Decreased muscle mass • Decreased total body water • Decreased plasma proteins	• Larger lipophilic drug volume of distribution • Smaller hydrophilic drug volume of distribution • Increased free fraction of protein-bound drug	• Increased elimination half-life • Increased serum concentrations • Increased activity
Metabolism	• Decreased liver mass • Decreased liver blood flow • Decreased first-pass effect	• Decreased inactivation of active metabolites • Decreased activation of prodrugs	Increased activity (except for prodrugs)
Excretion	• Decreased renal blood flow • Decreased kidney mass • Decreased glomerular filtration rate	Decreased elimination of drugs	Increased elimination half-life

assessment in these individuals should be guided by a more comprehensive approach, including an evaluation for changes in behavior, movement, facial expression, activity, and mental status.

Pain assessment can be further supplemented by utilizing pain assessment tools and accounts from family or caregivers where available.

PAIN ASSESSMENT TOOLS

Various tools have been formulated to aid the clinician in the assessment of pain in older adults. No single pain assessment tool has been found to be unanimously superior for measurement of pain in older patients. Therefore, the best approach to pain assessment will depend on feasibility, patient capacity, provider's preference, and ability to extrapolate data from multiple sources. **Table 2** outlines a few commonly utilized pain scales that could potentially be applied in the acute care setting.

MANAGEMENT

Goals of Acute Pain Management

In order to ensure the best patient-oriented outcomes for pain in the elderly, care must be taken to promptly and adequately assess and address their pain status. However, identification of pain is often confounded by the fact that older patients have varying degrees of chronic, nonspecific pain that limit their daily functioning. Therefore, management of acute pain in the geriatric population frequently involves utilizing a multifaceted approach, focusing on factors beyond the reduction of pain,

TABLE 2: Common pain assessment tools.

Name	*Description*	*Notes*
Intact cognition		
Faces pain scale (FPS)	Self-report of pain based on selection of visual graphics of facial expression	Can be useful even with mild-to-moderate cognitive impairment
Verbal descriptor scale	Series of phrases describing pain at varying intensities	Can be combined with a pain thermometer (Iowa pain thermometer) or a 10-cm visual analog scale (combination is termed graphics rating scale). Useful even with mild-to-moderate cognitive impairment
Numerical rating scale	Commonly used to assess pain on a 10-point numerical scale	Easy to use, minimizes translational errors
Impaired cognition		
The pain scale	Measures pain in nonverbal patients with dementia using rating of six questions—vocalization, facial expression, physical, physiologic, body language, and behavioral changes	Can be completed in approximately 1 minute
Checklist of nonverbal pain indicators (CNPI)	Score of six nonverbal manifestations of pain—vocalizations, grimaces, bracing, rubbing, restlessness, and verbal complaints—at rest and with movement	More reliable observations during movement than at rest
Pain assessment checklist for seniors with limited ability to communicate (PACSLAC-II)	Revised score for patients with dementia—assesses 31 behavioral traits related to pain (reduced from 60 items in original PACSLAC score). Items factored in activity, movement, facial expressions, social, physiologic, vocal, sleeping, and eating habits	Seemingly preferred by nurses despite a large quantity of variables assessed
Pain assessment in advanced dementia (PAINAD) scale	Measures pain on a 10-point scale for nonverbal patients with dementia using five observations in over 5 minutes—breathing, negative vocalization, facial expression, body language, and consolability	Requires at least 5 min to complete
Critical-care pain observation tool (CPOP)	Assesses for pain in nonverbal intubated or sedated patients by observing four items—facial expression, body movement, muscle tension, and either ventilation compliance (intubated patients) or vocalization (extubated)	Observations can be completed within 1 minute. Shows reliability for pain measurement in critically ill patients with varying levels of consciousness
Algoplus	Score of 0–5 based on the presence (yes/no) of five observations—facial expressions, look, complaints, body position, and atypical behaviors	Designed specifically to evaluate acute pain in elderly with inability to communicate verbally. Can be completed in less than 1 minute. Validated as reliable in five different languages and countries

such as patient history, baseline function, underlying disease and comorbidities, risk of adverse outcomes, side-effect profiles of medication, and, finally, patient preference.

Consequently, pain management strategies that ultimately lead to the best patient satisfaction integrate a shared decision-making approach to analgesia.

Approach to Analgesia

A variety of pharmacologic and nonpharmacologic options are available for pain control in geriatric patients. Pharmacologic therapy, however, remains the mainstay in acute care settings, with nonpharmacologic alternatives usually serving as adjuncts rather than substitutes to medication. Ultimately, the choice of therapy weighs the benefit of pain reduction against the potential side effects, interactions, and adverse outcomes related to the intervention.

Factors such as physiology, drug metabolism, and genotype contribute to the considerable variability in response to medication in older adults. Therefore, it is often recommended to commence drug therapy at lower dosages, especially when using opioids, implementing a *start low, go slow* strategy, with additional medication added sequentially rather than simultaneously. While this approach can mitigate dose-related toxicity, it is important to note that *staying low* and delaying analgesic escalation when needed, may contribute to undertreatment in some patient groups.

PHARMACOLOGIC OPTIONS

Acetaminophen

The American Geriatrics Society recommends acetaminophen as a first-line agent for the treatment of low-to-moderate pain in the elderly, especially when secondary to osteoarthritis. The mechanism of action for acetaminophen is complex and often debated, with central and peripheral inhibition of cyclooxygenase (COX), agonism at transient receptor potential channels, and actions on serotonergic, l-arginine/nitrous oxide, and cannabinoid pathways all being implicated for its analgesic effect.

When given at therapeutic doses that do not exceed the maximum recommended daily dosage of 4 g, the incidence of hepatotoxicity, nephrotoxicity, and gastrointestinal toxicity with acetaminophen use is relatively low. Among other pharmacologic agents, it perhaps has one of the best safety profiles, making it an ideal medication for acute pain of lower intensity. Of particular interest is acetaminophen's apparent synergistic effects when used in combination with other analgesics, thus improving pain management whilst lowering the dosage for each individual drug component. Intravenous formulations of acetaminophen are readily available for use in emergency settings and are similarly efficacious when compared to oral administration.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) exert their analgesic effects through the inhibition of COX enzymes, thereby preventing the conversion of arachidonic acid to thromboxanes, prostaglandins, and prostacyclins. The World Health Organization analgesic ladder traditionally classified NSAIDs as a "*step-up*" from acetaminophen for pain management. Despite their potential for superior analgesic efficacy, several professional societies caution against their use in the elderly due to an increased risk of gastrointestinal, renal, and cardiovascular side effects. This is further evidenced by the inclusion of NSAIDs in the American Geriatric Society's Beers criteria list of potentially inappropriate medication use for older adults.

When administered, care must be taken to use the lowest doses possible and avoid patients with contraindications to NSAID therapy, such as those with impaired renal function and gastric or cardiovascular disease. Adverse effects can further be ameliorated by co-administration of proton-pump inhibitors on discharge to prevent acid-related gastropathies. Examples of NSAIDs commonly used in the ED include ibuprofen, naproxen, and ketorolac.

Opioids

Opioid drugs act on mu, delta, and kappa opioid receptors to decrease the release of excitatory neurotransmitters and increase neuronal resistance to excitability, thereby reducing pain sensation. They are usually reserved for the treatment of moderate-to-severe pain and include medications such as morphine, hydromorphone, buprenorphine, and fentanyl.

Unlike acetaminophen and NSAIDs, opioids are not limited by a maximal dose beyond which no further pain reduction benefit can be produced (termed the analgesic ceiling). Dosing of opioids should therefore weigh the benefits of pain reduction against the risks of therapy-induced side effects, such as constipation, nausea, somnolence, and respiratory depression. In older patients, an increased fat to muscle mass ratio as well as decreased hepatic and renal clearance means that opioids should be initiated at lower dosages, approximately 25–50% of those used with younger adults.

Tramadol is a weak opioid analgesic that is occasionally used for acute pain relief, since its reduced action on mu receptors lends it the apparent advantage of decreased opioid-related side effects. However, tramadol's safety profile is compromised by its unique ability to lower the seizure threshold, cause metabolic derangements, and potentially cause serotonin syndrome due to its inhibition of serotonin and norepinephrine reuptake.

Ketamine

Ketamine is an N-methyl-D-aspartate (NMDA) receptor antagonist that has shown promise as an emerging therapy for pain relief. Motov et al. conducted a randomized controlled trial that revealed the analgesic effects of intravenous subdissociative ketamine to be comparable to morphine for acute pain in the geriatric ED population. Given its potential to reduce coanalgesic administration, coupled with a relatively low risk of side effects, ketamine is rapidly gaining popularity as a useful alternative to pain management in the acute care setting.

NONPHARMACOLOGIC OPTIONS

Regional Nerve Blocks

Regional nerve blocks are an effective method of targeted pain management in patients with extremity fractures. Perhaps the most well studied of these is the femoral nerve block, often

utilized to relieve pain secondary to hip fractures. Regional anesthesia, with or without the guidance of ultrasound, provides rapid analgesia that is selective to the site of pain, without the risk of adverse events normally associated with systemic pharmacologic drug profiles.

Other Nonpharmacologic Therapies

Very few, if any, nonpharmacologic therapies have been studied or are feasible to use in the ED for pain relief. However, preliminary knowledge of the advantages of incorporating these techniques upon discharge can lead to earlier initiation of effective multimodal pain management for the patient. Examples of nonpharmacologic pain management strategies include acupuncture, aromatherapy, transcutaneous electrical nerve stimulation, and cognitive, behavioral, and physical therapies. The use of these interventions has been shown to reduce pain signaling, implying that they may have a role in promoting overall patient comfort and satisfaction, especially in chronic pain.

REASSESSMENT

After initiation of pain management, it is crucial to reassess, at regular intervals, the adequacy of the administered treatment. Ideally, patient response to analgesia should be evaluated for change as early as 15 minutes after administration. Often, however, reassessment of pain status in older adults is performed more than 60 minutes after drug initiation, resulting in suboptimal pain management and aggravated patient discomfort. The Society for Academic Emergency Medicine Geriatric Task Force, in collaboration with members from the American College of Emergency Physicians (ACEP), devised the following quality indicators for geriatric emergency pain management:

- For every elderly patient presenting to the ED, a formal assessment for acute pain should be documented within 1 hour of arrival.
- For patients who remain in the ED for more than 6 hours, a second pain assessment should be done within 6 hours of arrival.
- If analgesic treatment was given in the ED, a reassement should be documented prior to discharge.
- If an older adult presenting to the ED has moderate-to-severe pain intensity, analgesic treatment should be started.
- For patients transferred from nursing homes to the ED, a medication list should be attached to the transfer papers.
- If specific tests have been requested by a nursing home provider from the ED, the physician should document the performance of those tests.

SUMMARY

Aging is an increasing phenomenon all over the world, and it alters how the body processes and the individual perceives pain. In addition to the natural aging process, the increased prevalence of comorbidities and disabilities complicates the detection and communication of pain in older adults. In the ED, undertreatment of pain is a serious barrier and should be resolved through increased training and awareness. Adjusting pain assessment and treatment according to age-related alterations enables an effective and safe practice of pain management.

183
CHAPTER

Geriatric Gynecology

Laxman Bhusal, Rabin Bom

INTRODUCTION

Patients at the extremes of age can present unique and challenging gynecologic-pathologic conditions. Care should be taken by the emergency physician to adapt to challenges in examining unestrogenized genitalia and consider age-specific pathologic conditions. Decreased estrogen production probably weakens the structures supporting the vagina, permits genital atrophy, and possibly contributes to osteoporosis, arteriosclerosis, and other illnesses. Atrophic vaginitis is a common complaint among postmenopausal women. Common symptoms include pruritus, dryness, dyspareunia, burning, and bleeding. Although postmenopausal bleeding is most commonly due to atrophic vaginitis, it should be considered a sign of gynecologic malignancy until proven otherwise. It is the most common cause of postmenopausal bleeding. Examination will reveal thin, pale, and friable mucosa. Conservative treatments, such as sitz baths, and careful hygiene constitute the first line of therapy. Topical estrogen therapy can reduce severity of symptoms and is available in a variety of preparations.

OSTEOPOROSIS

Women should be screened for osteoporosis with bone densitometry beginning at the age of 65 years. Low bone mineral density (BMD) is not required to diagnose osteoporosis in postmenopausal women who sustain a low trauma fracture or have significant kyphosis with multiple risk factors. Screening for vitamin D deficiency in community-dwelling women aged 65 years is becoming a standard of care. For a serum 25-hydroxy vitamin D level of 20 ng/mL, typical repletion regimens use 50,000 IU of cholecalciferol (vitamin D3) once weekly for 6–12 weeks followed by ongoing monitoring.

VULVOVAGINITIS

Both aging and long-term estrogen deficiency increase vulvar susceptibility to trauma and decrease vulvar immune function. The most common symptomatic vulvar and vaginal conditions in the elderly are typical postmenopausal ones, such as atrophy, lichen sclerosis, and candidiasis. Consanguineous vaginal discharge usually can be attributed to a secondary infection that may accompany atrophic changes. Other than topical estrogen, treatment is usually moderate-to-high potency topical glucocorticoids. Chronic vaginal discharge that has not responded to the usual creams and antibiotics may indicate inflammatory vaginitis. The incidence of vulvar cancer rises exponentially after the age of 65 years. Indications for biopsy are the same as in younger women: asymmetry, border irregularity, color variation, rapid change, bleeding, nonhealing ulceration, and lack of a firm diagnosis.

UROGYNECOLOGIC ISSUES

Urinary tract infection (UTI): UTI is the most frequent bacterial infection in the elderly. Management is complicated by diagnostic uncertainty, polypharmacy concerns, more resistant organisms, and host factors that reduce treatment efficacy. For recurrent UTIs, postvoid residual urine volume (PVR) measurement, topical estrogen, and urine cultures and sensitivities prior to initiating treatment are indicated. In frail elderly, the "symptom" might be lethargy, irritability, vague discomfort, or a fall, making this determination difficult.

Urinary incontinence: Evaluation of urinary incontinence includes medication review, examination for neurologic conditions, determination of mobility and dexterity issues, and assessment of medical conditions, such as peripheral edema, diabetes, and hypercalciuria. Fecal impaction should be ruled out, and fecal incontinence (FI) should be queried. Bladder relaxants are effective in older women, but anticholinergic medications may impair cognition and function.

BREAST CANCER

As breast cancer primarily affects women in the post-menopausal years, the number of cases of breast cancer in women in this age group is also increasing. The most common type of cancer is infiltrating ductal cancer; this applies to all ages. The patient should be taught to examine her breasts monthly and report any change to her physician. Hormonal therapy has been proven to be of benefit in appropriate patients with breast cancer; this has also been demonstrated in the elderly female population.

VAGINAL BLEEDING IN THE POSTMENOPAUSAL PATIENT

Vaginal bleeding in postmenopausal women is an important presentation in emergency departments. It is most commonly defined as vaginal bleeding after a period of no menses for at least 1 year. Although atrophic vaginitis may be the most common cause of postmenopausal vaginal bleeding, vaginal bleeding is a common symptom of gynecologic malignancies, such as endometrial, cervical, and, rarely, ovarian cancers. Endometrial cancer is the common gynecologic malignancy causing vaginal bleeding in the postmenopausal women. Emergency physicians should assess for symptoms, family history, and personal risk factors for various gynecologic malignancies. Common risk factors include older age, obesity, early menarche, late menopause, nulliparity, infertility, polycystic ovarian syndrome, diabetes, and estrogen therapy without progesterone and tamoxifen use. Pelvic examination should be performed, including speculum examination with examination of the vaginal walls and cervix. Bimanual examination may reveal fixed masses, nodularity in the cul-de-sac, and palpable ovaries. Therapy for most women with endometrial cancer includes hysterectomy with bilateral salpingo-oophorectomy.

OVARIAN CANCER

The risk factors for ovarian cancer include family history, hereditary breast and ovarian cancer syndrome (*BRCA* gene mutation), early menarche, late menopause, older age at childbirth, and low parity. The presentation can include vaginal bleeding, but, more commonly, a woman presents with nonspecific symptoms, such as abdominal and pelvic pain, bloating, fullness, dysuria, and early satiety. Most ovarian cancers are epithelial cell in origin and affect older women. These are mostly diagnosed in late stage, and proper treatment is difficult.

CERVICAL CANCER

Cervical cancer is the common gynecologic cancer in postmenopausal women. The risk factors include human papillomavirus exposure, early coitarche, sexually transmitted diseases, and multiple sexual partners. The presentation can include postcoital bleeding and vaginal discharge or spotting, and the diagnosis can be made via colposcopy and cervical biopsy. The most common type is squamous cell carcinoma (80%), followed by adenocarcinoma (15%). Treatment is according to the staging of the disease.

BENIGN CAUSES OF VAGINAL BLEEDING

The statement about all postmenopausal vaginal bleeding being cancer until proved otherwise is because of a high index of suspicion for cancer in postmenopausal women. However, most instances of postmenopausal bleeding have benign causes, such as atrophic endometriosis, cervicitis, cervical polyps, endometrial polyps, and hormone replacement therapy (HRT).

Transvaginal ultrasound is the imaging modality of choice for pelvic structures. Endometrial thickness is best measured in the long-axis transvaginal view of the uterus. In postmenopausal patients with atrophic endometrium, it appears as a thin pencil line. Endometrial thickness of 4 mm or less measured anterior to posterior in this view is considered normal and highly predictive that no endometrial cancer is present. Ovarian evaluation by transvaginal ultrasound supplemented by transabdominal ultrasound for extending masses is the imaging modality of choice for a suspected ovarian mass. Worrisome features on ultrasound include complex masses with cystic and solid components, septated cysts, thick cyst walls, and free fluid in the pelvis. Endometrial sampling by a patient's primary care provider or a gynecologist is indicated in postmenopausal women with vaginal bleeding and an endometrial thickness greater than 4 mm on ultrasound.

MENOPAUSAL SYMPTOMS AND HORMONE REPLACEMENT THERAPY

Menopause is defined as the cessation of menstrual periods for 1 year and occurs at the average age of 51 years. Preceding menopause is often a perimenopausal transition marked by hormonal fluctuations and irregular menses. Menopause is a normal physiological process, not a pathological process, clinically characterized as hot flashes, vaginal dryness, poor sleep, and painful intercourse, which are irritating to many women. The discomfort from hot flashes, characterized by intense flushing and sweating lasting for several minutes and potentially occurring multiple times a day, affects about 75% of women. The mechanism behind menopausal symptoms, such as hot flashes, is not known. It is suggested that estrogen withdrawal stimulates the release of norepinephrine and serotonin, which can alter the body's thermoregulatory mechanism in the hypothalamus, predisposing a woman to more intense fluctuations of body temperature. The roles of HRT, including compounded bioidentical hormones, and alternative nonhormonal and herbal remedies for the treatment of menopausal symptoms are described in the literature.

Hormone Replacement Therapy

Role of progesterone: The guidelines recommend that all women with a uterus who are taking systemic estrogen therapy should take progesterone therapy as well to decrease the risk of endometrial cancer. This includes oral and transdermal estrogen use but not local intermittent vaginal estrogen therapy. Women without a uterus do not require progesterone therapy. Although not recommended as primary therapy, progesterone therapy alone has shown benefit for relief of menopausal symptoms in several studies. Both oral megestrol acetate and oral and intramuscular medroxyprogesterone acetate have been beneficial in the reduction of hot flashes compared with placebo. The side effects of progesterone therapy alone include vaginal bleeding, headache, breast tenderness, nausea, and venous thromboembolism (VTE).

Available formulations for HRT: Current estrogen and estrogen–progestogen therapy (EPT) options include oral pills; transdermal patches, gels, and creams; vaginal creams, rings, and tablets; and intrauterine delivery systems. Systemic HRT should involve reassessment yearly

for possible tapering/discontinuation of medication as menopausal symptoms abate.

Special considerations: *Premature menopause*—This is diagnosed when it occurs at or before the age of 40 years. Risks of HRT are less in these young women who are ≤50 years of age. Guidelines support HRT in these premature menopause women until at least the average age of menopause. The current standard of care is to avoid HRT in breast cancer survivor patients.

Bioidentical hormones: These are plant-derived hormones that are created by a compounding pharmacy under a physician's direction. They come in various forms, including oral and injectable agents, are not regulated by the US Food and Drug Administration, and have not been subjected to rigorous testing. In general, compounded bioidentical hormones are not recommended for the treatment of menopausal symptoms.

Nonhormonal therapies: These therapies used for menopausal symptoms include antidepressants and gabapentin, herbal remedies, and lifestyle modifications. A potential mechanism of action for selective serotonin reuptake inhibitors and norepinephrine serotonin reuptake inhibitors in the treatment of hot flashes is an alteration in the set point of the hypothalamic thermoregulatory zone. None of these medications, however, carries an indication for the treatment of menopausal symptoms. In general, their benefits (lessening hot flashes by approximately 1 per day) are more modest than those of HRT (lessening hot flashes by 2 or 3 a day). Typical side effects to these medications include drowsiness, nausea, and headache. In addition, there is some concern that certain antidepressants (paroxetine and fluoxetine) can decrease the active metabolite of tamoxifen and endoxifen, which is used in the treatment and prevention of breast cancer. Thus, in patients receiving tamoxifen, menopausal therapy with venlafaxine or citalopram is preferred. Gabapentin carries an indication for the treatment of seizures and neuropathic pain. Evidence supports its use for the treatment of hot flashes at a dose of 900 mg daily, with typical side effects of dizziness, dry mouth, and fatigue. A few studies also show benefit with the use of pregabalin.

Herbal remedies: Phytoestrogens are plant-derived molecules with estrogenic activity and include products, such as isoflavones, lignin, and coumestans. Phytoestrogens are botanic supplements and thus do not undergo the same standardization and testing as do classic pharmaceuticals. Commonly tried remedies for menopausal symptoms are soy. It is an isoflavone with estrogen and antiestrogen properties, found in high concentrations in Asian diets. Some evidence exists for the reduction of hot flashes with soy supplementation, but reports are conflicting. Soy is not recommended for women with a contraindication to estrogen.

Bioidentical hormones and herbal remedies may carry the same risks as traditional HRT (e.g., increased risk of deep vein thrombosis), so emergency physicians should inquire about their use. Rarely should emergency physicians start a patient on HRT or other medication for menopausal symptoms. Instead, they can assure patients that various hormonal and nonhormonal therapies are available for symptom relief and prompt patients to follow up with a primary care provider or gynecologist.

PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (POP) is defined as the abnormal descent of pelvic structures due to weakening of the pelvic floor. It is classified on the basis of anatomic locations as anterior (bladder or urethral involvement), posterior (rectal involvement) and apical (uterine, cervix involvement). Prolapse occurs because of weakening of the pelvic floor musculature, which can happen in response to the following:

- *Vaginal childbirth*: Increasing parity increases risk (cesarean section is associated with POP as well).
- *Increases in intra-abdominal pressure*: Obesity, straining with chronic constipation, chronic cough
- Aging/menopause
- Genetic predisposition
- Connective tissue abnormalities

Symptoms of POP include a sensation of vaginal pressure or a bulge in the vagina, difficulty voiding or defecating, splinting (digital reduction of prolapse to facilitate voiding or defecation), or recurrent UTIs. Although POP is typically a benign condition, advanced-stage prolapse can cause significant complications, including hydronephrosis and obstructive uropathy, bowel obstruction, or strangulation of prolapsed organs. The first, and cheapest, nonsurgical treatment option is pelvic floor muscle strengthening with Kegel exercises. The other most commonly known option for nonsurgical treatment of POP is the pessary. Surgery remains an option for women in whom nonsurgical treatment was not successful. When anterior or posterior vaginal prolapse is the primary problem, colporrhaphy is used. Most cases of POP can be safely reduced in the ED and referred to outpatient gynecology. Advanced prolapse with evidence of obstruction of either the urinary system or bowel or evidence of pelvic organ ischemia should prompt urgent gynecologic evaluation.

SUMMARY

Vaginal bleeding in postmenopausal women is the most common presenting symptom of endometrial cancer. Thus, although vaginal bleeding is often benign, it always merits diagnostic evaluation. Emergency physicians should stabilize patients and perform a complete blood cell count, pregnancy test, speculum examination to evaluate for cervicitis and urogenital lesions, and bimanual examination. Transvaginal ultrasound or endometrial biopsy is necessary for further evaluation. Ultrasound and CA 125 level are performed if adnexal mass is suspected in postmenopausal patients. Menopause is a physiological process characterized by the cessation of ovarian function and menstrual periods treated with HRT, POP associated with difficulty with urinary, gastrointestinal, and sexual function. Treatment options include Kegel exercises, pessaries, and surgery.

CHAPTER

Emerging and Re-emerging Infections

Dharmesh Lal

INTRODUCTION

Emerging infectious diseases (EIDs) are either new to the human population or may experience sudden epidemic growth, and majority of them are zoonotic in nature. An emerging pathogen may be defined as a newly discovered pathogen that has recently appeared within the population. Their definition is on the basis of the appearance of pathogen within population the first time, rapid spread on the basis of increasing incidence, and/or spreading to new geographical areas. EIDs result in increased mortality and morbidity having damaging effects upon livelihood, social fabric, and economic status besides disrupting the existing health delivery system. Infectious diseases causing an increase in incidence and tending to spread geographically fast and wide within decades can be defined as emerging infections. EIDs are on rapid rise in recent years overwhelming the human population globally upsetting the milieu of societies.

IMPORTANT TERMS

Cross-infection: It means infection of one person with pathogenic organisms from another and vice versa. Cross-infection can occur anywhere (e.g., in military barracks, schools, and workplaces).

Epidemic: [From the Greek *epi* (upon), *demos* (people)] The occurrence in a community or region of cases of an illness, specific health-related behavior, or other health-related events clearly in excess of normal expectancy.

Epidemiology: The study of the occurrence and distribution of health-related states or events in specified populations, including the study of the determinants influencing such states, and the application of this knowledge to control relevant health problems and for health planning and management.

Incidence: The number of instances of illness commencing, or of persons falling ill, during a given period in a specific population, more generally, the number of new health-related events in a defined population within a specified period of time. It may be measured as a frequency count, a rate, or a proportion. It is a reflection of control of a health problem.

Endemic: It refers to the constant presence and/or usual prevalence of a disease or infectious agent in a population within a geographic area.

Pandemic: It refers to an epidemic that has spread over several countries or continents, usually affecting a large number of people.

Zoonosis is an infectious disease that has jumped from a nonhuman animal to humans. Zoonotic pathogens may be bacterial, viral or parasitic or may involve unconventional agents and can spread to humans through direct contact or through food, water, or the environment.

Re-emerging infectious disease are defined as "diseases that appear with significant increase in incidence after they have been on a significant decline." Re-emerging viruses, on the other hand, may be defined as viruses that continuously reappear, thus causing many epidemics/outbreaks. Causes for the same are breakage of the ecosystem and weakening of the health systems which can be because of breakdown in public health measures for diseases that were under control or due to appearance of new strains of organisms." Viruses such as enteroviruses (EV), dengue virus (DENV), influenza viruses (e.g., H1N1, H5N1, and H7N9) *Orthomyxoviridae, Paramyxoviridae, Picornaviridae, Coronaviridae, Adenoviridae, Herpesviridae* influenza, respiratory syncytial virus, adenovirus, parainfluenza virus, human coronavirus, to name a few, are considered re-emerging viruses due to their constant reappearance in the population and cause additional large mortality and morbidity. Some of these viruses have also caused huge respiratory damaging infections throughout the world in recent times. Other examples of such diseases are drug-resistant forms of tuberculosis, bacterial pneumonia, and malaria. Drug-resistant strains of the bacteria causing gonorrhea and syphilis are also becoming more widespread, raising concerns of untreatable infections.

Most of the countries despite rising EIDs are still having lower provisions for undertaking research activities. Respiratory infections with epidemic and pandemic potential that cause a global burden have plagued people since the beginning of human history.

ENABLING FACTORS

Any disease to cause epidemic and thereby spread in the community require the presence of three "elements" and their synergistic effects upon each other, called *epidemiological triad*, as shown in **Figure 1**. Each element has inherent characters known as enabling factors, and as is evident from the **Figure 1** most of the factors are human made and resulting from brazen eco-insensitive development causing newer pathogens to emerge or resurgence of earlier controlled pathogens. With changing demographical and environmental dynamics, the EIDs have emerged as posing increasing challenges to the humanity in last few decades. Demographic forces amplify the risks associated with EIDs. The global population is expected to grow to 8 billion within 8 years, with nearly 60% living in relatively crowded urban areas. By 2050, half the world's population will live in tropical environments, which bear a much larger burden of disease. Rapid aging of the global population will further increase susceptibility, as both abilities to fight off infection and efficacy of immunization wane with age. Additionally, air travel increases annually, with >100,000 flights per day as of 2014. These factors favor the emergence, evolution, and spread of new pathogens.

DISEASES PROFILE

For better management and control of these diseases, it is important to understand the causative agent, reservoir, risk factors, and mode of transmission as shown in **Table 1**. Identification, monitoring, and treatment of diseases are the primary objectives of all public health programs. As an example in case of coronavirus disease-2019 (COVID-19) pandemic, the virus is coronavirus, named as COVID-19, having possible reservoirs in bats, and risk factors include people who are elderly and having comorbid conditions while the transmission of the virus is through aerosols and airborne in nature. On the basis of these information, the nonpharmaceutical interventions (NPIs) are the mainstay of the prevention before roll-out of the effective medicines and pharma agents.

Majority of the EIDs are caused by viruses, mutations, and reassortments which are the factors that increase the pathogenicity of these viruses. The future will see more of pandemics due to mutations of viruses and reassortment [in which the host is infected with two different strains of viruses (animal and human viruses) resulting in newer virus with mixed genetic materials], examples of which are bird and swine influenza viruses. Adverse impacts of EIDs include: overwhelming of health systems severely affecting the normal health delivery services such as immunization, delaying, and/or missing even minimum mandatory clinical care like for cancer and tuberculosis (TB) patients, thus causing avoidable deaths and morbidity and mandate provisioning of additional scarce resources for survivors of these EIDs.

Although the majority of recent EIDs have been viral, bacterial infections are also a threat, with the devastating cholera epidemic in Haiti, the foodborne *Escherichia coli* O104:H4 outbreak in Germany in 2011, and the invasive nontyphoidal *Salmonella* in Africa representing prominent examples. Today, the major risk from bacteria comes from antibiotic-resistant strains, such as multiple drug-resistant *Staphylococcus aureus* (MRSA). Whether viral or bacterial, EIDs share common attributes of unpredictability, high morbidity, the potential for explosive growth of cases, and substantial social impacts. TB has been making resurgence due to resistance to various antitubercular drugs while malaria has been reported from many parts of world due to drug resistance and mosquitos showing resistant to various pesticides. Factors having bearing on spread of EIDs are microbiological features and genetic makeup of a pathogen and social determinants of health.

Throughout the years, many viruses have emerged and re-emerged. Viral adaptation mechanisms such as mutation

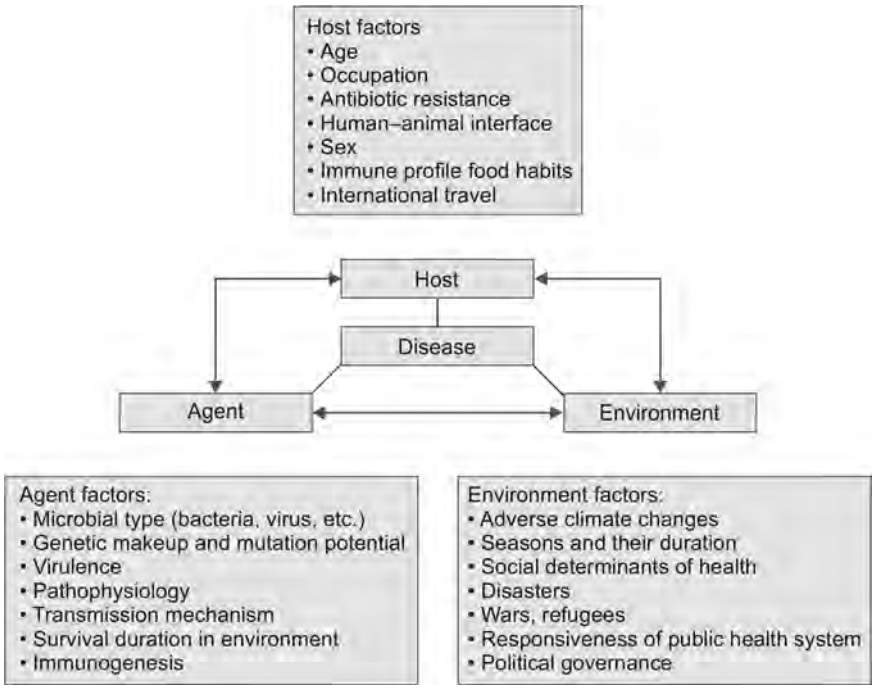

FIG. 1: Epidemiological triad-enabling factors and their interaction.

TABLE 1: Disease profile of various emerging/re-emerging diseases.

Disease	*Geographical distribution*	*Agent*	*Reservoir*	*Risk factors*	*Mode of transmission*	*Clinical features*
Avian influenza	Bangladesh, China, Egypt, India, Indonesia, Vietnam, and Cambodia	Avian influenza virus subtype A H5N1, H5N6, H6N1, H7N7, H7N9, H9N2, H10N8	Wild birds, waterfowl, and poultry	Direct or indirect exposure to infected—live or dead—poultry, and environments contaminated by the virus, are the biggest risk factors	Infection of humans from poultry but rare Human-to-human infection is even more rare, but through airborne	Flu-like symptoms, watery diarrhea, severe pneumonia, and multiorgan failure
Chikungunya	Nearly 40 countries in Asia, Africa, Europe, and the Americas	Togaviridae family of arboviruses, i.e., it is primarily spread by mosquitoes	Humans are the main reservoir in Asia, although monkeys are an important reservoir in Africa	Proximity of mosquito breeding sites to human habitation	Bite of female-infected mosquitoes, which bite throughout daylight hours	Sudden onset of fever, severe headache, chills, nausea, vomiting, and severe joint pains that may persist for weeks or months In some cases, joint pain may persist for several months or even years
Crimean-Congo hemorrhagic fever	More than 30 countries in the African, South-East Asia, European and Eastern Mediterranean regions of WHO	Nairovirus, of the *Bunyaviridae* family. All 32 members of the *Nairovirus* genus are transmitted by ticks, but only three viruses are known to cause disease in humans	Ostriches are carriers and become infected with CCHF from the bite of infected ticks	Majority of cases occur in people working in the livestock industry, since they come in close contact with infected animals. Healthcare workers are especially at risk of acquiring infection while providing intensive care	Direct contact with the blood or tissues of livestock, such as sheep, goats, or cattle but also from tick bites. Human-to-human transmission may occur by exposure to blood and excreta from the affected people, for example healthcare workers	Sudden onset of high fever and chills, headache, dizziness, and muscle pain. Abdominal pain, nausea, vomiting, and diarrhea. Bleeding from the nose, gums, kidneys, and gastric mucosa
Dengue	Worldwide, usually in tropical and subtropical regions	The four distinct but closely related serotypes of dengue virus (DEN-1, DEN-2, DEN-3, and DEN-4) Members of *Flaviviridae* family	Viruses are maintained in a human–mosquito cycle in tropical urban areas	Humans living in tropical and subtropical urban locations in dengue-endemic areas, particularly during the rainy season	Bite of infective female *Aedes* mosquitoes, which, in turn, have acquired the virus while feeding on the blood of an infected person	Flu-like illness with muscle and joint pains; few develop severe dengue or dengue shock syndrome. May include hemorrhagic rash (bleeding into the skin)
Ebola virus disease	Primarily in remote villages in Central and West Africa, near tropical rainforests	Ebolavirus belongs to the *Filoviridae* family (filovirus). Ebolavirus comprises five distinct species: 1. *Bundibugyo ebolavirus (BDBV)* 2. *Zaire ebolavirus (EBOV)* 3. *Sudan ebolavirus (SUDV)* 4. *Reston ebolavirus (RESTV)* 5. *Taï Forest ebolavirus (TAFV)*	Fruit bats of the *Pteropodidae* family are considered to be the natural host. Although nonhuman primates have been a source of infection for humans, they are not thought to be the reservoir but rather an accidental host like human beings	Human contact with infected fruit, bats, or monkeys/apes and the consumption of their raw meat. Human-to-human transmission is through direct or close contact with infected patients, and particularly through contact with blood and body fluids of an infected patient	Close contact with the blood, secretions, organs, or other bodily fluids of infected animals. In Africa, infection has been documented through the handling of infected chimpanzees, gorillas, fruit bats, monkeys, forest antelope, and porcupines found ill or dead or in the rainforest	Sudden onset of fever, intense weakness, muscle pain, headache, and sore throat. This is followed by vomiting, diarrhea, rash, impaired kidney, and liver function, and in some cases both internal and external bleeding

Disease	Geographical distribution	Agent	Reservoir	Risk factors	Mode of transmission	Clinical features
Hantavirus	North and South America, Europe, and the Asia-Pacific region, including India, Indonesia, Myanmar, Sri Lanka and Thailand	Part of the *Bunyaviridae* family	Wild rodents. Each strain of hantavirus possibly has its own rodent reservoir	Certain occupational groups—such as farmers, sweepers, and laborers who are likely to have high exposure to infected dust and those living in rural areas are at higher risk of infection	Inhalation of the virus in aerosols from urine or feces of infected rodents. Human-to-human transmission is uncommon but possible	Renal syndrome. Two types: HFRS affects the kidney, more common in Asia, while HPS affects the lungs, more commonly seen in the Americas. HFRS: Sudden onset of high fever, chills, and pain in the back, muscles, and abdomen. Profuse bleeding may occur, and kidney function can also be impaired. Tiny red spots and rashes appear on the face and elsewhere. Bleeding may also be seen from the nose and in the urine. HPS: An initial period of general fever, ache, and cough is followed by the sudden onset of acute respiratory distress
Hand, foot, and mouth disease	Worldwide, and increasing in the Asia-Pacific region	*Enterovirus* genus of the *Picornaviridae* family	Humans are the sole reservoir	• Poor hygiene and direct contact with infected patients • Children under the age of 10 years, and especially those under the age of 5 years, are at the greatest risk	Highly contagious and gatherings in places like kindergartens and schools facilitate disease transmission. The virus is transmitted through direct contact with nose and throat discharges, saliva, fluid from blisters, or the stool of infected persons	Usually mild and self-limiting. Typical symptoms are fluid-filled blisters on the hands, feet, and inside of the mouth and/or dehydration due to fever and poor fluid intake. Occasionally, meningoencephalitis in some children, pneumonia, and myocarditis
Japanese encephalitis	Mainly in the Asia-Pacific region	Member of the *Flavivirus* genus in the family *Flaviviridae*	• The virus circulates in ardeid birds (herons and egrets). Pigs are amplifying hosts in that the virus reproduces and infects mosquitoes that bite them but does not cause disease • Humans become infected as accidental hosts when those mosquitoes bite humans	Children in endemic areas are at risk when involved in outdoor activities during and immediately after the monsoon season, when mosquito numbers are at their highest. Travelers and expatriates who stay for prolonged periods in rural areas with active JE virus transmission are likely to have a similar risk to the susceptible resident	Outbreaks usually occur during the rainy season in paddy-growing territories Occasionally, outbreaks have been reported in periurban or slum areas where scavenging pigs are present and waterlogged conditions exist	Rapid onset of high fever, stiff neck, coma, tremors, and convulsions (especially in infants)

Continued

Disease	*Geographical distribution*	*Agent*	*Reservoir*	*Risk factors*	*Mode of transmission*	*Clinical features*
Nipah virus	Bangladesh, India, Malaysia, and Singapore	Member of Paramyxoviridae family	Fruit bats of the genus *Pteropus* (flying foxes) are the main reservoir. NiV is known to infect pigs, dogs, cats, horses, and humans when they consume contaminated food or drink that has been infected by bat secretion (saliva and urine)	• In Bangladesh, the cultural practice of drinking raw date palm sap is a major risk factor for human infection. Human-to-human transmission of NiV reported in recent outbreaks demonstrates the risk for healthcare workers of acquiring the virus from infected patients • Close contact with infected pigs who act as an intermediate and possibly amplifying host after contact with infected bats	NiV is transmitted to humans either from animals (contact with urine, saliva, or contaminated materials) or from other humans	Ranges from asymptomatic infection to fatal encephalitis. Some people can also experience atypical pneumonia and acute respiratory distress
Novel human coronavirus	Outbreaks were reported in China, Hong Kong SAR, Singapore, and Vietnam, and spread to many countries in 2002–2003, notably to Canada	SARS coronavirus (SARS-CoV)	The reservoir was initially thought to be the civet cat but is now believed to be the bat, with the civet cat acting as an intermediate host	Source of infection remains undetermined, although there is circumstantial evidence of animal-to-human transmission. Elderly and those with chronic, immunosuppressive diseases are particularly vulnerable	Close person-to-person contact, e.g., by inhaling droplets and can be transmitted during air travel	Sudden onset of flu-like symptoms. Severe cases progress to a respiratory disease and pneumonia
Rabies	Worldwide (except Antarctica), but >95% of human deaths occur in Asia and Africa	*Lyssavirus* is a genus of the family Rhabdoviridae	Warm-blooded mammals and bats—urban rabies primarily by dogs, and sylvatic rabies by wild animals	Rabid dog bite. Human deaths following exposure to mongoose, jackals, foxes, wolves, and other wild carnivore host species are very rare	Infected through the skin following a bite or scratch by an infected animal. infectious material—usually saliva—comes into direct contact with human mucosa or fresh skin wounds. May be contracted via transplantation of an infected organ such as a cornea	Initial pain or a tingling sensation at the site of the bite; hydrophobia, restlessness, excess salivation, convulsions, and finally death

Continued

Continued

Disease	Geographical distribution	Agent	Reservoir	Risk factors	Mode of transmission	Clinical features
Rift valley fever	Africa and occasionally reported in Middle East countries	*Phlebovirus*, a member of the Bunyaviridae family	Infected livestock (sheep, cattle, and goats) infect a variety of mosquito vectors. Virus often enters the bloodstream during early clinical illness in humans	Mainly affects persons in certain occupational groups—such as veterinarians, animal handlers, and slaughterhouse workers. Travelers visiting RVF-endemic locations during periods when sporadic cases or epidemics are occurring	Bite of infected mosquitoes or other insects. Contact with tissues and body fluids of infected animals and/or inhalation of aerosols produced during the slaughter of infected animals	Most human cases are relatively mild. Some patients develop severe flu-like symptoms. However, a small percentage of people develop a much more severe form of the disease that manifests as one or more of three distinct syndromes: ocular, meningoencephalitis, and hemorrhagic
Anthrax	Worldwide	*Bacillus anthracis*	Domestic and wild animals such as cattle, buffalo, sheep, goats, pigs, and horses	Infection in humans is rare. Skin contact with, or inhalation of, aerosolized spores and consumption of undercooked or raw meat or dairy products from infected animals	Cutaneous route; through consumption of undercooked or raw meat or dairy products from infected animals and by inhaling a large number of anthrax spores suspended in the air (the pulmonary form of anthrax, which is the rarest and most severe)	Red marks on the exposed area of skin, gastrointestinal form: pulmonary form
Botulism	Worldwide	*Clostridium botulinum*. Seven types: A, B, E and, rarely, F cause human botulism	Spores found in soil, aquatic sediment, the intestinal content of herbivores and fish. Botulism is caused by a toxin produced by this sporulated form. Type E toxin is associated with fish and marine mammals. Infant botulism is associated with the use of contaminated honey in milk formula	Foodborne botulism can occur in all age groups	Ingestion of preformed toxins; *ρ* wound botulism	Nausea, vomiting, sometimes constipation, followed by toxic effects on the central nervous system (drooping eyelids, blurred or double vision, dizziness, difficulty in swallowing, blurred speech, muscle weakness, and respiratory paralysis)

Continued

Continued

Disease	*Geographical distribution*	*Agent*	*Reservoir*	*Risk factors*	*Mode of transmission*	*Clinical features*
Brucellosis	Countries in Asia including China, India, Indonesia and Thailand, and also in South America, the Mediterranean and the Middle East	Various types of the *Brucella* species of bacteria exist (*B. abortus, B. melitensis, B. suis,* and *B. canis*). *B. melitensis* is the most virulent and causes the most severe and acute cases of brucellosis. *B. abortus* is associated with mild to moderate sporadic disease that rarely causes complications	Major reservoirs are cattle and buffalo (*B. abortus*), sheep and goats (*B. melitensis*), swine (*B. suis*), and dogs (*B. canis*). Infection persists throughout the lifetime of the animal	Person-to-person transmission is rare. People in close contact or working with animals are at a greater risk of developing the disease. However, the majority of cases are caused by consuming raw, unpasteurized milk or cheese from infected goats or sheep	• Direct contact with infected tissues or fluids • Ingestion of raw milk or dairy products such as soft cheese. Contamination of a fresh wound with infected matter from animals such as blood, urine, aborted fetuses, and placenta • Accidental needle-stick puncture with *Brucella* • Contact with urine or tissues from infected animals, usually rodents • Contact with surface water, soil, or plants contaminated with the leptospirosis bacteria from the urine of infected animals • Via skin abrasions or exposed mucous membranes, the most common entry point for infection • Human-to-human transmission is rare	• Gradual onset of persistent fever, chills, sweating, headache, muscle pain, backache, joint pain, fatigue, weakness, and weight loss • Chronic debilitating illness. Complications may affect any of the organ systems
Leptospirosis	Worldwide, but is the most common in tropical and subtropical areas with high rainfall	The bacteria *Leptospira interrogans*, of which there are 12 species and over 250 serological variants (serovars)	About 160 mammalian species serve as reservoirs. Rodents are a primary source of infection for humans	• Agricultural and farm workers (rice-paddy and sugarcane workers, for example), as well as those who work outdoors or with animals, are particularly at risk. Recreational hazard for those who swim or wade in contaminated water • At risk include pet shop workers, veterinarians, sewer workers, abattoir workers, meat handlers, and the military • Survivors of natural disasters (e.g., flooding) are also at high risk	• Contact with urine or tissues from infected animals, usually rodents • Via skin abrasions or exposed mucous membranes, the most common entry point for infection • Human-to-human transmission is rare	• Ranges from flu-like symptoms to complications involving pneumonia and multiple organ dysfunction syndromes • Headache, muscle pain, and conjunctival suffusion can develop with progression to severe jaundice, anuria, kidney failure, and even death

Continued

Continued

Disease	Geographical distribution	Agent	Reservoir	Risk factors	Mode of transmission	Clinical features
Listeriosis	Worldwide	The bacterium *Listeria* monocytogenes	*Listeria monocyto*genes mainly occurs in soil, forage, water, mud, livestock food, and silage. Animal reservoirs include infected domestic and wild mammals, fowl, and humans Animals can carry the bacterium without appearing ill and can contaminate foods of animal origin such as meat and dairy products	• Multiply in refrigerated foods that are contaminated • Although rare, listeriosis primarily affects older adults, pregnant women, newborns, and adults with weakened immune systems • Intensifies existing debilitating illnesses or conditions such as organ transplantation, diabetes, cirrhosis, renal disease, heart disease, HIV infection, and in persons with malignancies or on corticosteroids. Pregnant women are about 20 times more likely to get listeriosis than other healthy adults	• Consumption of foods contaminated with *Listeria monocytogenes* • Organism can be transmitted from mother to fetus in utero, or during passage through the infected birth canal	• Septicemia and meningitis • Pregnant women may experience a mild, flu-like illness followed by fetal loss or meningitis in their newborn. Acute gastroenteritis with high fever
Melioidosis	South-East Asia, China, and parts of Australia	*Burkholderia pseudomallei*	• No animal reservoir • Widespread in soil and muddy water in endemic areas • Common in moist clay soils	• Most people become infected directly from the environment, e.g., soil • Predisposed conditions—comorbidities/Steroids therapy • Agricultural, laboratory and healthcare workers are particularly vulnerable to occupational exposure	Human-to-human transmission is rare Direct contact with contaminated soil and surface water Infected animals can shed the organism on seeping wounds and, depending on the site of the infection, from other abscesses, nasal secretions, milk, feces, and urine	• Salivary glands—abscess among children • Acute localized infection sometimes occurs at the site of inoculation • Swelling of regional lymph nodes • Lung disease is the most common form • Septicemia • Abscesses and suppurative lesions in a variety of organs

Continued

Disease	*Geographical distribution*	*Agent*	*Reservoir*	*Risk factors*	*Mode of transmission*	*Clinical features*
Plague	Endemic in many countries in Africa, the Americas and Asia. Contact of infected wild rodents with domestic rats may initiate an urban cycle of spread	*Yesinia pestis*	• Rodents are the natural and maintenance hosts Domestic rodents are prone to both the infection and the disease, hence the phenomenon known as "rat fall" • Marmot is a primary carrier in many Asian countries • Dogs may become infected without showing any sign of illness and act as sentinel animals	Humans are at risk when they come into contact with rats in the same habitat. Pneumonic form transmits more efficiently through the inhalation of aerosols. Rodents and insects act as potential reservoirs and carriers of *Y. pestis*	• Indirect or direct transmission • Bite from an infected flea (bubonic plague): bubonic and septicemic • Direct transmission from a plague-infected rodent or animal while handling infected animals or carcasses • Human-to-human spread (pneumonic plague) • Direct contact with droplets contaminated with sputum • Contact with an animal with pneumonic plague, which occurs when *Y. pestis* infects the lungs or when the infected animal coughs near another animal • If a cat develops pneumonic plague, it becomes a source of infection for people through aerosol transmission	Usually start with flu-like symptoms Bubonic (through flea bites): fever, swollen lymph nodes (buboes) and signs of meningitis. Septicemic: Pneumonic (most virulent and least common form): fever, respiratory tract disease, and bright red sputum
Salmonellosis	Worldwide	*Salmonella species* (*S. typhimurium, S. enteritidis*, and >2,500 known types or serotypes)	Poultry (main reservoir), domestic and wild animals	Children are the most vulnerable. infants, the elderly, and persons with compromised immune systems	Consumption of raw or improperly cooked food of animal origin, although many other foods, including green vegetables contaminated from manure, have been implicated in its transmission	Diarrhea, vomiting, and low-grade fever Reactive arthritis

Continued

Continued

Disease	Geographical distribution	Agent	Reservoir	Risk factors	Mode of transmission	Clinical features
Scrub typhus	Endemic to a part of the world known as the "tsutsugamushi triangle", extending from northern Japan and the far-eastern Russian Federation to northern Australia and Pakistan. This includes Bhutan, India, Indonesia, Maldives, Myanmar, Nepal, Sri Lanka and Thailand	*Orientia tsutsugamushi*, which has five major serotypes.	Chigger mites act as the primary reservoirs for *O. tsutsugamushi*	Essentially, an occupational disease among rural residents in the Asia-Pacific region. An increase in the prevalence of scrub typhus has been reported from some Asian countries, which coincides with urbanization of rural areas	Transmitted to humans and rodents by some species of chigger mites (*Leptotrombidium deliense* and others)	• The chigger bite is painless and may be noticed as a transient localized itch, often found on the groin, armpits, genitalia, or neck • A scab is often seen at the site of the bite • Sudden shaking chills, fever, severe headache, infection of the mucus of the conjunctiva, and swelling of the lymph nodes are also seen • A spotted rash on the trunk may be present. Complications may include pneumonia and myocarditis
Tularemia	Endemic in many parts of the world including North America, Eastern Europe, China, Japan, and Scandinavia. It has been reported from Thailand	• *Francisella tularensis*. Currently, there are four recognized subspecies *F. tularensis (F. tularensis, F. holarctica, F. mediasiatica*, and *F. novicida*) • Clinicians should be aware of tularemia associated with handling of sick pet animals	Rabbits, hares, and rodents are natural reservoirs and often die in large numbers during outbreaks	An underlying disease that suppresses immunity is an important factor for contracting tularemia. Hunters, pet owners, and farmers are high-risk groups for exposure to infection	Contact with infected animals or bitten by ticks, deerfly. or other insects that feed on infected animals. Inhalation of dried animal matter, skinning or dressing killed animals, or drinking water contaminated by animal carcasses. No direct human-to-human transmission	• Sudden onset of high fever, headache, muscle and joint pains and swollen, and painful lymph nodes • Slow healing sores and lesions develop at the entry site of bacteria. Pneumonia is common after inhalation

Continued

Continued

Disease	Geographical distribution	Agent	Reservoir	Risk factors	Mode of transmission	Clinical features
Teniasis/ cysticercosis	• *Taenia solium (T. solium)* and *Taenia saginata (T. saginata)* are distributed worldwide • *T. saginata*—found in countries where cattle and buffaloes are raised for human consumption • *T. solium* where pigs are raised for human consumption • *T. solium* has been reported from India, Indonesia, Nepal, and other countries of the Asia-Pacific region	*T. solium* (pork tapeworm) and *T. saginata* (beef tapeworm). *T. solium* is responsible for human cysticercosis	Cattle and buffaloes for beef tapeworm and pigs for pork tapeworm	• Related to pig husbandry practice, and in countries where open defecation is common and scavenging pigs are found in the community • Lack of meat inspection, and consumption of raw or undercooked meat	Ingestion of raw beef/pork containing the cysticercus. Humans are the final host for both *T. saginata* and *T. solium*, but humans can also be the intermediate host for *T. solium*. However, carriers of *T. solium* carry a substantial risk of acquiring cysticercosis by feco-oral autoinfection and members of their households are also at increased risk	Intermittent fecal shedding of proglottids (segments), gastrointestinal discomfort, nausea, diarrhea, loss of appetite, and loss of weight. Seizures, headaches, learning difficulties, and convulsions are symptoms of neurocysticercosis. Cysticercosis of other tissues is almost always asymptomatic
Toxoplasmosis	Worldwide	*Toxoplasma gondii*	Cats and other felines. Intermediate hosts include most species of birds and mammals	• Very common • Infection is often highest in areas that have hot, humid climates, and low altitudes. • IUGR	Ingestion of undercooked, contaminated meat • Drinking water or milk contaminated with *Toxoplasma gondii*. • Mother-to-child (congenital) transmission (congenital) transmission or mother-to-fetus through the placenta. Animal-to-human (zoonotic) transmission • Accidentally swallowing the parasite through contact with cat feces that contain toxoplasma, such as while cleaning cat litter	• Mild flu-like symptoms • Enlarged lymph nodes in the head and neck • Pneumonia • Central nervous system disturbances • Complications of eyesight • Other systemic diseases
Trichinellosis	Worldwide, most frequently in regions with temperate climates, including mountainous regions in South-East Asia	*Trichinella spiralis*: *Trichinella larvae* are encysted in muscle tissue of meat from domestic or wild animals	Wild boar, domestic pigs, bears, rodents, and horses	Consuming raw or undercooked meat infected with the *Trichinella* parasite, particularly from wild game (e.g., boar) or pork	Consumption of raw or undercooked meat	Diarrhea, abdominal pain, nausea, vomiting. Eyelid or facial edema (fluid retention), conjunctivitis, fever-associated chills, muscle pain, and itchy skin. Occasional heart failure, pneumonia, or encephalitis

(CCHF: Crimean-Congo hemorrhagic fever; HFRS: hemorrhagic fever with renal syndrome, HPS: hantavirus pulmonary syndrome; NiV: Nipah virus; IUGR: intrauterine growth restriction)

[e.g., ribonucleic acid (RNA) viruses], reassortment (e.g., influenza virus), and recombination (e.g., enteroviruses) aid in the evolution of the virus, allowing it to cause new outbreaks, and potential pandemics, with each re-emergence. Emerging viruses such as severe acute respiratory syndrome-associated coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), Ebola virus, Zika virus (ZIKV), chikungunya virus (CHIKV), Nipah virus (NiV), and the most recent SARS-CoV-2 have also resulted in large epidemics and pandemics.

Costs associated with these EIDs are huge and unpredictable. The COVID-19 pandemic will likely end up costing between $8.1 and $15.8 trillion globally.

CONTROL MEASURES

Applications of "public health" measures mainly using the applied epidemiology are important to contain the spreading epidemics by understanding the causative and enabling factors for its spread and also the pathophysiology of disease for effective diagnosis and treatment as now being seen in COVID-19 pathogen. All the causative factors need to be studied in a disaggregated manner for understanding the major enabling causative factors of the disease. Predictability is an important factor for controlling these diseases, and many countries are still facing challenges on these accounts. Real-time data collection and capacity to respond accordingly play a major role in gravity of spread of the disease and its consequences.

In order to combat both emerging and re-emerging viruses, effective drugs and vaccines are needed to treat and prevent the viral infections. However, in order to do so, certain biosafety-level facilities are required for the handling of viruses that are considered to be highly pathogenic agents, such as biosafety level 3 (BSL-3) facilities for SARS-CoV-2, MERS-CoV, CHIKV, and avian influenza, and BSL-4 for Ebola, Marburg virus (MARV), Lassa virus (LASV), and NiV. This poses a major limitation in the development of vaccines and drugs against the viruses.

There is a need to identify first the causative pathogen, its microbiological features including genetic makeup, and its source of origin as mostly these are zoonotic in nature. Combined efforts of veterinarians and medical scientists need to work together for identifying the causative pathogen and its epidemiological features. Increasing human–animal interactions due to deforestation and adverse climatic changes are also leading to a newer infectious disease among human race. Lack of public health infrastructure and/or application of its scientific principles lead to EIDs as seen even during ongoing COVID-19 pandemic. Strengthening the public health systems with increasing focus on the surveillance system can help in checking the emergence and spread of these diseases and many governments around the world have been spending resources for these and many are committing after COVID-19 experience. Despite each EID having some unique features, they have certain basic commonalities which have been accepted in the form of International Health Regulations (IHRs, 2015). IHRs provide an overarching legal framework that defines countries' rights and obligations in handling public health events and emergencies that have the potential to cross borders. The IHRs are an instrument of international law that is legally binding on 196 countries, including the 194 WHO Member States. They create rights and obligations for countries, including the requirement to report public health events. The regulations also outline the criteria to determine whether or not a particular event constitutes a "public health emergency of international concern." At the same time, the IHRs require countries to designate a National IHR Focal Point for communications with WHO to establish and maintain core capacities for surveillance and response, including designated points of entry. Additional provisions address the areas of international travel and transport such as the health documents required for international traffic. Finally, the IHRs introduce important safeguards to protect the rights of travelers and other persons in relation to the treatment of personal data, informed consent, and nondiscrimination in the application of health measures under the regulations. Taking cues from IHRs, many countries have strengthened their response and surveillance systems but there remain gaps largely in poor countries to formulate the national action IHR plan and implement the strategies and policies due to political and economic differential priorities. Unpredictabilities of EIDs and their huge adverse impacts upon livelihood, community, and health system, there is requirement of more resources,development of ecofriendly policies and universal global response. Equally, the important element is the level of responsiveness of the public health system and its applications on the basis of strict scientific rationale.

ELEMENTS OF AN EPIDEMIC MANAGEMENT SYSTEM

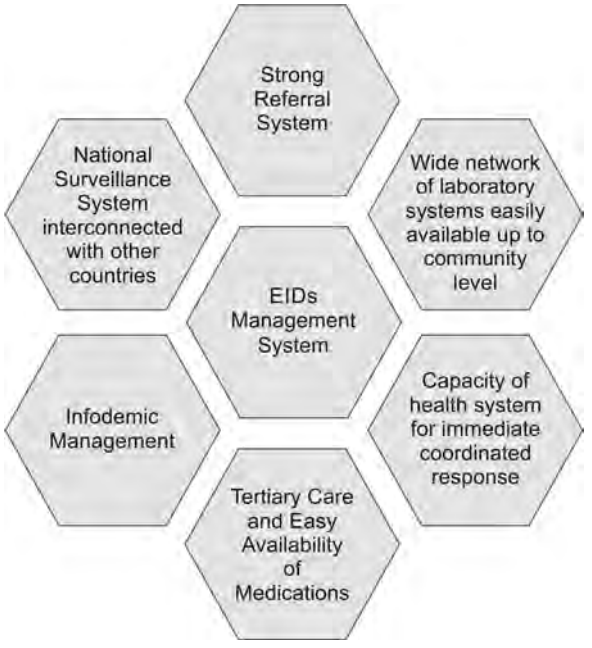
Emerging infectious diseases are the major threat to the community. A robust mechanism to manage the epidemic is necessary in any healthcare system management (**Fig. 2**). Components of the epidemic management system include good laboratory network, capacity of the healthcare system to respond quickly, well-equipped tertiary care center and availability of medication, infodemic management, national surveillance system, and strong referral system.

National Surveillance System interconnected with other countries: The surveillance system is an important component of the public health system where real-time data management aids in capturing the possibilities of outbreak and epidemic of diseases. For this, the country needs to have its IHR national plan in place and it entails the data sharing and management practices to control the epidemics among countries.

Strong referral system: Ideally, an effective referral system is to have seamless and coordinated functional complementary relationships among all tiers of the health delivery system as depicted in **Figure 3** so as to able to deliver the timely and best possible care at all levels. This becomes all the more important during an epidemic where patients requiring tertiary care including intensive care unit (ICU) services, as seen during the ensuing COVID-19 epidemic, can be shifted to higher medical centers as part of the referral system.

Wide network of laboratory systems easily available up to the community level: Laboratory-based testing such as RT-PCR and antigen diagnostic tests form the mainstays of managing an epidemic and its spread and finally its control as even for COVID-19 pandemic. WHO advocates "Test, Test and Test strategy." Laboratory services need to have in-built quality

control measures along with integration across different tiers of the health systems and other related branches such as virology, microbiology, and even with the veterinary department. Uniformity in laboratory services across the country in an integrated fashion plays an important role in surveillance and epidemiological management of the epidemics. A network of laboratory systems right from the community level till the national level is crucial in effective management of an epidemic and needs to be included in the country's health delivery strategy and budgeting.

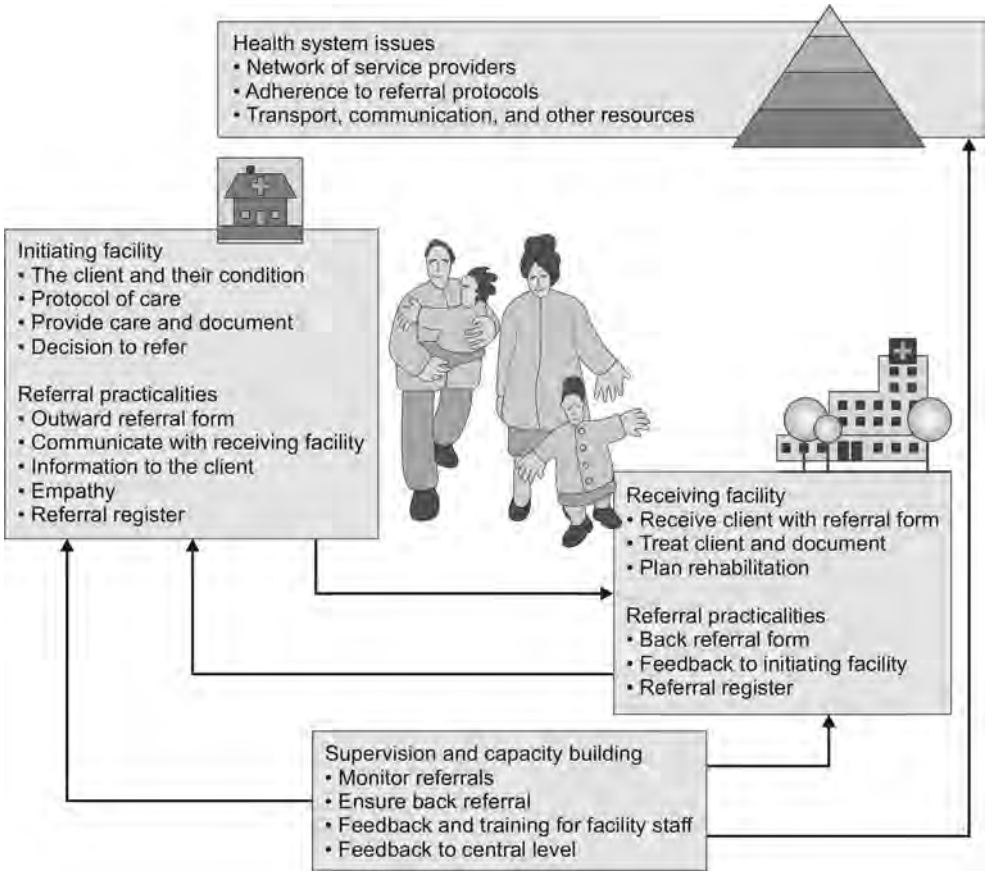


Strong Referral System
National Surveillance System interconnected with other countries
Wide network of laboratory systems easily available up to community level
EIDs Management System
Infodemic Management
Capacity of health system for immediate coordinated response
Tertiary Care and Easy Availability of Medications

FIG. 2: Elements of a robust emerging infectious disease (EID) management system.

Infodemic management system: Right information at right time in right format are the three important elements of a commutation strategy generating appropriate health-seeking behavior, particularly during the ensuing epidemic. This was also experienced during polio management and is currently being experienced during the COVID-19 pandemic in many countries. Complete elimination is not possible but infodemic can be controlled to a large extent so as not to affect the containment strategy of an epidemic. For this, ensure that people have access to factual information in a timely manner that is easily understood and from a credible source and in an easy-to-understand language. The information to be shared should be based on existing scientific evidences in a transparent manner using mix of communication strategies and with the principle of reinforcing and continuous learning.

Tertiary care and easy availability of medication: High standard of equitable tertiary care plays a significant role in reducing the adverse outcomes among patients infected by the pathogen causing the epidemics and also in transmission among the community. Hospitals should have a readily available plan and capacity to be rolled out during overflow of the patients due to ensuing epidemic including documented exclusive epidemic response plan detailing the restructuring of logistics, infrastructure, functions, and manpower.



Health system issues
• Network of service providers
• Adherence to referral protocols
• Transport, communication, and other resources
Initiating facility
• The client and their condition
• Protocol of care
• Provide care and document
• Decision to refer
Referral practicalities
• Outward referral form
• Communicate with receiving facility
• Information to the client
• Empathy
• Referral register
Receiving facility
• Receive client with referral form
• Treat client and document
• Plan rehabilitation
Referral practicalities
• Back referral form
• Feedback to initiating facility
• Referral register
Supervision and capacity building
• Monitor referrals
• Ensure back referral
• Feedback and training for facility staff
• Feedback to central level

FIG. 3: Referral system.

Easy and freely availability of medication as part of clinical management as standardized by the nodal governmental agency, of the patients arising from an epidemic, helps in reducing the adverse effects among the diseased, as experienced in COVID-19 pandemic using dexamethasone and oxygen therapy. Continuity of the pharmacy along with nonepidemic services also needs to be continued like elective and emergency care. Delivery of medication at the community level also plays an important role during an epidemic situation as part of containment strategy and reducing the morbidity and mortality. Inventory management protocols in conformity with the national epidemic response plan are to be developed and followed for ensuring sufficient and timely supplies of the necessary items including medication.

Capacity of the health system for an immediate coordinated response: Health system preparedness during an epidemic situation needs to be of such a level so as to be able to cope with a sudden surge of patients during an epidemic besides maintaining the routing healthcare services. All the components of the health system, private and public, besides those provided by nongovernmental organizations (NGOs), trusts, etc., must be able to adapt to the national epidemic plan in a unison coordinated manner for testing, referral, hospital care, and community-based services. Using IT platforms, all these components may be networked and deliver the services in a swiftly, coordinated and synergistic manner. During an epidemic situation, the legal and statutory provisions as applicable in a country's context may also be used as contained in the national epidemic response plan.

VACCINE DEVELOPMENT

A vaccine is a kind of drug used largely for prevention of diseases by producing immunity through stimulating T cells and B lymphocytes for varied duration and is the most cost-effective way to control the spread of diseases. Vaccines are designed to elicit antibody responses greater and more effective than the natural infections (by antigens) but without any disease's signs and symptoms. Effective antibodies are to be of the neutralizing type able to effectively negate the infectivity of the pathogen's ability to infect host cells. Neutralizing antibodies vaccines include those for influenza and smallpox. Some of the vaccines like those for tuberculosis and HIV require cell-mediated immunity (CMI). Effectivity and duration of protection for any vaccine depends on genetic characteristics, of the pathogen, quality of the immunogenicity produced, and mechanism of action. Mutations may make the vaccine redundant as it changes the antigenic composition of the pathogen. Vaccines have been produced and are in use for many diseases saving billions of lives globally. The latest to join the group is the COVID-19 vaccine (refer to COVID vaccine) produced using a different platform technology. However, for many infections, the vaccines are yet to be found.

Stages of Vaccine Development

Vaccine development follows the stringent robust scientific protocols before being introduced for mass usage by the community (**Flowchart 1**). Many international agencies and countries have their own regulatory authorities to approve the introduction of a particular vaccine for their nationals. Development of vaccines including after introduction for human use, need more stringent protocol for their usage particularly for infants elderly, pregnant women and even for healthy people. The COVID-19 vaccine is going to be given to almost everyone globally.

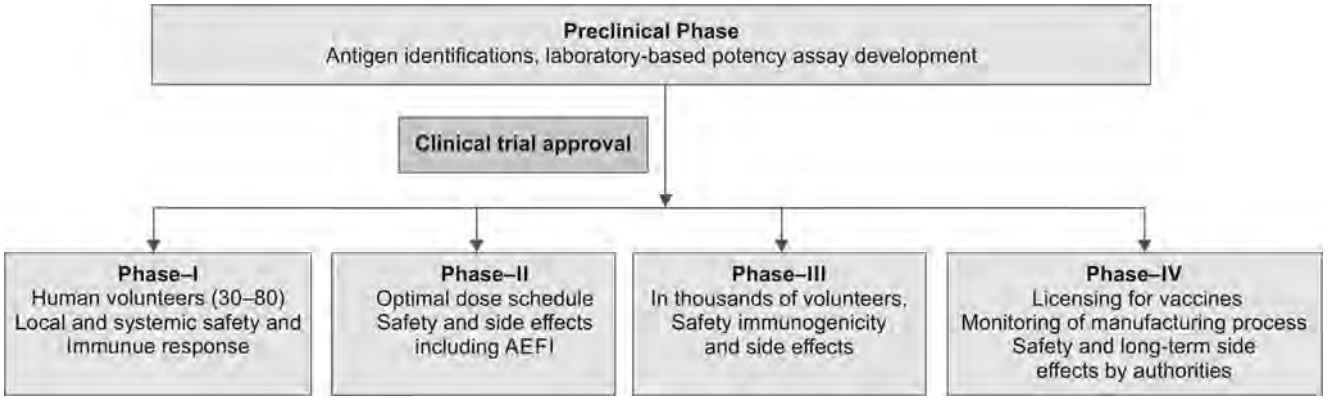
Preclinical Phase

During this phase, the substance is identified to act as an antigen to elicit an immune response in the body similar to the pathogen against whom the vaccine is to be developed. A number of such candidates are tried and the chosen one has the best immunogenic response and level of protection.

Phase I: During this phase, the vaccine is first time tested on human volunteers, usually 30–80, to assess its safety and level of immune response.

Phase II: Hundreds to few thousands volunteers are part of this phase. Phase II studies aim to determine the most effective dose and expand the safety experience with the vaccine. Side effects such as pain/swelling at the injection site, myalgia, headache, and possible adverse effects following immunization (AEFI) are seen.

Phase III: In this stage of the clinical trial, thousands of volunteers receive the vaccine to study its effectiveness. A comparison study is done where an equal number of participants gets the vaccine under study and other group receive the placebo. These groups are followed for months, as



(AEFI: adverse effects following immunization)

FIOWCHART 1: Stages of vaccine development.

in COVID-19 vaccine, to years to see the development of any side effects and level of immune response. Reporting of any serious AEFIs leads to pause the continuation of the trial till all the data are reviewed in depth to decide the continuation of the trial or otherwise. Recently, there were some reports of serious AEFIs during this phase from the AstraZeneca vaccine trial and it was paused before restarting again after a thorough review by regulatory authorities.

Most of the countries as an exception have given Emergency Use Authorization (EMU) after reviewing the data from Phase III trial where the occurrence of side effects, both local and systemic, are studied including efficacy and upon fulfilling the set norms the vaccine is permitted for mass human use, though the usual practice is after Phase IV as described below.

Phase IV: After licensing of the vaccine for production and usage, the regulatory authorities continue to monitor the manufacturing processes so as to monitor the safety and long-term side effects, also known as "postmarketing surveillance." During this phase the manufacturing practices, AEFIs, and duration of immunity are monitored for safety and effectiveness.

SUMMARY

The COVID-19 pandemic has made us realize the huge inadequacies in responding to the EIDs. EIDs have been posing a huge socioeconomic and health burden across countries as the world is now increasingly being connected and therefore there is a strong need for greater responsiveness of the health systems. Real-time surveillance backed by laboratory facilities is the most important aspect to prevent occurrence of these EIDs and for controlling during their occurrence. Implementation of IHRs as now being further strengthened by the WHO in the wake of the COVID-19 pandemic by each country including a global co-ordinated response system will help in containment at the country level and largely at the global level.

185 CHAPTER

Immunization and Postexposure Prophylaxis for Infections

Sara Nooruddin Kazim, Devendra Richhariya

INTRODUCTION

Immunization is the process of stimulating the body's own immune system to produce specific proteins called antibodies against specifically selected bacteria or viruses in order to prevent illness. To achieve this process, substances called vaccines are used; hence, the process is referred to as either immunization or vaccination. Where does the patient live, what vaccines did he/she receive during childhood, where is he/she planning to travel, how long will the trip last, and what are the activities planned to be carried out— are the factors that will determine which vaccines are recommended for an adult. Usually, vaccines provide lifelong protection from the disease; in some situations, specially if given during childhood, some vaccines need a second dose, which is referred to as a booster dose. Associated medical conditions also determine indications of vaccination in adult and travelers.

There are different types of vaccines, active, passive, and toxoids. Regardless of the type, the process is similar. Unlike immunity gained naturally by getting the disease and falling ill, this process is based on weakening the substances used, to a point where they are sufficient to stimulate the immune system to create antibodies against the bacteria or virus without yet actually causing the disease. Active vaccination refers to using the specific bacteria or virus that causes the disease in order to stimulate the immune system to generate its own antibodies.

Another form of active immunization is toxoids, which are used for diseases where the bacteria itself does not cause the disease but a specific toxin that it releases does, e.g., diphtheria and tetanus. Similarly, a weakened form of this toxin is used to stimulate the immune system to generate its own antibodies. On the other hand, passive vaccination or immunization refers to giving the patient preformed antibodies from donors that have generated these antibodies against specific organisms. Unlike active immunization, passive immunization is a weaker process, which is not recommended for healthy adults but may be required in certain situations, such as in immune-compromised individuals.

As a general rule, vaccines are mostly considered safe. They have a long history of preventing death and saving lives all over the world, with a good safety profile. In very rare instances like with any other medical substance, they can cause an allergic reaction or some form of encephalopathy or encephalitis leading to seizures. The more common effects are mild and include local redness, soreness, or a low-grade fever. The next section will summarize the most common vaccines recommended. For each vaccine, we will review the etiology/causes, clinical presentation, investigations (suspected lab abnormalities), and vaccine/treatment and we will end with special considerations (immune-compromised, pregnancy/breastfeeding, healthcare professionals, and travelers).

INFLUENZA

Viral infections are highly contagious and are commonly referred to as the flu. Common presenting features are fever lasting 2–5 days, headache, myalgia, runny nose, and sore throat. *Investigations*: Clinical diagnosis and testing are sometimes done for documentation in a new outbreak or in patients at risk of complications. The vaccine is available in three different forms: Intramuscular (IM), intradermal (ID), or nasal spray. The ID vaccine and nasal spray uses a smaller dose. For elderly or patients with risk of severe infection, the IM higher dose is recommended or the vaccine with an adjuvant which increase the effectiveness of the vaccine. Mostly symptomatic, antiviral medications are used either for treatment or for prevention of illness. For treatment, they decrease the duration of illness by approximately 1 day. They are not recommended if symptoms >48 hours. They are usually used for elderly patients or patients with chronic medical illnesses who are at risk of developing severe complications. For prevention, they are used for the same group of patients mentioned above after exposure who did not take the vaccine.

Special considerations:

- Immune-compromised—recommended
- Pregnant/breast feeding—inactive form recommended (preferably before pregnancy if possible)
- Healthcare professionals—recommended
- Travelers—depending on the season of travel (spreads in the winter)

Haemophilus influenza type-B—*Haemophilus influenza* serotype b (Hib) bacteria. *H. influenza* is the leading cause of bacterial meningitis. Due to its vascular invasion tendency, it has the ability to cause other disease, such as epiglottitis, pneumonia, empyema, pericarditis, bacteremia, and septic

arthritis. Clinical presentation will depend on the area involved. It mainly requires a clinical diagnosis, and treatment is started empirically. For invasive disease, microbiological testing with cultures is required from sterile sites for confirmation. Active vaccination with two to three primary doses and a booster dose as part of childhood vaccination has a protection efficacy against ~95% of the disease. Beta-lactam agents (e.g., amoxicillin or a second- or third-generation cephalosporin) are the preferred antimicrobial agents. Alternative agents include fluoroquinolones, macrolides, tetracyclines, and aminoglycosides.

Special considerations:
- Immune-compromised—recommended (specifically post splenectomy)
- Pregnancy/breast feeding—no specific recommendation as long as it was taken as part of childhood vaccine, no specific contraindication; if needed, preferably during third trimester
- Healthcare professionals—no specific recommendation as long as it was taken as part of childhood vaccine.
- Travelers—no specific recommendation as long as it was taken as part of childhood vaccine

PERTUSSIS

Bordetella pertussis bacteria cause protracted illness, presenting with paroxysmal coughing, affecting daily function. It leads to serious complications, including failure to thrive, apnea, pneumonia, respiratory failure, seizures, and death threat in younger patients. Pertussis is mainly a disease of clinical diagnosis, although cultures or molecular testing can be used for suspicious cases. Due to the duration, treatment is started on clinical suspicion, to prevent spread of the disease. Pregnant women who have been previously immunized with a full three-dose series of tetanus and diphtheria (Td) vaccine should receive a single dose of tetanus, diphtheria, pertussis (Tdap) vaccine, ideally during the early part of the 27–36-week gestational age range. For suspected cases of pertussis and cough ≤3 weeks, antibiotics are recommended. Macrolides are the antibiotics of choice. Azithromycin or clarithromycin have a better compliance profile and are better tolerated than erythromycin. For patients who have macrolide intolerance, trimethoprim-sulfamethoxazole is an acceptable alternative. If cough is persistent for 3–6 weeks, antibiotic may not affect the cough duration or severity but are used to reduce the likelihood of transmission to others. Therefore, for pregnant women, healthcare workers, and individuals working with infants, antibiotics are recommended for persistent cough up to 6 weeks.

Special considerations:
- Immune-compromised—no specific recommendations
- Pregnancy/breast feeding—recommended booster for 27–36 weeks if previously immunized. If not, a full three dose series is required
- Healthcare professionals—no specific recommendations
- Travelers—no specific recommendations

DIPHTHERIA

Gram-positive bacillus *Corynebacterium diphtheriae* may lead to a respiratory disease, a cutaneous disease, or an asymptomatic carrier state. Classical throat examination demonstrates an adherent gray pseudomembrane that bleeds with scraping. Definitive diagnosis requires culture of *C. diphtheria* with specimens collected from respiratory tract secretions or cutaneous lesions and a positive toxin assay. Routine laboratory results are usually nonspecific and may include a moderately elevated white blood cell count and proteinuria. Depending on the location and severity of infection, a combination of antitoxin and antibiotics is required. In general, erythromycin or procaine penicillin G are the antibiotics used. Antibiotics are used to decrease the growth preventing further toxin production, slows local spread, and reduce transmission.

Special considerations:
- Immune-compromised—no recommendations
- Pregnancy/breast feeding—recommended
- Healthcare professionals—no recommendations
- Travelers—no recommendations

TETANUS

Toxin-producing anaerobe *Clostridium tetani causes tetanus.* Tetanus can present in one of four clinical patterns: generalized, local, cephalic, and neonatal. The most common and severe clinical form of tetanus is generalized tetanus. Generalized tetanus characteristically has tonic contraction of their skeletal muscles and intermittent intense muscular spasms. Since patients with tetanus have no impairment of consciousness or awareness, both the tonic contractions and the spasms are intensely painful. Clinical diagnosis is based on typical presentation. Since tetanus is one of the few bacterial diseases that does not confer immunity following recovery from acute illness, all patients with tetanus should receive active immunization with a total of three doses of tetanus and diphtheria toxoid spaced at least 2 weeks apart, commencing immediately upon diagnosis. Tetanus toxoid should be administered at a different site than tetanus immunoglobulin. Treatment is usually in the intensive care unit, symptomatic management with airway observation, and management as needed.

Special considerations:
- Immune-compromised—no specific recommendations
- Pregnancy/breast feeding—recommended
- Healthcare professionals—no specific recommendations
- Travelers—no specific recommendations

PNEUMOCOCCUS

Pneumococcus is as gram positive diplococci, e.g., *Streptococcus* may give rise to noninvasive infections: Ear sinus infections and pneumonia; and invasive infections: Bacteremia and meningitis. *Diagnosis is by* isolation of the organism from blood or other normally sterile body sites, such as cerebrospinal fluid (CSF), more than 25 white blood cells and fewer than 10 epithelial cells per high-power field, and a predominance of gram-positive diplococci on Gram stain. There is also the urinary antigen test based on an immunochromatographic membrane technique to detect the C-polysaccharide antigen of *Streptococcus pneumoniae*. Vaccination is recommended for: Infants and children below 2 years and adults 65 years and older and special groups:

Special groups: Children, elderly people with chronic illness, with cochlear implants, or CSF leaks, or who smoke cigarettes.

Antibiotics in penicillin and erythromycin are used for the noninvasive group. Wide-spectrum antibiotics are used for the invasive group. Once the sensitivity of the bacteria is known, a more targeted antibiotic may be selected. Two types of vaccines are available: (1) Pneumococcal conjugate *vaccine (PCV13)* and (2) *pneumococcal polysaccharide vaccine (PPSV23)*.

Special considerations:
- Immune-compromised—recommended
- Pregnancy/breast feeding—not recommended
- Healthcare professionals—no specific recommendation
- Travelers—no specific recommendation

MENINGOCOCCUS

Neisseria meningitidis bacteria cause meningococcal meningitis which present as: fever, headache, stiff neck, nausea, vomiting, photophobia), altered mental status (confusion), lethargy, and poor feeding and irritability in newborn. *Meningococcemia*: Sepsis and rash; fever; fatigue; vomiting; cold hands and feet; cold chills; severe aches or pain in the muscles, joints, chest, or abdomen; rapid breathing, and diarrhea. Isolation and identification of *N. meningitidis* are done with a Gram stain of the CSF sediment or by detection of specific antigens in the CSF by a latex agglutination test or using rapid diagnostic tests (RDTs). Positive results for any of these tests can rapidly provide evidence of infection, even if cultures fail to grow. Meningococcal conjugate vaccines and serogroup B meningococcal vaccines are recommended. Prompt treatment with antibiotic upon clinical suspicion, cardiopulmonary support, and wound care is recommended as needed.
- 11–12 years old—should be vaccinated
- 16 years old—may give a booster dose
- 16–23 years old—to be vaccinated with a serogroup B meningococcal vaccine if—they have complemented component deficiency, functional or anatomic asplenia; they are living with an HIV patient; they are a first-year college student living in a residence hall; or they are a military recruit.

Special considerations:
- Immune-compromised—recommended
- Pregnancy/breast feeding—If high risk, no contraindication to administration
- Healthcare professionals—they are a microbiologist who is routinely exposed to *N. meningitidis*
- Travelers—recommended for those traveling or residing in countries in which the disease is common

HERPES ZOSTER (VARICELLA)

Varicella zoster virus (VZV) *causes* fever, malaise, and painful rash with dermatomal distribution.

It can be identified by polymerase *chain reaction (PCR)*: Live vaccine recombinant zoster vaccine is recommended for people aged 50 years and older. Antiviral medications, acyclovir, valacyclovir, and famciclovir, are recommended to shorten duration and analgesia.

Special considerations:
- No specific recommendation
- Pregnancy/breast feeding—not recommended, post-exposure prophylaxis with varicella zoster immunoglobulin can be given in nonimmune pregnant women
- Healthcare professionals—no specific recommendations
- Travelers—no specific recommendations

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) is a sexually transmitted disease. It causes common warts. Persistent infection can lead to: Cervical, vaginal, and vulvar cancers in women; penile cancers in men; and oropharyngeal and anal cancers in both men and women. Pap test is recommended for precancer changes and HPV DNA test for HPV. *Vaccine*: 9-valent HPV is given to all adolescents of 11–12 years through to 15 years of age in a two-dose regimen, second 6–12 month from the first dose. It contains inactivated human papillomavirus.

Special considerations:
- Immunocompromised—a three-dose regimen is recommended (0, 1–2, 6 months)
- Pregnancy/breast feeding—not recommended, limited safety profile
- Healthcare professionals—no specific recommendations
- Travelers—no specific recommendations

TUBERCULOSIS

A bacterium called *Mycobacterium tuberculosis* causes fever, chills, night sweats, weight loss, cough, gastrointestinal (GI) symptoms, and bone pain, depending on the affected area. Tuberculosis (TB) skin test (Mantoux) tells if a person is infected or not. TB blood test [interferon-gamma release assays (IGRAs) or T spot] signifies if a person has latent TB infection (LTBI) and acid–fast bacilli (AFB) on a sputum smear along with chest X-ray diagnosis of TB disease. Bacillus Calmette–Guérin (BCG) vaccine is given to infants in countries where TB is common.

The four-drug regimen for LTBI uses isoniazid (INH), rifapentine (RPT), or rifampin (RIF). It should be modified if the patient is drug resistant. For TB disease: INH, RIF, ethambutol (EMB), and pyrazinamide (PZA) are given.

Special considerations:
- Immune-compromised—contraindicated
- Pregnancy/breast feeding—not recommended
- Healthcare professionals—recommended for high percentage or continuous transmission or exposure with isoniazid- and rifampin-resistant TB
- Travelers—no specific recommendations

MEASLES/MUMPS/RUBELLA

Measles: RNA virus from genus *Morbillivirus*. *Mumps*: RNA mumps virus. *Rubella*: RNA virus classified as Rubi virus. Measles presents as fever, cough, maculopapular skin rash, and conjunctivitis with serious illnesses, such as pneumonia and encephalitis. Mumps presents as fever, headache, muscle aches, tiredness, loss of appetite, tender swollen salivary glands, deafness, and in severe cases encephalitis. Rubella presents as fever, sore throat, conjunctivitis, arthritis in women, and miscarriages and birth defects in pregnant

women. Measles can be identified by detection of measles-specific IgM antibody and measles RNA by real-time PCR (RT-PCR) through nasopharyngeal swaps.

- *Vaccine*—live, attenuated vaccine recommended
- *Second doses*—first at 12–15 months of age and second at 4–6 years of age
- Two doses, 28 days apart for teenagers without evidence of immunity
- One dose at least for adults without evidence of immunity

Special considerations:

- Immune-compromised—not recommended.
- Pregnancy/breastfeeding—not recommended, IV immunoglobulin for postexposure within 6 days (measles)
- Healthcare professionals—if no evidence of immunity
- Travelers—unvaccinated adults and infants from 6 through 11 months

CHICKENPOX

Varicella zoster virus infection manifests as a nonspecific viral illness followed by a vesicular rash. The patient's condition can progress to more serious pneumonia and encephalitis. It can be detected by direct virology or PCR detection from body fluids and vesicles scraping. It is a live attenuated virus vaccine. Routine vaccination is recommended for all patients. For patients aged above 60 years of age, note the previous history of chickenpox and chronic medical condition. Antiviral reduces the duration and severity of illness if the patient receives it within 24–48 hours after new vesicle formation. It can be managed by supportive treatment and management of complications.

Special considerations:

- Immune-compromised—varicella vaccine is recommended for patients with mild-to-moderate immune suppression. It is recommended for patients at least 14 days before receiving immunosuppressive therapy.
- Pregnancy/breastfeeding—varicella vaccine is not recommended to be administered during pregnancy. Pregnant women suspected to be at risk of varicella zoster infection are given two vaccines postpartum: One immediately in the postpartum period and the second vaccine at 4–8 weeks postpartum.
- Healthcare professionals—no specific recommendations
- Travelers—no specific recommendations

HEPATITIS A

Hepatitis A virus (HAV) presents as fever, abdominal pain, loss of appetite, vomiting, and jaundice.

Detection of antihepatitis A virus (anti-HAV) IgM antibodies and the determination of total anti-HAV by enzyme immunoassay for diagnosis: inactivated (killed) vaccine, routinely given to children 12 through 23 months of age.

Special considerations:

- Immune-compromised—no specific recommendation
- Pregnancy/breast feeding—no specific recommendation
- Healthcare professionals—no specific recommendation
- Travelers—recommended for high-risk areas

HEPATITIS B

The clinical features of hepatitis B virus (HBV) are fever, liver cirrhosis, liver cancer, liver failure, and death. *Children and adults*: Three-dose vaccine series administered IM, the second and third administered 1 and 6 months after the first months (**Table 1**).

Special considerations:

- Immune-compromised—recommended if not vaccinated
- Pregnancy/breast feeding—not contraindicated if high risk of exposure
- Travelers—no specific recommendations if previously vaccinated

A seroprotective (adequate) level of anti-HBs after completion of a vaccination series is defined as anti-HBs ≥10 mIU/mL; a response <10 mIU/mL is inadequate and is not a reliable indicator of protection.

YELLOW FEVER

The causative agent is a single-stranded RNA virus and a member of the Flavivirus family. Yellow fever is a mosquito-borne viral hemorrhagic fever which presents as a mild, nonspecific febrile illness to severe life-threatening hemorrhage with multiorgan failure. Nucleic acid amplification test is done to detect yellow fever virus (YFV) in various body fluids (urine, serum, and CSF). YFV-specific IgM or fourfold raise in IgG levels is found. A single live attenuated virus vaccine is recommended for a person more than 9 months of age traveling to or living in areas with a high risk of virus transmission. *Treatment*: Mainly supportive treatment and management of complications. Antivirals and steroids are of no proven benefit in treating yellow fever.

Special considerations:

- Immune-compromised—patients require revaccination every 10 years before traveling to endemic areas with YFV.
- Pregnancy/breastfeeding—patients require revaccination regardless of the trimester before traveling to endemic areas with YFV.
- Healthcare professionals—workers dealing with live YFV require revaccination every 10 years.
- Travelers—travelers who have had their vaccination more than 10 years ago and are traveling to high-risk areas and intend to stay for prolonged periods require revaccination.

POLIO

Poliovirus is a member of the enterovirus family that colonizes the gastrointestinal tract. Transmission is mainly through the fecal-oral route. *Mucocutaneous and respiratory manifestations*: Nonspecific febrile illness followed by maculopapular rash on palms and soles and upper and lower respiratory tract infections. *Neurologic and systemic manifestations*: Present as aseptic meningitis, acute flaccid paralysis, and encephalitis. Nucleic acid amplification test (NAAT) is done to detect poliovirus through various body fluids (urine, serum, and CSF). Poliovirus-specific IgM antibodies in the CSF or serum are found. *Inactivated polio vaccine (IPV)*: Incorporated into routine vaccination schedule given at age of: 2 months,

TABLE 1: Postexposure prophylaxis for hepatitis B.

Vaccination and antibody response status of exposed person	*Status of source*		
	Source HBsAg-positive	*Source HBsAg-negative*	*Source not tested or status unknown*
Unvaccinated	HBIG × 1; initiate HB vaccine series	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated			
Known responder	No treatment	No treatment	No treatment
Known nonresponder			
After 3 doses	HBIG × 1 and initiate revaccination	No treatment	If known high-risk source, treat as if source were HBsAg-positive
After 6 doses	HBIG × 2 (separated by 1 month)	No treatment	If known high-risk source, treat as if source were HBsAg-positive
Antibody response unknown	Test exposed person for anti-HBs: • If adequate-no treatment • If inadequate - HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBs: • If adequate-no treatment • If inadequate-initiate revaccination

(HBIG: hepatitis B immune globulin; HBsAG: hepatitis B surface antigen)

4 months, 6–8 months, and 4–6 years. *Oral polio vaccine (OPV)*: Live attenuated, oral drops which are given during polio eradication campaigns. Antivirals and immunoglobulins are of no proven benefit in treating poliovirus infection.

Special considerations:
- *Immune-compromised*—IPV is recommended for patients traveling to high-risk areas.
- Pregnancy/breast feeding—IPV is not contraindicated in breastfeeding mothers. It is recommended for patients traveling to high-risk areas.
- Healthcare professionals—IPV is indicated in personnel in close contact with patients who traveled to an area with a high risk of polio.
- Travelers—IPV is indicated for travelers to high-risk areas.

TYPHOID

Salmonella typhi and paratyphi A, B, and C cause typhoid through the fecal-oral route transmission. Typhoid and paratyphoid fever have an incubation period from 6 to 30 days. The onset of symptoms is insidious with gradually increasing fever, fatigue, and abdominal pain. Complications causing death include gastrointestinal hemorrhage and perforation. Bone marrow blood culture is done for detecting . species. Vaccine: *Indications*
- Travelers to areas endemic with *Salmonella typhi*
- Person with close contact with a documented *Salmonella typhi* carrier
- Microbiologists and laboratory workers working with cultures of *Salmonella typhi*

Management includes mainly supportive treatment and management of complications in addition to early antibiotic treatment. Quinolones and third-generation cephalosporins are associated with higher cure rates.

Special considerations:
- Life attenuated vaccine is contraindicated in immunocompromised, and the oral vaccine is of limited efficacy.
- Pregnancy/breastfeeding—oral live attenuated virus is contraindicated while there is no evidence that a parenteral form is contraindicated.
- Healthcare professionals—no specific recommendations
- Travelers—travelers to endemic areas require immunization to be completed at least 2 weeks prior to exposure.

JAPANESE ENCEPHALITIS

Japanese encephalitis virus (JEV) is a mosquito-borne Flavivirus. This virus is found in Asia and parts of the western Pacific at agricultural areas where rice farming is prominent. The incubation period of Japanese encephalitis (JE) ranges from 5 to 15 days. The prodromal phase of JE starts as a nonspecific febrile illness (fever, nausea, vomiting, headache, and malaise). This phase is followed by the encephalitis phase. Encephalitis presents with altered mental status, focal neurological deficit, and abnormal movements. Status epilepticus and motor neuron weakness are poor prognostic signs. JEV-specific IgM antibodies are found in the CSF or serum. NAAT to detect viremia is insensitive to diagnose JE. Virus-specific IgM antibodies can be detected from CSF or serum. Preventive measures to prevent JE include mosquito control, animal immunization, and human immunization.

Vaccine: Recommended for residents of endemic areas, laboratory workers exposed to live infectious JEV, and travelers who plan to stay more than 1 month in endemic areas during JE outbreaks. Management includes mainly supportive treatment and management of complications. Antivirals and steroids are of no proven benefit in treating JE.

Special considerations:
- No specific recommendations for vaccination in immunocompromised patients
- Pregnancy/breast feeding—JE vaccine is recommended for pregnant women traveling to endemic areas and planning to stay for a long period.
- JE vaccine is not contraindicated in breast-feeding women.

- Healthcare professionals—JE is recommended for laboratory workers dealing with live infectious JEV.
- Travelers—JE is recommended for travelers intending to stay for >1 month in an endemic area with JE.

RABIES

Rabies is caused by an RNA virus of the *Rhabdoviridae* family. Transmission occurs via saliva of an infected host to an uninfected victim through bites. Rabies infection in human presents in five phases.

The incubation period ranges between 1 month and 2 months but can be as early as 7 days postexposure and up to >6 years postexposure. *Prodromal phase*: Nonspecific symptoms includes nausea, vomiting, fever, and paresthesia at the bite site. *Acute neurological phase—encephalitic (furious) rabies*: Hyperactive symptoms aggravated by thirst, fear, light, or noise. During this phase characteristic phobic spasms occur, mainly aerophobia and hydrophobia .

Paralytic (dumb) rabies: It is ascending paralysis that is difficult to diagnose since it resembles other neurological diagnoses that present with progressive paralysis. *Coma*: Common precipitants include spasm of respiratory muscles, nodal dysrhythmia, and cardiogenic shock. Recovery is mainly noted in patients who received immediate postexposure prophylaxis (PEP). Direct fluorescent antibody (DFA) is carried out on two samples from brain tissue. *Human*: Antirabies virus antibody detection in serum, CSF, and saliva. Reverse transcriptase followed by RT-PCR in saliva or nuchal biopsy is carried out for detecting rabies virus RNA. DFA testing is carried out for detecting rabies virus.

Inactive vaccine can be given as preexposure prophylaxis or as PEP. Rabies immunoglobulin is administered post exposure in high-risk groups.

Preexposure prophylaxis is indicated for: Personnel at risk of exposure to live rabies virus (laboratory staff, veterinarians, animal handlers, and wildlife officers), children living or visiting rabies-endemic areas, and travelers visiting rabid-endemic areas. *Dose regimen*: Rabies vaccine is administered IM on days 0, 7 and 21 or 28.

Postexposure prophylaxis steps: *Wound treatment*: Immediate wound washing and flushing in addition to disinfection with detergent. Avoid suturing the sound. Rabies vaccine and immunoglobulins (RIG) are administered according to the category of exposure (**Table 2**).

Rabies vaccine is administered IM on days 0, 3, 7, and 14. Rabies immunoglobulin, 20 IU/kg body weight, is infiltrated around and into the wound. The remaining volume is administered IM at an anatomically distant site from the vaccination area. Wound cleansing and supportive care are recommended. Antirabies vaccine and immunoglobulins are administered for bites from infected animals.

Rabies vaccination is deferred in immune-compromised: Until immune suppression status resolves. If not possible, then a preexposure regimen is administered and antibody response is checked in 2–4 weeks. *PEP measures of immunocompromised are:* Wound cleansing. RIG administration for category II and III exposures. Rabies vaccine regimen is changed from the four-dose regimen to the five-dose regimen (0, 3, 7, 14, and 28).

TABLE 2: Recommendation of postexposure prophylaxis.

Category of exposure	*Description*	*Postexposure prophylaxis*
Category I	• Touching or feeding a potentially rabid animal • Licks on intact skin	• Not clinically relevant exposures • No PEP indicated
Category II	• Licking uncovered skin • Minor scratches or abrasions without bleeding	• Wound disinfection • Antirabies vaccine only
Category III	• Single or multiple transdermal bites • Contamination of exposed skin or mucus membranes with saliva	• Wound disinfection • Antirabies vaccine • Rabies immunoglobulin

(PEP: postexposure prophylaxis)

If possible, withhold other immune-suppressant agents during PEP.

Pregnancy and breast feeding are not contraindications for PEP.

Preexposure prophylaxis is indicated for personnel at risk of exposure to live rabies virus (laboratory staff, veterinarians, animal handlers, and wildlife officers) and for travelers to rabid-endemic areas.

SMALLPOX

Variola virus transmission occurs through person-to-person contact and saliva droplets. Signs and symptoms occur after an incubation period. This is followed by a prodromal phase (2–3 days) which is characterized by high-grade fever (40°C). This is followed by the most contagious stage which starts with red spots in the mouth and tongue followed by vesicular or pustular rash spreading down from face to limbs and trunk that finally scabs off 3 weeks after the appearance of rash. *Electron microscopy*: This is done at the World Health Organization (WHO) smallpox biological safety level 4 laboratory. *Polymerase chain reaction* is done to detect variola virus DNA. Vaccinia vaccine is not recommended for the general population. Its use is indicated for: Laboratory personnel in direct contact with cultures or animals contaminated with orthopoxviruses causing infection in humans (variola, monkeypox, and cowpox). The mainstay of treatment is supportive in addition to antivirals (tecovirimat, brincidofovir, or cidofovir) in outbreak cases. Vaccinia vaccine is an absolute contraindication in immune-compromised, pregnancy, and breast feeding unless there is a smallpox outbreak. Vaccination in travelers and healthcare professionals is contraindicated unless the patient is in close contact with orthopoxvirus–infected humans, tissue, or animals.

ANTHRAX

Anthrax is a zoonotic disease caused by gram-positive, spore-forming bacteria *Bacillus anthracis*. Although *B. anthracis* spores are used as a biological weapon, outbreaks of the infection are not uncommon. Humans exposed to *B. anthracis* spores by direct contact or through inhalation

TABLE 3: Recommended Adult Immunization Schedule.

Recommended vaccination / Age group	Influenza inactivated/ Influenza recombinant or Influenza live attenuated		Tetanus Diphtheria Pertussis (Tdap, Td)	Measles Mumps Rubella	Varicella	Zoster recombinant or Zoster live		Pneumococcal	Meningococcal	Haemophilus influenzae Type B	Hepatitis A	Hepatitis B	Human papillomavirus
18–25	One dose annually	One dose annually	One dose Tdap then Td/Tdap booster dose every 10 years	One/two dose as indicated	Two doses (if born post-1980)	Not Applicable	Not Applicable	One/Two doses in additional risk factors	One/Two doses depending on vaccine and if additional risk factors and clinical decision making	One or three doses depending on indications and if additional risk factors are present	Two/three doses depending on vaccines with additional high-risk patient	Two/three doses depending on vaccines with additional high-risk patient	Two/three doses depending on age at initial vaccination or condition
26–50	One dose annually	One dose annually	One dose Tdap then Td/Tdap booster dose every 10 years	One/two dose as indicated	Two doses (if born post-1980)	Not Applicable	Not Applicable	One/Two doses in additional risk factors	One/Two doses depending on vaccine and if additional risk factors	One or three doses depending on indications and if additional risk factors are present	Two/three doses depending on vaccines with additional high-risk patient	Two/three doses depending on vaccines with additional high-risk patient	Two/three doses depending on age at initial vaccination or condition
51–65	One dose annually	Not Applicable	One dose Tdap then Td/Tdap booster dose every 10 years	Not Applicable	Two doses recommended if added risk factors or another indication	Two doses	Not Applicable	One/Two doses in additional risk factors	One/Two doses depending on vaccine and if additional risk factors	One or three dose depending on indications and if additional risk factors are present	Two/three doses depending on vaccines with additional high-risk patient	Two/three doses depending on vaccines with additional high-risk patient	Not Applicable
>65 years	One dose annually	Not Applicable	One dose Tdap then Td/Tdap booster dose every 10 years	Not Applicable		Two doses	One dose	One/Two doses in additional risk factors	One/Two doses depending on vaccine and if additional risk factors	One or three dose depending on indications and if additional risk factors are present	Two/three doses depending on vaccines with additional high-risk patient	Two/three doses depending on vaccines with additional high-risk patient	Not Applicable
Additional risk factors: Diabetes; End-stage renal disease or on hemodialysis; Chronic liver disease; Heart or lung disease; Chronic alcoholism; Asplenia; Complement deficiency; Pregnancy; Healthcare worker													

(Td: tetanus and diphtheria; Tdap: tetanus, diphtheria, pertussis)

develop anthrax that presents in one of the following forms: symptoms related to anthrax exposure are nonspecific and resemble other viral infections. Patients can exhibit itchy blisters that progress to painless ulcers with black center (eschar). Other nonspecific features include dyspnea, chest tightness, nausea, vomiting, fever, and abdominal pain. Diagnosis of *B. anthracis* depends on the history of exposure to an infected animal and the presence of prodromal symptoms in addition to demonstrating gram-positive bacilli in tissue cultures or blood stream. Tissue cultures might be negative in patients who receive antibiotics prior to sample retrieval. Vaccination against *B. anthracis* is not routinely recommended for the general population. *B. anthracis* vaccines are given as pre-event or postevent vaccination. *Pre-event vaccination*: *B. anthracis* vaccination is only recommended for high-risk population at an increased risk of occupational exposure.

The recommended dose is five IM doses administered at days 0, week 4, and months 6, 12, and 18. The population at high risk of exposure includes: Laboratory workers who are at a high risk of repeated exposure to virulent *B. anthracis*, military personnel who are at a risk of exposure to aerosolized *B. anthracis*, environmental investigators who repeatedly enter contaminated areas with *B. anthracis* spores, and emergency response personnel who are at a risk of encountering aerosolized *B. anthracis*. *Postexposure prophylaxis*: The Center for Disease Control and Prevention recommends PEP with 60 days of appropriate antibiotics in addition to three subcutaneous doses of the *B. anthracis* vaccine. PEP is recommended for unvaccinated personnel after exposure to *B. anthracis*. The mainstay of treatment is supportive care in addition to early antibiotic initiation. Ciprofloxacin and doxycycline are preferred antibiotic choices for anthrax PEP.

Special considerations:

- Not recommended in immune-compromised
- Pre-event vaccination is not recommended in pregnant and breast-feeding women who have low-risk exposures. PEP is recommended following exposure to *B. anthracis* and breast feeding is not a contraindication for vaccine administration.
- Pre-event vaccination is generally not recommended in children.
- Postexposure prophylaxis is recommended following exposure to *B. anthracis*.
- Healthcare professionals—pre-event vaccination is generally not recommended. PEP is recommended following exposure to *B. anthracis*.
- Travelers—pre-event vaccination is generally not recommended. PEP is recommended following exposure to *B. anthracis*.

SUMMARY

The main objective of the immunization is the stimulation of the body's own immune system to produce specific proteins called antibodies against specifically selected bacteria or viruses in order to prevent illness. Vaccines are used for this purpose; the process is referred as either immunization or vaccination. Various factors determine the vaccination, e.g., epidemiology, childhood vaccination, travel plan, travel duration. Usually vaccines provide lifelong protection against the disease; in some situations, specially if given during childhood, some vaccines need a second dose, which is referred to as a booster dose. Associated medical conditions also determine indications of vaccination in adult and travelers (**Table 3**).

186
CHAPTER

Tropical Infections in Travelers

Ananthakrishnan C, Devendra Richhariya

INTRODUCTION

The world has become a small place. Globalization has promoted traveling, and connectivity has improved, and thus people are traveling far more than before. In 2019, almost 27 million people traveled out of India and in December 2019, around 1.2 million tourists arrived in the country.

India, being a tropical country, is endemic to many of the tropical diseases that can present as pyrexia of unknown origin. Since most of them present as fever, diagnosing an infection can be a challenge and requires a thorough history and clinical examination to rapidly narrow down the differential diagnoses.

ETIOLOGY/CAUSES

Fever is the most common symptom encountered in tropical infections. In the present pandemic situation, it has become a norm for the emergency physician to consider every fever in a person with travel history as COVID-19 infection unless other causes are diagnosed. Common causes of fever in a returning traveler are dengue, malaria, enteric fever, leptospirosis, scrub typhus, and chikungunya. It is equally important for the clinician to consider other causes of fever, such as autoimmune diseases, drugs, and malignancy, while evaluating the patient. A history of travel to different areas in the tropics may provide a clue to the emergency physician in diagnosing the clinical condition of the patient (**Table 1**).

EVALUATION: HISTORY AND PHYSICAL EXAMINATION

A detailed history and a good clinical examination will direct initial tests and management and inform any infection control measures that need to be taken. A good and meticulous history taking will help in narrowing down the differential diagnosis. A good history includes assessing the onset of travel and its relation to the onset of illness, if the travel was to a rural or urban area, the type of accommodation, food and water, activities such as freshwater swimming and caving, contact with any sick patient, animals, or new sexual partners. It is also important to record exposure to any insect bites and examine for the same. Incubation periods for common infectious agents are given in **Table 2**. Mostly travelers present with infections have incubation periods of <21 days and several travelers can clinically manifest after return for >30 days (e.g., malaria, tuberculosis, hepatitis, filariasis). The most common infection presenting >30 days after exposure is *P. vivax* malaria (25% of patients with this infection present after 30 days). While evaluating a traveler with a febrile illness, the emergency physician should inquire about the following topics:

- Details about travel dates/season
- Countries and destinations visited (rural/urban locations)
- Exposure to bites/vectors/animals

TABLE 1: Infections according to geographic distribution.

Geographic area visited	*Common diagnosis to be considered*	*Differential diagnosis*
Caribbean	Chikungunya, dengue, malaria (Hispaniola), Zika	Acute histoplasmosis, leptospirosis
Central America	Chikungunya, dengue, malaria (primarily *Plasmodium vivax*), Zika, enteric fever	Leptospirosis, histoplasmosis, coccidioidomycosis, leishmaniasis
South America	Chikungunya, dengue, malaria (primarily *P. vivax*), Zika	Bartonellosis, leptospirosis, enteric fever, histoplasmosis
South Central Asia	Dengue, enteric fever, malaria (primarily nonfalciparum)	Chikungunya, scrub typhus
Southeast Asia including India	Dengue, malaria (primarily nonfalciparum)	Chikungunya, leptospirosis
Sub-Saharan Africa	Malaria (primarily *P. falciparum*), tickborne rickettsiae (main cause of fever in southern Africa), acute schistosomiasis (Katayama fever), dengue	African trypanosomiasis, chikungunya, enteric fever, meningococcal meningitis

- Types of food and water consumed
- History of vaccination and chemoprophylaxis
- Unprotected intercourse and partners
- Timing and sequence of illness/symptoms

Examination should comprise an assessment of how unwell the patient is along with a meticulous examination to look for any localizing features which may point to a diagnosis, such as jaundice, rash, skin lesions, lymphadenopathy, retinal or conjunctival changes, hepatosplenomegaly, or neurological findings. The examination should include looking for genital lesions and a thorough examination for eschars (pointing to rickettsial infections) as these are often found in "hard-to-assess" places such as the natal cleft and under the breasts. Patients with respiratory distress, hypotension or shock, hemorrhage, confusion, meningism, or other neurological findings should be urgently investigated. Even if an initial physical examination is unremarkable, it should be repeated if the diagnosis is unclear, as new findings may appear in due course of hospitalization that will help in the diagnostic process (such as skin lesions or a tender liver).

Fever associated with any of the following syndromes (**Table 3**) deserves special importance, because it may indicate a disease of public health importance, where immediate infection control and containment actions may be warranted (**Table 4**).

- Skin rash with or without conjunctivitis (seen in measles, meningococcemia, hemorrhagic fevers such as Ebola, dengue, and hemorrhagic fever)
- Rapid respiratory rate [seen in COVID-19 pneumonia, avian influenza, Middle East respiratory syndrome (MERS)]
- Persistent cough (seen in COVID-19, pulmonary tuberculosis, pertussis)
- Decreased consciousness (seen in meningococcal meningitis, rabies)
- Bruising or unusual bleeding without injury (seen in hemorrhagic fevers)

TABLE 2: Incubation periods for common and severe infections acquired during travel.

Short <10 days	Typhoid, dengue, rickettsial, meningitis, encephalitis, chikungunya, *Shigella Salmonella*, VHF, influenza, *Legionella* mononucleosis
Medium 11–21 days	Malaria, typhoid, leptospirosis, brucellosis, hepatitis A, schistosomiasis, amebic liver, abscess Q fever, African trypanosomiasis, rickettsial, VHF, HIV, seroconversion
Long >30 days	Tuberculosis, reactivation, malaria, leishmaniasis, filariasis, schistosomiasis, rabies, African trypanosomiasis, enteric protozoal, enteric helminthic

(HIV: human immunodeficiency virus; VHF: viral hemorrhagic fever)

TABLE 3: Fever-associated syndrome.

Common clinical findings	*Infections to consider after tropical travel*
Fever and rash	Dengue, chikungunya, Zika, measles, spotted fever or typhus group rickettsioses, enteric fever (skin lesions may be sparse or absent), meningococcemia, acute HIV infection, varicella
Fever and abdominal pain	Enteric fever, amebic or pyogenic liver abscess
Fever and normal or low white blood cell count	Dengue, malaria, rickettsial infection, enteric fever, chikungunya, Zika, acute HIV
Fever and hemorrhage	Viral hemorrhagic fevers (e.g., dengue, yellow fever, Ebola, Lassa fever), meningococcemia, leptospirosis, spotted fever group rickettsial infections
Fever and arthralgia or myalgia (sometimes persistent)	Chikungunya, dengue, Zika, Ross River virus, muscular sarcocystosis, trichinellosis
Fever and eosinophilia	Acute schistosomiasis, drug hypersensitivity reaction, fascioliasis, sarcocystosis, trichinellosis, angiostrongyliasis, and other parasitic infections (rare)
Fever and respiratory symptoms/pulmonary infiltrates	Influenza and other common bacterial and viral pathogens, COVID-19 legionellosis, tuberculosis, acute schistosomiasis, Q fever, leptospirosis, Middle East respiratory syndrome, acute histoplasmosis or coccidioidomycosis, psittacosis, melioidosis, pneumonic plague
Fever and altered mental status/central nervous system involvement	Cerebral malaria, arboviral encephalitis (e.g., Japanese encephalitis, West Nile virus), meningococcal meningitis, rabies, African trypanosomiasis, scrub typhus, angiostrongyliasis, tickborne encephalitis, rabies
Fever and jaundice	Acute viral hepatitis (A, B, C, E), yellow fever and other viral hemorrhagic fevers, severe malaria, leptospirosis
Mononucleosis syndrome	Epstein–Barr virus infection, cytomegalovirus infection, toxoplasmosis, acute HIV infection
Fever persisting >2 weeks	Malaria, enteric fever, Epstein–Barr virus infection, cytomegalovirus infection, toxoplasmosis, acute HIV infection, acute schistosomiasis, brucellosis, tuberculosis, Q fever, visceral leishmaniasis (rare)
Fever with onset >6 weeks after travel	*Plasmodium vivax* or *ovale* malaria, acute hepatitis (B, C, or E), tuberculosis, amebic liver abscess, melioidosis, African trypanosomiasis

TABLE 4: Red flags requiring further infection prevention measures in travelers.	
Risk of viral hemorrhagic fever	Fever in the past 24 h and travel to viral hemorrhagic fever–endemic country in the past 21 days plus any of the following: • Travel to area with known current viral hemorrhagic fever outbreak • Living in basic rural conditions in Lassa-endemic area • Visited caves or mines or had contact with or eaten primates, antelopes, or bats in area with Ebola or Marburg outbreak • Had tick bite or contact with animal slaughter in an area with Crimean–Congo hemorrhagic fever • Contact with known or strongly suspected case of viral hemorrhagic fever in the past 21 days
Risk of Middle East respiratory syndrome coronavirus	Severe respiratory infection requiring hospitalization and fever and clinical or radiological evidence of pneumonia plus any of the following: • Travel to area with known Middle East respiratory syndrome coronavirus outbreak in the past 14 days • Contact with confirmed case of Middle East respiratory syndrome coronavirus in the past 14 days • Contact with camels or consumption of camel products in area with Middle East respiratory syndrome coronavirus in the past 14 days
Risk of avian influenza	Fever and clinical or radiological evidence of pneumonia or other severe illness suggestive of infectious process plus one of the following: • Travel to China in the past 10 days, or • Contact with a known case of avian influenza in the past 10 days

- Persistent voluminous diarrhea (seen in cholera)
- Jaundice (seen in hepatitis A, leptospirosis)

CLINICAL PRESENTAION

Pyrexia of unknown origin: It is defined as fever >38.3°C (101°F) on several occasions in a patient with more than three outpatient visits or 3 days' admission in a hospital. Most of these happen within 2 weeks of travel and the most common cause is malaria, especially in travelers retuning from Sub-Saharan Africa. Other causes include dengue (particularly travelers returning from Southeast Asia), typhoid or paratyphoid fever, and rickettsia. Other infections, such as HIV, mononucleosis, leptospirosis, schistosomiasis, amebic liver abscess, brucellosis, and toxoplasmosis, should be considered and advice from infectious diseases units is advised unless the cause is quickly apparent.

Fever and respiratory symptoms: Upper respiratory infections are mostly viral. *Streptococcus* and *Haemophilus* are also usual causes. Differentials for a lower respiratory tract infection must include *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Legionella*, and respiratory syncytial virus. Less prevalent pathogens such as *Staphylococcus aureus*, avian influenza viruses, and Middle East respiratory syndrome coronavirus must be considered in patients who travel to high-risk regions. Pulmonary edema is a rare complication of severe malaria. Hence, in patients who are suspected with malaria, fluid resuscitation should be exercised with caution.

Fever and central nervous system (CNS) symptoms: Specific neurological diagnoses in a traveler are rare. Fever and headache are common symptoms and seen in systemic infections such as malaria, dengue and chikungunya infection, and rickettsial diseases. Malaria and meningitis are the most common treatable causes of fever and CNS symptoms and must always be excluded first. Cerebral malaria is caused by *Plasmodium falciparum* and can present with confusion, headache, seizures, or decreased consciousness. Any patient with neurological symptoms and a history of travel to a malaria-endemic region should be considered to have cerebral malaria and investigated. Other causes of fever and encephalopathy include bacterial infections (typhoid, Lyme disease, leptospirosis) and HIV seroconversion.

Fever and eosinophilia: Acute allergic reaction, malignancy, or parasitic infection are the common causes of *peripheral* eosinophilia. In the context of a returning traveler, fever and eosinophilia give rise to a high index of suspicion for helminthic infections. Mild elevation of peripheral eosinophil count (351–1,500 cells/mL) can be considered as nonspecific; moderate (1,500–5,000 cells/mL) to severe (>5,000 cells/mL) elevations in traveling individual are highly suggestive of invasive helminthic infection. In febrile travelers with eosinophilia, the following differential diagnoses should be considered: Schistosomiasis (Katayama fever), hyperinfestation of strongyloidiasis, lymphatic filariasis, invasive hookworm disease, and migratory ascaris lumbricoides. Stool analysis should be done as initial workup for ova and parasites, serology for strongyloidiasis, and depending on the clinical picture and the area of travel, examination of blood smears and skin snips to detect microfilariae.

Fever and skin manifestations: Skin manifestations in travelers include rashes, ulcers, bites, and stings. The differential diagnosis is wide (**Table 5**). For maculopapular rashes, these include dengue, rickettsial disease, and mononucleosis-type syndromes include acute HIV infection; purpuric rashes may be seen in dengue hemorrhagic shock, meningococcal infection, sepsis with disseminated intravascular coagulation, and viral hemorrhagic fevers; and urticarial rashes can be seen in acute schistosomiasis. Eschars are commonly caused by rickettsial disease such as African tick bite fever or anthrax or can be mistaken for a chancre.

TROPICAL INFECTIONS PRESENTING AS UNDIFFERENTIATED FEVER

After international travel, fever can be present without localizing symptoms in approximately 3% of patients. Because

TABLE 5: Differentiating cause of fever on the basis of rash type.

Rash	*Infections*
Purpuric	Dengue, hemorrhagic syndrome, meningococcal infection, viral hemorrhagic fever, rickettsial infection, severe leptospirosis
Maculopapular	Arboviral infection, rickettsial infection, VHF, HIV, seroconversion, typhoid, dengue, fever leptospirosis, brucellosis
Vesicular	Herpes simplex virus varicella
Ulcerative	Chancre: Trypanosomiasis, Eschar: Anthrax, African tick typhus, Ulcer: Leishmaniasis, syphilis, tropical ulcer

(HIV: human immunodeficiency virus; VHF: viral hemorrhagic fever)

of chief complaint, a person usually seeks medical care after travel. Generally, a nonspecific viral illness is considered the common cause of fever in patients presenting after travel, the same as in persons who have not left their home country; however, additional diseases including malaria, dengue, typhoid, and hepatitis must be considered. Following malaria, the most common imported communicable diseases causing undifferentiated fever are dengue, enteric fever, and rickettsial disease. Certain travel destinations are associated with a higher risk of acquiring specific diseases. Thus, the date of return to the home country and the date of the onset of symptoms should be included in a detailed travel history. The incubation period for the disease is important to know if an illness began after the patient's return and after the termination of exposure to exotic pathogens. The incubation period has an important role to play in the differential list of diseases that would be consistent with the time course.

Malaria

Regardless of travel duration or use of chemoprophylaxis, in patients having fever after returning from malaria-endemic regions, the diagnosis must be excluded. Of the several species, four *Plasmodium* species are of clinical relevance that cause disease in humans: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Of these, *P. falciparum* is responsible for complicated and severe disease while *P. vivax* is responsible for chronic and recrudescent disease. Bite of the female anopheles mosquito and other multiple species as well is responsible for transmission. The life cycle consists of hepatic and hematologic stages; the intraerythrocytic stages are responsible for the clinical spectrum of disease. Most clinical symptoms of malaria develop between 9 and 14 days after exposure (median 12), and the minimum incubation period for *P. falciparum* is 6 days. Significantly, longer incubation periods are observed for *P. vivax* and *P. ovale* ranging from 8 days to several months. Vivax infection presents within 2 months after the exposure in the majority of cases; however, cases of *P. vivax* and *P. ovale* have presented several years after exposure, which is likely to constitute disease recrudescence. No specific signs and symptoms are pathognomonic for malaria. Fever, myalgia, arthralgia, and headache are the common clinical presentations in most of the patients. Abdominal pain, diarrhea, cough, and dyspnea may present in few patients. Rash and lymphadenopathy are rarely present and are clues to an alternative diagnosis. Renal failure, jaundice, and respiratory failure, including acute respiratory distress syndrome, may be the features of severe and complicated cases of *P. falciparum* infection. Children with severe disease typically present with severe anemia, acidosis, and respiratory distress. Severe disease can present with CNS involvement in both adults and children, can lead to neurologic sequelae in survivors, and carries a 15–20% mortality rate. After returning from the tropics, patients who present with fever and neurologic findings should be evaluated for malaria and meningitis and treated promptly. Laboratory diagnosis of malaria is classically made by examination of Giemsa-stained thick peripheral blood films. Thick peripheral blood films have increased sensitivity and advantage of allowing more red blood cells to be examined per high-powered field in comparison with thin films. Similar to other point-of-care tests, malarial rapid diagnostic tests (RDTs) have been introduced into clinical practice for antigen detection. RDTs are fairly simple to use. It is important that when severe *P. falciparum* infection is suspected, diagnosis should never supersede empiric treatment. Two major classes of drugs are available for the parenteral treatment of severe malaria: the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate and artemether). *See Chapter 190: Malaria for details*.

Dengue

Dengue fever represents an arboviral disease caused by a family of four arboviruses that are endemic in most tropical and subtropical regions. The viruses are transmitted primarily by day-biting mosquito *Aedes aegypti* and has an affinity for water-filled small containers and water pools in urban environments. A high prevalence of dengue fever is seen in Southeast Asia, Oceania, the Caribbean, and Latin America. Approximately one third of the world's population lives in dengue-endemic countries. In febrile travelers returning from Southeast Asia, dengue is currently more than twice as common as malaria. The incubation period of dengue virus is 4–8 days.

The clinical syndrome of classic dengue fever is characterized by a retroorbital pain (typically lasting 5–7 days), myalgia, arthralgia ("break-bone fever"), and petechial appearance rash. The petechiae usually seen on the face, soft palate, extremities, and axilla appear during the early febrile phase. Dengue infection presents as a wide spectrum of diseases ranging from mild febrile illness (dengue fever) to dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS). A more serious spectrum of DHF/DSS is characterized by coagulopathy and increased vascular permeability. Easy bruising, bleeding at venipuncture sites, and a positive tourniquet test are the hemorrhagic manifestations. Often, as the fever subside in 3–7 days, edema, effusions, and the circulatory collapse develop due to changes in vascular permeability and may lead to DSS. The initial diagnosis of dengue fever in individuals returning from endemic areas is based on fever and constitutional symptoms. Laboratory investigations suggestive of dengue infection include thrombocytopenia, leukopenia, and elevated levels of liver enzymes. DHF is defined as the triad of thrombocytopenia, hypoproteinemia, or evidence of effusions. DSS is characterized by hypotension (systolic blood pressure <90%, a narrow pulse pressure <20 mm Hg). Profound hemodynamic shock occurs in patients with DHF/DSS and Leukopenia (<5,000/mL) along with thrombocytopenia and require admission to a high level of care.

Serologic diagnosis relies on acute and convalescent serum titers, with convalescent samples drawn 3 weeks after infection. Antipyretics, oral fluids, and bed rest are the mainstay of treatment for mild or classic dengue fever. Capillary leakage usually occurs between days 4 and 7 of illness, and more severe disease can develop. Aggressive fluid replacement with normal saline or lactated Ringer solution is appropriate if DHF/DSS is suspected. At present, no effective vaccine exists for the virus. *See Chapter 189: Dengue for further details.*

Enteric Fever (Typhoid and Paratyphoid)

Two serotypes of the gram-negative bacillus *Salmonella enterica*, (1) Serovar Typhi; and (2) Serovar Paratyphi, are the main causative agents for typhoid fever. When these disseminate to cause systemic illness, they are collectively called enteric fever. Infection comes from contaminated food and water where standards of personal and environmental hygiene are low and occur via an oral-fecal route. Typhoid fever has an incubation period of 7–18 days. Affected individuals invariably present with fever. Intestinal mucosa can be invaded by bacteria and then reach to bloodstream through lymphatics, where they replicate and cause systemic illness. Clinical features start as low-grade fever and then become persistent and high grade by the second week. Other common symptoms are headache (typically dull and frontal), abdominal pain, constipation or diarrhea, and cough. During early in the course of the disease, "rose spots" (2–3-mm blanching, pink-red macules) appear for a brief period seen mostly in fair-skinned persons. Theoretically "Faget sign" (relative bradycardia during high fever) has been described in association with typhoid fever but is rarely seen in clinical practice. Complications such as disseminated intravascular coagulation, intestinal perforation, gastrointestinal bleeding, and meningitis/encephalitis occur in 10–15% of patients, most commonly as delayed manifestations. Peyer patches within the intestinal mucosa are the focus for gastrointestinal hemorrhage and perforation. Blood culture is considered as gold standard for diagnosis of enteric fever, although stool cultures, urine cultures, bone marrow biopsy, and serology can play a role. During the first week of illness, blood cultures have their highest yield, but their diagnostic sensitivity is only 40–80%, which underscores the importance of serial cultures. Bone marrow biopsies can have a higher yield though rarely indicated. Serologic testing using the Widal test is not recommended because of its poor sensitivity (47–77%) and specificity (50–92%). Empiric treatment should be started based on clinical diagnosis and in suspected cases because culture results and serology take time to be obtained. Early administration of appropriate antibiotics, supportive care, and correction of fluid losses is the mainstay of treatment. Hospitalization is recommended for diagnostic and therapeutic purpose in patients suspected of having enteric fever (*Salmonella typhi* or *Salmonella paratyphi* bacteremia). Third-generation cephalosporins are considered first-line therapy because fluoroquinolone-resistant strains are all sensitive to ceftriaxone. Gastrointestinal bleeding and perforation should be suspected if a patient with enteric fever clinically presents with abdominal tenderness; a low index of suspicion should be maintained for complications; early imaging and surgical consultation are recommended for peritonitis.

Rickettsial Infection

Rickettsial diseases are classified as zoonotic infections caused by obligate intracellular, gram-negative bacteria. The arthropods vectors are typically ticks, fleas, lice, and mites. The common cause of undifferentiated fever in returned travelers must be excluded. Following a bite from an infected arthropod vector, rickettsial diseases typically have an incubation period of 1–2 weeks. Short (5–7 days) incubation periods in classic rickettsial disease consist of primary lesions (eschars) at the bite site, fever lasting for a few days up to 2 weeks, lymphadenitis, and a maculopapular rash that develops 3–5 days after onset of symptoms. About half of the patients present with the classic triad of eschar, lymphadenitis, and rash. Headache, myalgia, arthralgia, malaise, and diarrhea may also present. An eschar at the site of a tick or louse bite may be seen on physical examination which the patient describes as lasting for 1 or 2 weeks, but its absence does not rule out the disease. The next most common examination finding is lymphadenitis. The clinical presentation of rickettsial disease is similar to that of other diagnoses presenting with undifferentiated fever after travel. Polymerase chain reaction (PCR), culture, and serologic analysis are available for definitive microbiological diagnosis. PCR is sensitive, specific, and rapid. Because diagnosis is difficult to make and is frequently delayed, initiate prompt and appropriate treatment in the absence of confirmatory data on the basis of clinical suspicion and presumptive diagnosis. The mainstay of treatment (preferred regimen) is tetracyclines with doxycycline (100 mg twice daily for 3–14 days, depending on the clinical scenario). Patients should improve within the first 48 hours. Failure to do so should prompt the treating physician to review the original diagnosis.

Leptospirosis

Leptospirosis is acquired by humans after contact with contaminated soil or water and caused by a spirochete. Swimming or boating in contaminated fresh water as well as gardening or farming is associated with infection. Leptospirosis is most commonly seen in travelers returning from tropical and subtropical climate regions. Returning travelers with fever, myalgia, headache, rash, and a history of fresh water exposure should prompt suspicion for leptospirosis. Uveitis, conjunctivitis, hematuria, and aseptic meningitis can also associate with illness. Most commonly, serology testing is used for the diagnosis but this method is usually not rapid. Dark-field microscopy and subsequent culture may also be helpful. Blood and cerebrospinal fluid are ideal within the first 10 days of disease. Urine samples have a better yield after the first week of illness. Leptospirosis is self-limited in most of the cases. Treatment with penicillin or tetracycline is effective and is recommended in all cases. Complications associated with leptospirosis are by renal failure, acute respiratory distress syndrome, or myocarditis. Liver failure, if present, is usually reversible.

HEPATITIS A

Hepatitis A is caused by a virus spread by fecal-oral contact, one of the most common vaccine-preventable, travel-related infections. Traveling to endemic areas, such as Latin America,

Asia, and Africa, is associated with a higher risk of infection. Factors responsible for spread of hepatitis A are poor water quality and poor sanitation. Hepatitis A infections have decreased significantly over the last 20 years as vaccination is most effective when given at least 4 weeks before travel. It may be protective even if given on the day of travel. The incubation period of hepatitis A is 28–30 days. Patients typically may present with complaints of anorexia, nausea, vomiting, or malaise with fever, right upper quadrant pain, and jaundice. Liver function tests reveal elevations of aminotransferases, possibly into the thousands, and identification of anti-hepatitis A virus IgM antibody is diagnostic. Most cases are self-limited and treatment is supportive, but fulminant liver failure is a rare complication.

MENINGOCOCCAL MENINGITIS

Meningococcal disease is potentially a life-threatening illness in cases of meningococcal sepsis even with appropriate antibiotic regimens. Hearing loss, neurologic damage, or loss of an extremity are seen as significant long-term complications of the illness in survivors. Vaccination is available and should be given at least 7–10 days before travel. The incubation period typically ranges between 2 and 10 days. Clinical features start with fever and malaise followed by severe headache, nausea, vomiting, and stiff neck. The most common skin finding in this disease is petechiae or ecchymotic lesions and may occur early in the course before systemic complications develop. High-dose parenteral antibiotics such as ceftriaxone and vancomycin should be started in suspected cases. The steroid is probably not beneficial in meningococcal disease. Once the gram-negative cocci are isolated in cerebrospinal fluid, definitive therapy should be started. Antibiotic prophylaxis with rifampin or ciprofloxacin should be started in close contacts of patients.

TROPICAL DISEASES PRESENTING AS DIARRHEA

Traveler's Diarrhea

Traveler's diarrhea, most frequently associated with enterotoxigenic *Escherichia coli* or *Campylobacter*, is the most common travel-related infection due to increased exposure to local food and water. It is defined as an illness after travel featuring three or more unformed stools in 24 hours and is associated with at least one symptom of enteric disease, such as cramping, abdominal pain, nausea, vomiting, and fever. Traveler's diarrhea needs to be distinguished from dysentery, which is defined as the presence of visible blood in the stool. Dysentery may be caused by *Salmonella*, *Shigella*, and many of the same organisms that cause uncomplicated traveler's diarrhea, such as *Campylobacter*. Patients who present with acute nonbloody diarrhea may be treated empirically with fluids, antibiotics, and antimotility agents. Most cases can be cured by a single dose of ciprofloxacin, 750 mg, or azithromycin, 1 g, by mouth. Additionally, for reducing the duration of symptoms, antimotility agents such as loperamide are safe and effective. Although multiple prophylactic regimens are available for the prevention of traveler's diarrhea, they are not generally recommended for several reasons. Prophylactic therapy of a newer agent, rifaximin, can be recommended especially in immunocompromised patients. For dysentery, a 3-day course of ciprofloxacin or azithromycin is recommended.

Cholera

Cholera is caused by *Vibrio cholerae*, a gram-negative rod, acquired via contaminated water or food and clinically presents with watery diarrhea and acute dehydration. Primary treatment for cholera is oral rehydration and intravenous fluids, and electrolyte replacement should be administered in patients with severe illness. Antibiotics are helpful in shortening the clinical course of the disease and lowers the *V. cholerae* excretion, thus reducing the potential spread of the disease. Antibiotics used in traveler's diarrhea, such as ciprofloxacin, doxycycline, and azithromycin, are also effective against *V. cholerae*. Antimotility medications carry a risk of prolonging the disease and are not recommended and should be avoided.

TROPICAL INFECTIONS WITH A PRIMARILY DERMATOLOGIC PRESENTATION

Cutaneous Larva Migrans

Cutaneous larva migrans infection presents as an epidermal eruption and occurs mostly in Africa, the Caribbean, and Southeast Asia. It is caused by infiltration of hookworm larvae through intact skin, usually in the feet. It also includes a history of exposure of walking barefoot at a beach in most of the cases. The incubation period ranges from minutes to weeks. The cutaneous larva migrans lesions are intensely itchy and erythematous tracts are serpiginous, growing a few centimeters each day.

The foot, buttock, and abdomen or trunk are the most commonly affected anatomic sites. Topical thiabendazole 15% for 1–2 weeks is used for effective treatment of cutaneous larva migrans. Oral thiabendazole is associated with side effects, such as altered mental status, gastrointestinal upset, or rash. A single dose of ivermectin can be used as a more recent treatment approach. Cryotherapy can be tried in pregnant patients but is often ineffective.

Cutaneous Myiasis (Furuncular Myiasis)

Cutaneous myiasis, caused by the human botfly or the tumbu fly, it is the implantation and development of fly larvae in human skin. The larvae are transmitted to humans via a mosquito bite or by eggs hatching on the skin with subsequent penetration. The incubation period varies with the type of fly; the incubation period of botfly is usually 5–12 weeks and that of the tumbu fly is usually 7–10 days. The typical lesions are 1–2 cm furuncle-like with crusting, odoriferous, purulent, or serosanguinous discharge, and larval movement can be seen within central punctum. Patients often have a painful feeling of crawling sensations within the lesion and itching, head, forearms, and legs are often involved. The diagnosis is clinical, and treatment consists of manual removal of the larva; applying occlusive substances on lesion can cause the larva to migrate to the skin surface. To avoid hypersensitivity or foreign body reactions to the larval antigens, it is important not to rupture the larva. Surgical excision is generally not required.

Leishmaniasis

Leishmania is caused by a tiny intracellular protozoan parasite of the genus *Leishmania* transmitted by the bite of the sandfly and symptoms occur 1 week and 3 months after the bite. Visceral and cutaneous are the two major forms identified; visceral leishmaniasis is rare in travelers, but cutaneous cases are occasionally seen. Cutaneous leishmaniasis clinically presents as nonpainful, slowly growing multiple violaceous and granular ulcers (3–12 cm in diameter), typically affecting lower legs and face. Diagnosis is made by skin scraping. Although some lesions may heal spontaneously, treatment consists of prolonged intravenous therapy with sodium stibogluconate, a pentavalent antimony compound.

Lyme Disease

Lyme disease is caused by a bacterial spirochete *Borrelia burgdorferi* and transmitted to humans through a prolonged bite of the Ixodes tick. The initial skin lesion, erythema migrans rash, is present in 60%–80% of patients and generally appears 3–30 days after the bite. This skin lesion starts with an erythematous papule at the site of the bite, which expands over the next days to weeks with central clearing to result in the classic annular lesion. Malaise, myalgia, arthralgia, and generalized lymphadenopathy are the other early manifestations of Lyme disease. The disease progresses to monoarticular or oligoarticular arthritis in 60% of untreated patients. In a small group of patients, neurologic complaints, such as facial nerve palsy, or cardiac complications, most commonly atrioventricular block, are seen. Diagnosis is largely clinical on the basis of characteristic rash, else serology can be used. Early disease can be treated with cefuroxime, doxycycline, or amoxicillin for 21 days. Tick's bite can be prevented by wearing long sleeves and long pants, avoiding walks in heavily forested areas, and wearing insect repellent. A single 200-mg dose of doxycycline is effective at preventing the disease in an area endemic for Lyme disease.

IMPORTANT TROPICAL DISEASES RARELY OCCURRING IN TRAVELERS

Yellow Fever

Yellow fever can occur in unvaccinated travelers and manifests as hemorrhagic fever. Yellow fever is caused by virus which is small (40–60 nm), single-stranded RNA virus of the family *Flaviviridae* and transmitted by *Aedes* species mosquitoes. Jungle areas in South America and Africa are the endemic areas for this disease. Prevention of mosquito bites and immunization against the yellow fever are the most important methods of prevention. The vaccine, a live attenuated vaccine, is usually well tolerated and should be taken 4 weeks before travel. Post vaccination yellow fever like systemic disease within 5 days have been reported, i.e., yellow fever vaccine associated viscerotropic disease, yellow fever vaccine associated neurotropic disease and post vaccination encephalitis. Fever, jaundice, hemorrhage, and renal failure are the common clinical presentations of yellow fever with high viral load within 2–3 days after infection. The clinical course of illness is described in three phases:

1. *First phase is seen for 36–48 hours*: Fever, malaise, myalgia, nausea, vomiting, irritability, and dizziness are the initial symptoms with laboratory features of leukopenia and elevated transaminase levels.
2. *Second phase (latent phase up to 48 h)*: Fever subsides. Improvement of other symptoms is seen and patients recover without development of jaundice.
3. *Third phase*: Recurrence of initial symptoms in 10–15% of patient with the addition of jaundice and bleeding diathesis followed by multiorgan system failure. Diagnosis can be confirmed by enzyme-linked immunosorbent assay (ELISA). Treatment is supportive and for severe cases, intensive care treatment is given.

Avian Flu

Millions of cases of influenza A occur every year mostly with an identified close contact with chickens, waterfowl, or other birds. The patient usually presents with febrile respiratory illness 2–5 days after exposure, often accompanied by leukopenia or lymphopenia. The few initial influenza symptoms may progress to subsequent pneumonia and worsening respiratory distress. Pharyngeal swabs are preferred for detection of H5-specific RNA (diagnostic) because the virus is present in higher concentrations in the throat and lower respiratory tract. Zanamivir and oseltamivir neuraminidase inhibitors should be started in any suspected cases. The mainstay of prevention of annual influenza is the influenza vaccine.

African Sleeping Sickness

African trypanosomiasis (sleeping sickness) is caused by *Trypanosoma* parasites and transmitted by Glossina tsetse flies. If the untreated disease is fatal, death occurs within weeks to years from the time of infection depending on the type of parasite infection. The risk to travelers is low, but there are approximately one or two imported cases each year. Thirty-six countries of sub-Saharan Africa are the endemic areas for this disease. The symptoms of this illness are similar to several other travel-related infections, including malaria and rickettsia infection. The common symptoms of african trypanosomiasis are lethargy, headache, gastrointestinal symptoms, myalgia, and delirium are the other associated symptoms. The parasites can be identified in the blood or other aspirates to confirm the diagnosis. Travelers who present with fever and cutaneous chancres should prompt suspicion of trypanosomiasis. Central nervous system involvement should be ruled out by lumbar puncture, because it dictates the choice of antiparasitic therapy. In patients without central nervous system involvement, treatment with suramin is indicated. A 200-mg test dose should be given before administering the drug by slow infusion due to a risk of anaphylaxis.

PEDIATRIC CONSIDERATIONS

After travel, illnesses in children are grouped into four general categories: (1) Diarrheal syndrome, (2) Dermatologic disorders, (3) Systemic febrile illness, and (4) Respiratory disorders. Children should also receive pretravel advice, like in adults. They may present to a clinician with illness in the early phase and require hospitalization also. A high index of suspicion should be maintained for children, the same as for adults, presenting with undifferentiated fever after travel and all evaluations for fever should be performed considering malaria, dengue, and enteric fever. Pediatric patients with

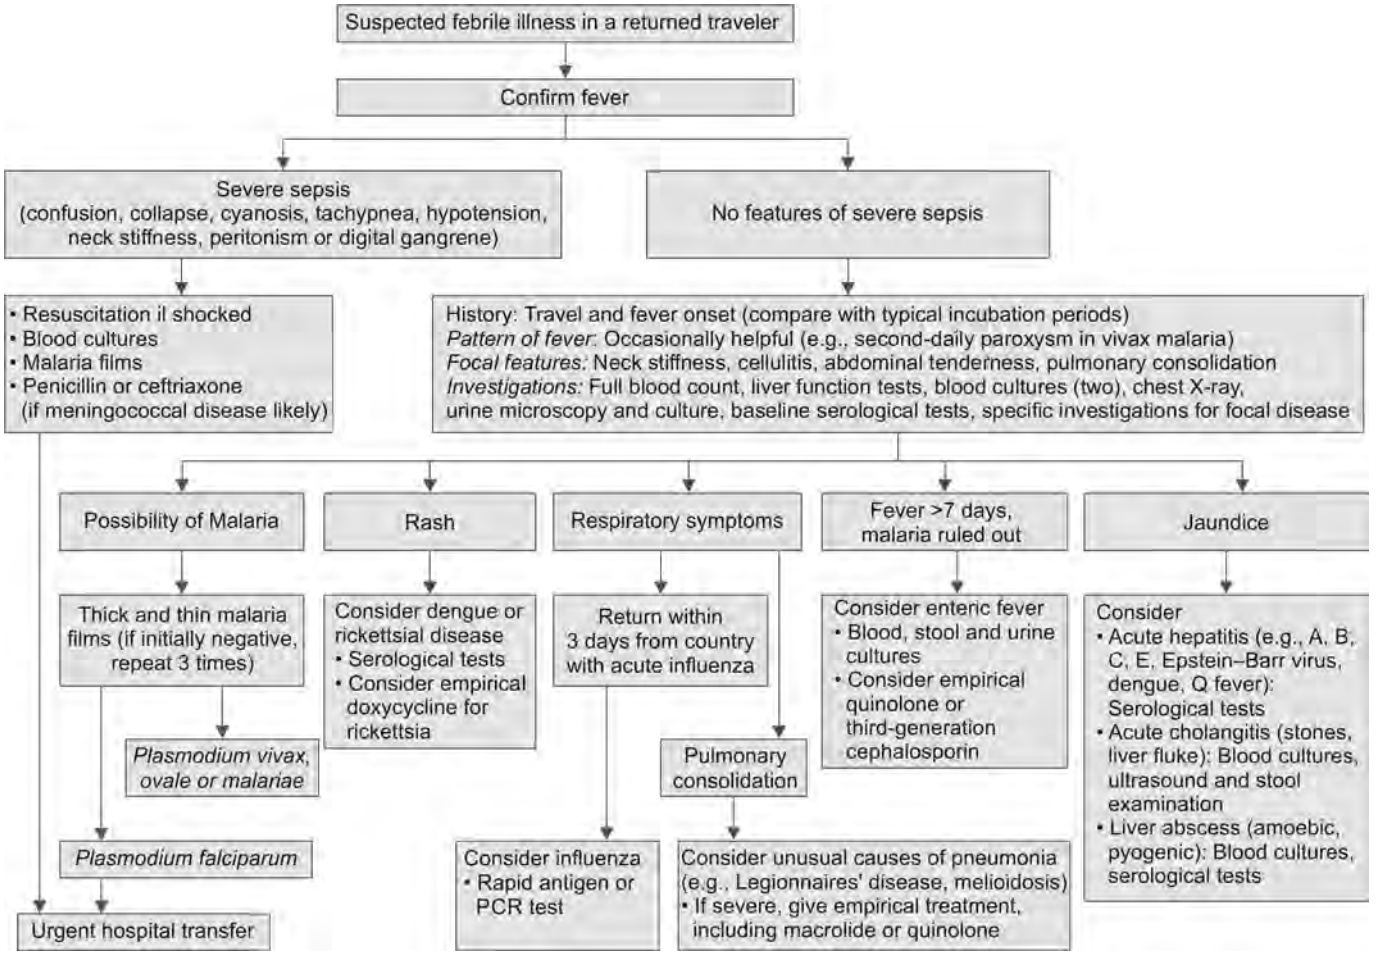
undifferentiated fever after travel should be admitted promptly for management.

PROTECTION OF CONTACTS AND STAFF

Routine infectious precautions and local hospital guidelines should be followed with source isolation and respiratory/droplet confinement and should be implemented for all patients with undifferentiated fever after travel to the tropics until potentially hazardous diseases are excluded. COVID-19, anthrax, diphtheria, encephalitis, enteric fever, hepatitis (acute), novel influenza, measles, meningitis, mumps, pertussis, plague, poliomyelitis, rabies, tuberculosis, travelers with respiratory illness and rash, varicella and herpes zoster, and viral hemorrhagic fever are the infections which require special consideration. Laboratory staff are also at risk so they should therefore be informed if any of the following infections are being considered: Enteric fever, brucellosis, Q-fever, melioidosis, and, in particular, the viral hemorrhagic fevers. Notification of certain infectious diseases is mandatory for local health authorities, and public health surveillance should begin at local, state, and regional levels. Clinicians should be familiar with state and national requirements during working with patients who return ill from travel. Healthcare providers must be aware about reporting and surveillance within the scope of practice, essential for proper surveillance and disease control.

SUMMARY

One of the common problems presenting to the emergency department is infections in travelers. A detailed travel history will provide clues to the clinician regarding the risk of unusual tropical infections and one should enquire about places visited, the activities enjoyed, and the living conditions. Evaluation of tropical infections in travelers is summarized in **Flowchart 1**. *Plasmodium* infection should be ruled out by the use of blood smears in any patient returning from a malaria-endemic region with an undifferentiated fever. The traveler's diarrhea is also most the common condition in returning travelers, which can be effectively managed with antibiotics and antimotility agents. Rare diseases in the returning traveler are avian flu, yellow fever, and African sleeping sickness. Adequate care must be taken for COVID-19 infection. Overseas acquired infection can be prevented by vaccines, food and water precautions, and insect bite avoidance. For travel to certain regions, yellow fever vaccine is required. Avoiding uncooked foods, eating thoroughly washed foods in clean water, and eating only peeled fruit will help in reducing the infection during travel. Most of the cases require empiric treatment based on the clinical presentation because acquisition of confirmatory laboratory data is often delayed.



Suspected febrile illness in a returned traveler
Confirm fever
Severe sepsis
(confusion, collapse, cyanosis, tachypnea, hypotension, neck stiffness, peritonism or digital gangrene)
No features of severe sepsis
• Resuscitation if shocked
• Blood cultures
• Malaria films
• Penicillin or ceftriaxone
(if meningococcal disease likely)
History: Travel and fever onset (compare with typical incubation periods)
Pattern of fever: Occasionally helpful (e.g., second-daily paroxysm in vivax malaria)
Focal features: Neck stiffness, cellulitis, abdominal tenderness, pulmonary consolidation
Investigations: Full blood count, liver function tests, blood cultures (two), chest X-ray, urine microscopy and culture, baseline serological tests, specific investigations for focal disease
Possibility of Malaria
Rash
Respiratory symptoms
Fever >7 days, malaria ruled out
Jaundice
Thick and thin malaria films (if initially negative, repeat 3 times)
Consider dengue or rickettsial disease
• Serological tests
• Consider empirical doxycycline for rickettsia
Return within 3 days from country with acute influenza
Consider enteric fever
• Blood, stool and urine cultures
• Consider empirical quinolone or third-generation cephalosporin
Consider
• Acute hepatitis (e.g., A, B, C, E, Epstein–Barr virus, dengue, Q fever): Serological tests
• Acute cholangitis (stones, liver fluke): Blood cultures, ultrasound and stool examination
• Liver abscess (amoebic, pyogenic): Blood cultures, serological tests
Plasmodium vivax, ovale or malariae
Pulmonary consolidation
Plasmodium falciparum
Consider influenza
• Rapid antigen or PCR test
Consider unusual causes of pneumonia (e.g., Legionnaires' disease, melioidosis)
• If severe, give empirical treatment, including macrolide or quinolone
Urgent hospital transfer

FLOWCHART 1: Summary of evaluation of tropical infections in travelers.

187
CHAPTER

Zoonotic Infections

Olita Shilpakar, Devendra Richhariya

INTRODUCTION

Zoonosis is a term that describes diseases transmitted from vertebrate animals or insects to or from humans. It is caused by bacteria, viruses, fungi, or parasites. One of the most important vectors causing zoonotic infections is ticks. Risk factors include occupational exposure to animals, immunocompromised patients, or recent travel history, mostly during spring or summer (**Table 1**). Zoonotic infections can present with fever, myalgias, headache, and malaise. The common zoonotic infections are listed in **Table 2**.

TICK-BORNE INFECTIONS

Ticks are arthropods distributed worldwide and are hematophagous parasites of humans and animals. They transmit rickettsial, bacterial, spirochetal, viral, and protozoal diseases. During a bite, the saliva of ticks produces inflammatory factors or toxins that can cause local inflammation, edema, hemorrhage, or hyperemia. A common finding that accompanies the bite of blood-sucking ticks is a characteristic rash seen as an erythematous lesion of 1–4 mm in size. The common tick-borne infections are listed in **Table 3**.

TABLE 1: Risk factors for zoonotic infections.

Population at risk	*Examples*
Agricultural workers	Farmers, cattle ranchers
Animal processing workers	Slaughterhouse workers, animal product handlers
Pet owners	Owners of dogs, cats, rodents, birds, fishes
Professional animal handlers	Veterinarians, animal researchers
Immunocompromised patients	HIV, diabetes mellitus, carcinoma, congenital immunodeficiencies

(HIV: human immunodeficiency virus)

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is an acute, febrile, systemic tick-borne illness. The causative agent is *Rickettsia rickettsii* which is an obligate intracellular pleomorphic organism. *Dermacentor* ticks (*D. variabilis* and *D. andersoni*) and *Rhipicephalus sanguineus* ticks are the vectors while dogs, rodents, horses, cattle, cats, and deer are the animal reservoirs.

Clinical Features

Children are more commonly affected by RMSF than adults. The incubation period ranges from 2 to 14 days. A history of tick bite may not always be reported by the patient and may present with fever, headache, myalgia, malaise, nausea, vomiting, diarrhea, and abdominal pain during the early stage of the disease. As the disease progresses, respiratory failure, renal insufficiency, neurological deficits, meningismus, and myocarditis may be evident. The triad of fever, rash, and tick bite is the classical presentation of RMSF. The rash is seen as an erythematous blanching maculopapular lesion and petechiae over the arms, forearms, feet, and ankles occurring 2–4 days following fever. However, it is not pathognomonic of this disease.

Diagnosis and Treatment

Laboratory studies are nonspecific, but RMSF can be suggested in cases of normal total counts, decreased platelets, elevated liver enzymes, and hyponatremia. The diagnosis can be confirmed by a rise in the antibody titer between acute and convalescent serum, skin biopsy, or a culture. Doxycycline is the treatment of choice in rickettsial diseases for all age groups (**Table 4**).

TICK PARALYSIS

Tick paralysis occurs worldwide and is more common in children than adults. It results from injection of neurotoxic

TABLE 2: Common systemic zoonotic infections.

Agent and reservoir	*Clinical findings*	*Investigations*	*Treatment*
Brucella canis (dogs)	Nonspecific fever	Serology blood culture	Doxycycline plus gentamicin or rifampin
Chlamydophila psittaci (birds)	Fever, flulike illness, pneumonia, endocarditis	Serology sputum culture	• Doxycycline • Alternative: ○ Azithromycin ○ Levofloxacin
Coxiella burnetii (cattle, sheep, goats, cats)	Fever, pneumonia, hepatitis, meningitis, endocarditis	Serology PCR	Doxycycline or fluoroquinolone or macrolide
Ehrlichia species (ticks)	Nonspecific fever, hepatitis, meningitis	Serology, peripheral blood smear, PCR	Doxycycline or Rifampin as alternative
Leptospira species (birds, rodents)	Fever, pneumonia, conjunctivitis, lymphadenopathy	Serology, darkfield microscopic examination of body fluids	• Penicillin G IV. Ceftriaxone IV as alternative • Mild disease: Oral doxycycline or azithromycin
Francisella tularensis (rabbits, cats)	Fever, rash, sepsis, pneumonia	Serology	IV aminoglycosides. Alternative: doxycycline
Rickettsia rickettsii (ticks)	Fever, diarrhea, or typical presentation of Rocky Mountain spotted fever	Clinical diagnosis, skin biopsy, antibody titer	Doxycycline or chloramphenicol
Salmonella enterica (dogs, cats, turtles)	Fever, abdominal pain, meningitis, endocarditis	• Blood culture • Stool culture	• Fluoroquinolones • Third-generation cephalosporins
Yersinia pestis (rodents)	• Bubonic: Fever, buboes • Pneumonic: Cough, dyspnea, shock	• Blood culture • Culture from sites	Doxycycline, fluoroquinolones, streptomycin, or chloramphenicol

(PCR: polymerase chain reaction)

TABLE 3: Tick-borne infections.

Disease and pathogen	*Arthropod vector*	*Animal reservoir*	*Clinical features*
Babesiosis (*Babesia microti*)	Ixodes dammini, Ixodes scapularis	Cattle, horses, dogs, cats, rodents	Fatigue, fever, anorexia, nausea, headache, abdominal pain, emotional lability, rash
Colorado tick fever (*Orbivirus*)	*Dermacentor andersoni* (wood tick)	Deer, porcupine	Fever, myalgias, photophobia, abdominal pain, sore throat, conjunctivitis, lymphadenopathy
Human granulocytic Anaplasmosis (*Anaplasma phagocytophilum*)	*I. scapularis, I. pacificus*	Dogs, deer	Fevers, chills, malaise, nausea, cough, sore throat, pulmonary infiltrates
Lyme disease (*Borrelia burgdorferi*)	*I. dammini*	Deer, sheep, deer mice	Erythema migrans, meningitis, encephalitis, neuropathy, arthralgia
Rocky Mountain spotted fever (*Rickettsia rickettsii*)	• *D. andersoni* • *D. variabilis*	Mammals	Petechiae, pulmonary infiltrates, jaundice, myocarditis, encephalitis, lymphadenopathy
Relapsing fever (*Borrelia* species)	*Ornithodoros* species	Body lice, rodents, humans	Fever, chills, headache, myalgias, arthralgias
Tularemia (*Francisella tularensis*)	• *Dermacentor* species • *Amblyomma* species	Rabbits, deer, dogs	Pneumonia, lymphadenopathy, arthralgias inoculation site ulceration

substances secreted by the salivary glands of ticks during a blood meal. Prolonged attachment of the tick for 2–7 days can result in paralysis of the host. Symptoms begin with weakness in the lower extremities. The paralysis ascends to the trunk, upper extremities, and head within hours and may lead to respiratory failure and death. It is diagnosed by the presence of tick on the body though a cerebrospinal fluid (CSF) analysis is usually normal. Removal of ticks and symptomatic management are the keys to its treatment.

LYME DISEASE

Lyme disease, the most common vector-borne disease in the United States, is a tick-borne illness caused by the spirochete *Borrelia burgdorferi*. The black-legged tick, also known as the *Ixodes* deer tick, is the vector, whereas deer, sheep, and deer mice are the reservoirs of this disease. The longer time taken by the ticks to feeds on the host causes more risk of acquiring the infection.

TABLE 4: Treatment of tick-borne infections.

Tick-borne zoonotic infection	*Specific treatment*
Rocky Mountain spotted fever	• *Adult*: Doxycycline 100 mg PO or IV twice a day for 7 days or for 2 days after temperature normalizes • Consider initial loading dose of 200 mg IV for seriously ill patients • Though contraindicated, it can be used in pregnancy during life-threatening conditions • *Children (<45 kg)*: Doxycycline 2.2 mg/kg twice daily • *Chloramphenicol (alternative)*: 50 mg/kg/day divided into four doses for 7 days
Lyme disease	• *Early stage or mild secondary*: 14–21 days of doxycycline (100 mg PO twice a day), amoxicillin (500 mg PO three times a day in adults, 50 mg/kg/day divided into three times a day in children), or cefuroxime (500 mg PO twice a day in adults, 30 mg/kg/day divided into three times a day in children) • *Severe illness, CNS positive, or high-degree heart block*: Ceftriaxone 2 g IV for 14–30 days • A single 200-mg oral dose of doxycycline given within 72 h of a high-risk deer tick bite is effective in preventing Lyme disease
Tick-borne relapsing fever	Doxycycline (100 m PO/IV twice a day for 7–10 days) Alternative: Erythromycin (500 m PO/IV four times a day for 7–10 days)
Tularemia	• *Adults*: Streptomycin 1 g IM/IV twice a day, or gentamicin 5 mg/kg IV divided every 8 h. Treat for 10 days • *Children*: Streptomycin 15 mg/kg IM twice daily (max 2 g/day) • *Mild disease*: Ciprofloxacin 750 mg PO twice a day, or doxycycline 100 mg PO twice a day. Treat for 21 days • *Prophylaxis for lab exposures*: Doxycycline 100 mg PO twice a day or ciprofloxacin 500 mg PO twice a day. Treat for 14 days
Babesiosis	• Atovaquone (750 mg PO every 12 h) plus azithromycin (500 mg PO on day 1, then 250 mg daily). Treat for 10 days • If relapse occurs, treat for 6 weeks or 2 weeks after negative blood smear • *Severe disease in adults*: Clindamycin (1,200 mg IV twice a day or 600 mg PO three times a day) + quinine (650 mg PO three times a day). Treat for 7–10 days
Ehrlichiosis and anaplasmosis	• Doxycycline 100 mg PO twice a day for 7–14 days • For children weighing <45 kg, the dose is 2.2 mg/kg twice a day

(CNS: central nervous system)

Clinical Features

There are three stages of Lyme disease:

1. The *first stage (early Lyme disease)* usually begins with *erythema migrans*, a slow expanding erythematous plaque with central clearing, also known as the bull's eye or target lesion, which occurs at the site of the tick bite. It is seen in approximately 80% of cases and develops within 2–30 days after the bite. If untreated, erythema migrans resolves spontaneously in 3–4 weeks. Low-grade intermittent fever, chills, fatigue, myalgias, anorexia, nausea, vomiting, arthralgias, and lymphadenopathy are the presenting symptoms.
2. The *second stage (early disseminated disease)* occurs within a few days to months following the initial infection. It is characterized by fever, neuropathies, cardiac abnormalities, arthritis, ocular manifestations, and multiple annular or target skin lesions. *Facial nerve palsy* is the most common neurologic manifestation. Headache, neck stiffness, altered mentation, cerebellar ataxia, encephalitis, radiculopathy, mononeuritis multiplex, and facial palsy can occur in neuroborreliosis. The patient may present with joint abnormalities in the form of asymmetric oligoarticular arthritis of the knees or with cardiac abnormalities, such as varying degrees of atrioventricular block, ST and T wave changes, conduction delay, or congestive heart failure.
3. The *third stage (late disseminated stage)* of illness involves continuous inflammation for more than a year after the initial infection. It is characterized by chronic arthritis, myocarditis, subacute encephalopathy, axonal polyneuropathy, and leukoencephalopathy. Exacerbation and remission of arthritis may extend for several years.

Diagnosis

The presence of erythema migrans is an aid in diagnosing the disease early. Polymerase chain reaction, fluorescence immunoassay, or Western immunoblot testing are done in the later stages of the disease. Treatment of Lyme disease is with doxycycline or amoxicillin or third-generation cephalosporins (**Table 4**).

TICK-BORNE RELAPSING FEVER

Relapsing fever is caused by gram-negative bacteria of the *Borrelia* species and Spirochaetales order. Human *Borrelia* infections are associated with arthropod vectors known as *Ornithodoros* ticks. The principal zoonotic reservoirs are wild rodents, specifically tree squirrels, rats, mice, and chipmunks.

Clinical Features

Fever, chills, myalgia, malaise, arthralgia, abdominal pain, and a rash or a pruritic eschar of 1–3 mm at the site of a tick bite may be the initial presentation of tick-borne relapsing fever (TBRF). The average incubation period is 7 days. Characteristically, the 3-day-long febrile episodes alternate with 7-day-long afebrile periods. This cycle repeats three to five times before resolution. Relapse is caused by the spirochete's ability to undergo antigenic variation within the body of the infected host. Two classical stages of clinical illness are manifested. The first stage is called the *chill phase* with high fevers, mental status changes, tachycardia, and tachypnea lasting approximately 30 minutes, followed by a *flush phase* with a rapid decrease in temperature and sweating. Neurological involvement is less common but may cause nuchal rigidity, peripheral neuropathies, and papillary abnormalities. Laboratory investigations may reveal leukocytosis and thrombocytopenia. The disease is usually self-limited, if untreated.

Diagnosis

Diagnosis is confirmed by darkfield microscopy or Wright- or Giemsa-stained peripheral blood smears. Tetracycline is the drug of choice (**Table 4**). Postexposure doxycycline is considered for prophylaxis of patients with a confirmed tick bite from endemic areas.

TULAREMIA

Tularemia is caused by a gram-negative, nonmotile, intracellular, coccobacillus *Francisella tularensis*. Ticks of the *Dermacentor* species (wood tick, dog tick) and the *Amblyomma* species (lone star tick) are the zoonotic vectors. Animal reservoirs are rabbits, hares, and deer. Tularemia is contracted through bites, inhalation, or through open wounds while in contact with an infected zoonotic host. The incubation period is between 3 and 6 days but may range from 2 hours to 3 weeks. Six important clinical forms occur, namely *ulceroglandular*, *glandular*, *typhoidal*, *pneumonic*, *oculoglandular*, and *oropharyngeal*. The *ulceroglandular form* occurs in 80% of cases and presents with fever, chills, myalgias, and a maculopapular skin lesion. The *glandular form* consists of painful adenopathy. The *typhoidal form* presents with high fever, chills, and abdominal pain and can cause organ failure and death. Pneumonic tularemia is the deadliest form of the disease. Laboratory findings of tularemia are nonspecific. The drug of choice is streptomycin. Alternative treatment includes gentamicin, ciprofloxacin, imipenem, doxycycline, and chloramphenicol (**Table 4**).

BABESIOSIS

Babesiosis is transmitted by ticks which carries *Babesia microti*. *Ixodes* ticks are the principal vectors and the zoonotic reservoirs are domesticated mammals, rodents, and deer. Symptoms occurs 1–4 weeks after exposure with malaise, anorexia, fever, chills, myalgia, headache, and hemolytic anemia. Risk factors involve immunocompromised patients and splenectomy. Laboratory finding are anemia, thrombocytopenia, and liver and renal failure. A Giemsa- or Wright-stained peripheral blood smear may show an erythrocytic ring that is seen in malaria. Treatment involves atovaquone plus azithromycin or clindamycin for 7–10 days (**Table 4**).

TREATMENT OF TICK-BORNE INFECTION

Early removal of ticks can help in prevention of the disease since the time required for the infection is at least 24–48 hours of attachment to the host. An embedded tick can be removed manually by tweezers or forceps gently without puncturing its body which may otherwise lead to the release of pathogens. The skin surface is cleansed and disinfected after removal of the tick.

Measures to help prevent tick exposure include avoiding tick-infested areas, wearing clothes covering the body, using tick repellents or application of topical ointment containing *N,N*-diethyl-m-toluamide to exposed skin, permethrin for clothes, and use of bed nets.

The indications of prophylactic treatment of tick bite include:

- Identification of the tick as *Ixodes scapularis*
- Tick attachment for >36 hours with tick engorgement
- Tick bite in an area with a *Borrelia burgdorferi* carrier rate of >20%

Prophylaxis includes a one-time dose of doxycycline 200 mg for adults or 4 mg/kg in children.

ZOONOTIC MENINGITIS AND ENCEPHALITIS

Zoonotic encephalitis is an arboviral infection transmitted via the hematogenous route by an arthropod or insect vector from an animal host. *Brucella canis*, borreliosis, *Coxiella burnetii, Ehrlichia* species, leptospirosis, Lyme disease, RMSF, and psittacosis are important nonviral zoonotic infections where encephalitis may be evident. The initial clinical features include fever, malaise followed by headache and altered mental status. The CSF analysis shows elevated opening pressure, slightly elevated proteins, normal glucose, and lymphocytic predominance although CT scan of head may not show any significant finding. CSF cultures are usually sterile; however, the organism can be detected by using an enzyme-linked immunosorbent assay of serum. Supportive care is the mainstay of treatment.

Zoonotic meningitis can be caused by brucellosis, listeriosis, plague, salmonellosis, tularemia, leptospirosis, Lyme disease, ehrlichiosis, Q fever, RMSF, or psittacosis. CSF findings are the same as in encephalitis. In case of a suspected case, empirical coverage of antibiotics should be administered immediately to reduce mortality and morbidity.

ZOONOTIC RESPIRATORY INFECTION

Upper respiratory zoonotic infection: Upper respiratory infection of zoonotic origin can present with prolonged exudative recurrent pharyngitis. The patient can present with sore throat, fever, and leukocytosis and is refractory to antistreptococcal therapy. *Bordetella* species, *Yersinia pestis*, *Streptococcus* species, and *Corynebacterium ulcerans* are some of the common causes of exudative pharyngitis. Household pets, such as dogs, cattle, and birds, can be the source of these infections in humans.

Lower respiratory zoonotic infection: Community-acquired pneumonia presenting atypically with cough, fever, chills, myalgias, and rash can be considered as a case of zoonotic pneumonia. Occupational history, history of recent travel, or animal exposure holds importance in the diagnosis. The important zoonotic pneumonias are inhalational anthrax, brucellosis, psittacosis, Q fever, pasteurellosis, and pulmonic plague. The treatment of important lower respiratory zoonotic infections is mentioned in **Table 5**.

ZOONOTIC DERMATOLOGIC INFECTION

Dermatologic zoonotic infections result from inoculation of the skin of hands and forearms with bacteria, viruses, and fungi and may present as a nonspecific generalized maculopapular rash. *Bacillus anthracis* (anthrax), *B. henselae* (cat-scratch disease), *Erysipelothrix rhusiopathiae* (erysipeloid), *Francisella tularensis* (tularemia), and *Listeria monocytogenes* (listeriosis) are some of the important bacterial zoonotic dermatoses. Most of the infections are noticed in animal handlers, livestock workers, veterinarians, and slaughterhouse workers. More than 95% of all anthrax infections are due to cutaneous anthrax, also known as woolsorter's disease. *Blastomyces dermatitidis* (cutaneous blastomycosis) and *Sporothrix schenckii* (sporotrichosis) cause fungal zoonoses. Viral zoonotic dermatoses include *Vaccinia* species (cowpox) and *Paravaccinia* species (pseudocowpox).

TABLE 5: Zoonotic pneumonias.

Disease	*Specific treatment*
Inhalational anthrax (*Bacillus anthracis*)	• *Adult*: Initially, ciprofloxacin 400 mg IV every 12 h + clindamycin 900 mg IV every 8 h + rifampicin 300 mg IV every 12 h + one-time infusion raxibacumab 40 mg/kg diluted over 2.25 h • *Once stable, oral*: Ciprofloxacin, 500 mg PO every 12 h + clindamycin 450 mg PO every 8 h + rifampicin 300 mg PO every 12 h • Continue for 60 days
Brucellosis (*Brucella* species)	• *Mild disease*: Doxycycline 100 mg PO twice daily for 6 weeks + gentamicin, 5 mg/kg daily for 7 days • *Alternative*: Doxycycline 100 mg PO twice a day, + rifampin 600–900 mg PO daily for 6 weeks • *Neurologic involvement*: Doxycycline 100 mg IV/PO twice a day + rifampin 600–900 mg PO daily + ceftriaxone 2 g IV twice a day • Continue treatment until cerebrospinal fluid normalizes
Q fever (*Coxiella burnetii*)	• Doxycycline 100 mg PO twice a day for 2–3 weeks • *Alternative*: 2–3 weeks of a fluoroquinolone or a macrolide
Psittacosis (*Chlamydophila psittaci*)	• Doxycycline 100 mg PO for 5–7 days • *Alternative*: Azithromycin dose pack or levofloxacin 750 mg PO for 5–7 days
Pulmonic plague (*Yersinia pestis*)	• Gentamicin 5 mg/kg IV daily for 10 days • *Alternative*: Streptomycin 15 mg/kg IV/IM twice a day for 10 days • *Postexposure prophylaxis*: Doxycycline 100 mg PO twice a day or ciprofloxacin 500 mg PO twice a day for 7 days

ZOONOTIC INFECTIONS FROM PETS

Majority of zoonotic infections are caused by household pets, such as dogs and cats, and a small number by pet birds, reptiles, rodents, and fishes. Anthrax, brucellosis, campylobacteriosis, cryptosporidiosis, echinococcosis, toxocariasis, and tularemia are some of the important zoonoses with dogs and cats as the definitive host. Similarly, birds and fowls account for zoonoses, such as psittacosis, ornithosis, listeriosis, and salmonellosis.

EMERGING ZOONOTIC VIRUSES OF BAT ORIGIN

Over the last few years, it is evident and recognized that emergence of zoonotic infections is on the rise. The increase is due to both the increase in the rate of zoonotic infections globally and also improved ability to detect and identify agents. New technologies have expanded the sensitivity and scope of our detection and diagnostic capability. However, if there is no significant disease outbreak, a pathogen may remain undetected. Zoonotic agents from their natural reservoir host rarely transmit species to another species, and in most zoonoses human-to-human transmission is rare. However, increased spill over events will increase the chances of the emergence of an adapted virus that will be highly transmissible. The number and diversity of viruses identified in bats is extraordinary and is the subject of many recent reviews. Most significant bat-related zoonotic viruses which have had a major impact on public health in different parts of the world over the past 2 decades are discussed further.

Paramyxoviruses

Hendra virus: The first detection of "Hendra Virus (HeV)" emergence was in 1994. Although the virus appears to have been circulating in Australian flying foxes for a long time. Over the last few years, the incidence of HeV spill over events in Australia has drastically increased, peaking in 2011 with 18 independent outbreaks in horses in Queensland and New South Wales. All human infections can be traced back to close contact with infected horses and there is no evidence of human-to-human infection so far.

Nipah virus: In 1998, another bat-related paramyxovirus emerged in Malaysia, named "Nipah virus", (NiV) this highly infectious virus was first detected in humans and commercially farmed pigs exhibiting respiratory and neurological disease. A slightly different NiV detected in Bangladesh and India in 2001 and causing regular outbreaks of fatal encephalitis in humans, with evidence of direct bat-to-human and human-to-human transmission and mortality of between 70 and 100%.

Coronaviruses

Severe acute respiratory syndrome virus: Severe acute respiratory syndrome (SARS) emerged in late 2002 and represents the best examples of emergence of infectious disease. Palm

civets were found infected with SARS virus but further extensive epidemiological and surveillance studies demonstrated that the true reservoir of the SARS and SARS-like coronaviruses was bats of the genus *Rhinolophus*, civets were probably an amplifying and/or adaptation.

Middle East respiratory syndrome virus: Recently, another coronavirus responsible for an acute respiratory disease has emerged named as "Middle East respiratory syndrome (MERS)". The fatality rate is between 40 and 50%. Genome sequencing has confirmed that this virus is most closely related to coronaviruses in bats in Asia, South Africa, and also in different parts of the world. All these indicating that bats are likely natural hosts of MERS or MERS-like viruses and that the emergence of similar viruses in other parts of the world is a significant possibility. The route of introduction into the human population remains unknown. A serological study detected neutralizing antibodies in camels from the Middle East but exact role of camels (or other animals) in MERS coronavirus (CoV) transmission to humans is yet to be established.

Filoviruses

Ebola and Marburg viruses are among the deadliest viruses known to humankind and Ebola has caused massive die-offs of great apes in Central Africa. The transmission of filoviruses to humans is believed to occur mainly through "bushmeat" activities, i.e., the capture and slaughtering of wild animals, including nonhuman primates. Recent data indicated that bats could be the potential natural hosts of Ebola and Marburg viruses in Africa. Filovirus RNA has been identified in a number of fruit bat species from central African countries. It has also been shown that the incidence of Marburg hemorrhagic fever in mine workers in southern Uganda could be attributed to possible transmission from infected bats (*Rousettus aegyptiacus*) that had colonized the mine. Genetic analysis confirmed that the Marburg virus isolated from the infected mine workers was similar to those circulating in the *R. aegyptiacus* population. This virus posing a significant potential threat to public health as this virus emerged in the pig population in the Philippines. Detection of Ebola–Reston specific antibodies in *R. amplexicudatus* bats suggests that bats may also be the natural host of Ebola–Reston virus.

Other Bat-borne Viruses

These include viruses of known zoonotic transmission, such as the Menangle virus in Australia and the related Tioman and Melaka viruses in Malaysia, and many other related bat reoviruses. Bat viruses related to known human pathogens have also been detected in large numbers, including bat lyssaviruses, parainfluenza viruses, hantaviruses, hepaciviruses, and pegiviruses. The public health threat of these viruses is unknown, but it would be judicious to place these viruses under a close watch for potential spill over.

EMERGING ZOONOTIC VIRUSES FROM OTHER SOURCES

It should be emphasized that, while bat viruses represent one of the most important sources of recent emergence, there are many other important zoonotic viruses with a significant impact on public health that have emerged or re-emerged.

West Nile virus (WNV): It is a member of the family *Flaviviridae* and is endemic in many parts of the world. As an arbovirus, WNV is transmitted by mosquitoes between birds and mammals.

Chikungunya virus (CHIKV): It is a member of the genus *Alphavirus*, family *Togaviridae* and first isolated from a febrile patient in Tanzania in 1952. It is an enzootic virus found in tropical and subtropical regions of Africa, in Indian Ocean Islands and in some parts of Asia. Serological and virus isolation studies confirm that nonhuman primates are the host in CHIKV transmission and *Aedes* mosquitos are the main vectors. There is emerging genetic evidence to suggest that the virus has acquired multiple mechanisms for evolutionary adaptation to the vector. There is a significant impact of climate change on mosquito distribution and evolution, thus CHIKV will be an important zoonotic virus to be monitored for further spread and future outbreaks.

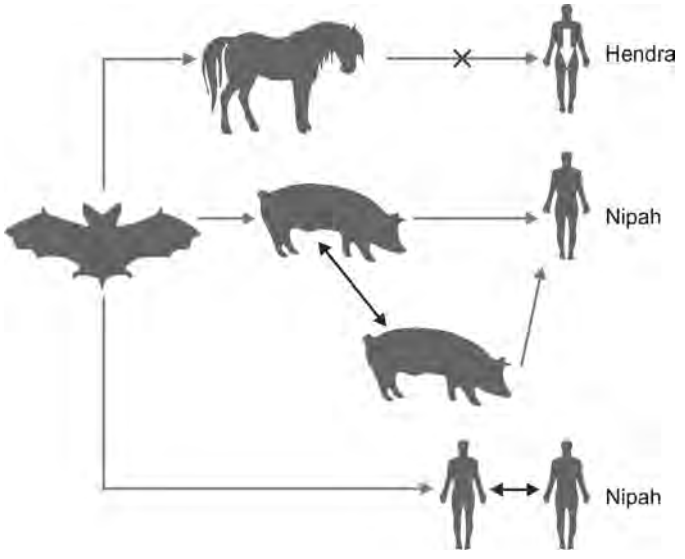
Crimean–Congo hemorrhagic fever virus (CCHFV): It is a member of the genus *Nairovirus*, family *Bunyaviridae*. Ticks of the genus *Hyalomma* are considered to be both the main vector and the natural reservoir. These ticks are present on the ground and can infest a number of small and large mammals so that they can carry the virus without any symptoms, in their blood for further transmission to other animals and/or humans. Although tick bites are the main route of transmission to humans, direct contact with the body fluids, and tissue or blood of infected animals can also lead to human infections. Most infections with CCHFV lead to a mild and nonspecific febrile illness, some patients develop severe hemorrhagic disease, as suggested by its name. The fatality rate of CCHFV infection in humans can vary from 5 to 30% depending on the virus strain, the location, and the public health infrastructure associated with outbreaks. Climate change could be the risk factor that has the greatest potential to cause an expansion in the geographical distribution of CCHFV.

PREVENTION AND CONTROL OF EMERGING ZOONOTIC DISEASES

Emergence of zoonotic disease is multifactorial process. The environmental factors which significantly affect the pathogens and their reservoir hosts are constantly changing with significant pace. Climate and habitat changes have a significant effect on vector distribution. The environmental changes are due to the modernization of farming practices, habitat destruction, human encroachment, and climate change. It is very important to understand the impacts of these changes on the interactions between pathogens and their hosts and between the host and other species because these interactions are responsible for disease emergence. Understanding the environmental changes and their impacts allow us to develop mitigation strategies and effective and timely response. It is believed that the initial transmission of the SARS coronavirus from a currently unidentified bat species to the amplifying hosts, including the civet cat, occurred due to drastic changes in farming and trading activities. The geographical distribution

of zoonotic pathogens such as WNV, CHIKV, and dengue virus are also changing and expanding due to newly established habitats. It is important to recognize various influencing factors and their roles in the emergence of different viruses and make the strategy to control them.

One Health approach: The "One Health Initiative" defines "One Health" as "the collaborative efforts of multiple disciplines working locally, nationally and globally to attain optimal health for people, animals, plants, and our environment". Emerging interspecies and transboundary zoonoses infections require improved understanding between various groups to develop control strategies, implementation of surveillance and response activities between the animal–human. Consider the interactions of humans and animals with ecosystems and the environment as important control strategies (**Fig. 1**).



(×: vaccine to prevent transmission to human; ↓: postexposure human antibodies to reduce viral replication)

FIG. 1: One Health strategies: Human-Animal-Environment ecosystem.

SUMMARY

Zoonotic diseases are infectious diseases that are naturally transmitted from vertebrate animals to humans and vice versa. They are caused by all types of pathogenic agents including bacteria, parasites, fungi, viruses, and prions. Since last few decades, their impact on public health has increased although they have been recognized for many centuries. Currently, world is experiencing huge socioeconomic impact of zoonotic pathogens transmitted from animals to humans worldwide. As the emergence of SARS-CoV-2 from an unknown reservoir leading to the pandemic require effective communication between all levels of response, understanding the origins and evolution of the pathogen to develop policies that can mitigate its spread. It is being increasingly recognized that a "One Health approach" at the Human-Animal-ecosystem interface is needed for effective investigation, prevention, and control of any emerging zoonotic disease.

188
CHAPTER

Tetanus

Sayuri Enriquez Saenz, Devendra Richhariya

INTRODUCTION

The tetanus is characterized by muscular rigidity and spasms caused by tetanus toxin (tetanospasmin), which is produced by *Clostridium tetani*, an anaerobic bacillus, whose spores survive in soil and cause infection by contaminating wounds. The estimated global incidence of tetanus is approximately 1 million cases annually. Mortality rates due to tetanus vary across the world, depending on healthcare access, and in the absence of medical treatment the mortality rate reaches to almost 100%. This chapter discusses the pathophysiology, symptomatology, and medical treatment of *C. tetani* infection and the possibility of using botulinum toxin for tetanus-induced rigidity and spasms.

PATHOPHYSIOLOGY OF TETANUS TOXIN

Tetanus toxins act by a mechanism similar to botulinum toxin. Tetanus toxin is taken up into nerve terminals of lower motor neurons, the nerve cells that activate voluntary muscles. It is a zinc-dependent metalloproteinase that targets a protein [synaptobrevin/vesicle-associated membrane protein (VAMP)] that is necessary for the release of neurotransmitter from nerve endings through fusion of synaptic vesicles with the neuronal plasma membrane. Flaccid paralysis may be the initial symptom of local tetanus infection, caused by interference with vesicular release of acetylcholine at the neuromuscular junction, as occurs with botulinum toxin. Extensive retrograde transport of tetanus toxin occurs in the axons of lower motor neurons, and tetanus toxin reaches the spinal cord or brainstem. Tetanus toxin crosses the synapses and is taken up by nerve endings of inhibitory gamma-aminobutyric acid (GABA)ergic and/or glycinergic neurons that control the activity of the lower motor neurons. Once tetanus toxins inside the inhibitory nerve terminals, they cleave VAMP, thereby inhibiting the release of GABA and glycine, resulting in functional denervation of the lower motor neurons, which leads to rigidity and spasms due to hyperactivity and to increased muscle activity.

SYMPTOMATOLOGY OF TETANUS

Tetanus toxin causes rigidity and spasms due to hyperactivity of voluntary muscles. Rigidity is the tonic, involuntary contraction of muscles while spasms are short-lasting muscle contractions that can be elicited by sensory stimulation or by stretching of the muscles; they are termed "reflex spasms." A highly reduced ability to open the mouth as rigidity of the temporal and masseter muscles leads to trismus (lockjaw). During physical examination, attempts at opening the mouth may induce spasms that cause the complete clenching of the jaws. Tetanus can be classified as *generalized tetanus*, *neonatal tetanus* (which is a generalized form in children <1 month), *local tetanus*, and *cephalic tetanus* (which tetanus is localized to the head region). Generalized and neonatal tetanus affect the muscles of the whole body and lead to opisthotonos (the backward arching of the column due to rigidity of the extensor muscles of the neck and back) and may cause respiratory failure and death due to rigidity and spasms of the laryngeal and respiratory muscles. Local and cephalic tetanus account for only a minority of cases; however, they can develop into the generalized form. Depending on the type of the tetanus local/cephalic or generalized/neonatal, tetanus typically manifests as trismus/lockjaw, risus sardonicus, dysphagia, neck stiffness, abdominal rigidity, and opisthotonos, i.e., hyperactivity of muscles of the head, neck, and trunk. The limbs tend to be less severely affected, but with full opisthotonos, decorticate posture occurs (flexion of the arms and extension of the legs). In both local/cephalic and generalized tetanus, trismus is frequently the initial symptom but the tetanus may present in any form described above. In addition, general muscle ache, focal flaccid paralysis, and an array of unusual symptoms reflecting unusual patterns of neuronal inactivation, including diplopia, nystagmus, and vertigo, may occur. The tetanus toxin affects not only the motor system but also the autonomic system. Episodes of tachycardia, hypertension, and sweating, sometimes rapidly alternating with bradycardia and hypotension, are common autonomic dysfunction, especially in generalized tetanus. Autonomic symptoms usually occur a week after the occurrence of motor symptoms. Tetanus-mediated respiratory insufficiency is a treatable condition with the availability of modern intensive care; autonomic dysfunction has become a major cause of death in tetanus victims. Sensory nerves may also become invaded by the tetanus toxin, causing altered sensation, such as pain and allodynia.

DIAGNOSIS

Tetanus is largely a clinical diagnosis, and no laboratory test is recommended to diagnose the tetanus. Tetanus mostly occurs in a person with an inadequate or unknown immunization history and tetanus can even occur in a person with protective antitetanus antibodies. Strychnine poisoning may present as generalized tetanus. Other differential diagnoses of tetanus are drug-induced dystonic reaction, hypocalcemia tetany, malignant neuroleptic syndrome, serotonin syndrome, Stiff person syndrome, peritonsillar abscess, peritonitis, bacterial meningitis, rabies, and temporomandibular joint disease.

TREATMENT OF TETANUS

Treatment of tetanus is supportive and consists of identification of wound and debridement and removal of spores, and further toxin production can be prevented. As the disease itself does not provide the immunity so tetanus immunization should be provided. A patient with respiratory compromise should be admitted in the intensive care unit for immediate neuromuscular blockade and intubation support. Treatment is summarized in **Table 1**.

Wound cleaning and antibiotic are the mainstay of the acute treatment of tetanus and are based on the eradication of *C. tetani*, e.g., with *intravenous metronidazole*, 500 mg every 6 hourly, or penicillin, 100,000–200,000 IU/kg/day for 7–10 days. *Tetanus immunoglobulin* is given once intramuscularly to inactivate any free tetanus toxin; doses of 250 IU intramuscularly in an adult and 4 unit/kg in children are given as postexposure prophylaxis, while 3,000–6,000 IU intramuscularly is recommended for treatment of clinical tetanus, though the tetanus immunoglobulin does not reduce the symptoms of tetanus but may reduce the mortality. A part of the tetanus immunoglobulin dose should also be infiltrated in and around the wound. Muscle symptoms may aggravate further, although the clostridia have been eradicated and antitoxin has been given, because the tetanus toxin continues to be transported axonally and trans-synaptically and to cleave VAMP. A meta-analysis indicated that intrathecal administration of antitoxin could inactivate tetanus toxin during its trans-synaptic transport; intrathecal administration is also superior to the intramuscular route with respect to survival. Vaccination should be included in the treatment because immunity may not develop after an episode of tetanus. Give tetanus toxoid (0.5 mL intramuscularly) at the time of presentation, at 6 weeks and 6 months after injury. Muscular rigidity and spasm often interfere with respiration and is a likely cause of death, so treatment of these features is of vital importance. The patient also suffers from severe pain due to rigidity and spasms, which stimulates muscle activity. Muscle relaxation is customarily achieved with benzodiazepines, which augment the effect of GABA on the GABAA receptors of lower motor neurons. *Baclofen* may also be effective which acts on GABAB receptors; when given intrathecally, its sedative effect is avoided. In the setting of an intensive care unit, propofol, another GABAA receptor modulator, may be used as may nondepolarizing muscle relaxants (pancuronium and pipecuronium), which act directly on the muscle motor end plates by competing for the acetylcholine-binding site. *Magnesium*, a calcium antagonist, may be effective in relieving rigidity and spasms and acts by reducing both acetylcholine release and the muscle response to acetylcholine. Magnesium also seems to reduce autonomic dysfunction, which is of importance, because antiadrenergic drugs, especially β-blockers, may produce untoward effects, including cardiac arrest. *Dantrolene* reduces calcium mobilization and muscle contraction by binding to the ryanodine receptor in muscle. To avoid the triggering of spasms by noise or other sensory stimulation, tetanus patients should be in a calm environment. Immunization with formaldehyde-inactivated tetanus toxin (toxoid) is recommended to achieve the prophylaxis against tetanus. For instance, contamination of the umbilical stump of the newborn is a primary cause of neonatal tetanus. These issues are interrelated: A good immunization status in pregnant women leads to reduction in the prevalence of neonatal tetanus, because maternal antitetanus toxin antibodies are transferred across the placenta to the child in utero.

TABLE 1: Summary of tetanus treatment.

Steps	*Interventions*
Wound	Identify wound and wound debridement.
Antibiotic therapy	Metronidazole 500 mg IV 6 hourly, theoretically penicillin can enhance the effect of tetanospasm
Immunization	• Tetanus toxoid (TT) 0.5 mL IM at presentation, then after 6 weeks and then after 6 months • Tetanus immunoglobulin 3,000–6,000 units IM (opposite arm of TT and some amount around the wound site)
Muscle relaxation	Diazepam
Respiratory distress management	Sedation neuromuscular blockade (succinylcholine/vecuronium for intubation) mechanical ventilation
Autonomic dysfunction management	• Magnesium sulfate loading dose 40 mg/kg IV, then continuous infusion 2 g/h or • Labetalol 0.25–1 mg/min IV infusion • Morphine sulfate 0.5–1 mg/kg/h • Clonidine 300 μg every 8 hourly

(IM: intramuscularly; IV: intravenously)

THE ROLE OF BOTULINUM TOXIN IN TETANUS-INDUCED RIGIDITY AND SPASMS

The botulinum toxins are zinc metalloproteinases which enter the nerve terminals of lower motor neurons that attack synaptic vesicle proteins. Botulinum toxin A cleaves synaptosomal-associated protein (SNAP-25); botulinum toxins B, D, F, and G cleave synaptobrevin (which is also attacked by tetanus toxin); and botulinum toxin C cleaves SNAP-25 and syntaxin. The botulinum toxins undergo less axonal and trans-synaptic transport as compared to tetanus toxin. Therefore, the nerve terminals of lower motor neurons are affected by botulinum toxins, inhibiting the release of acetylcholine and activation of voluntary muscles. For this reason, they may have a role in reducing the muscular hyperactivity in tetanus patients. Theoretically, the action of botulinum toxin could be more rapid in tetanus in which the activity of the lower motor neurons is much increased. Dosage varied somewhat but resembled those commonly used to treat dystonia.

ADVANTAGES AND DISADVANTAGES OF BOTULINUM TOXIN TREATMENT IN TETANUS

Early and common symptoms of tetanus, in both generalized and cephalic, are trismus and dysphagia. These features cause major threats for the patient including respiratory failure and autonomic dysfunction described above. A patient of tetanus cannot swallow normally or evacuate the mouth and predisposes to aspiration of normal salivation and pneumonia. Difficulty in eating and problem in maintaining oral hygiene occur due to trismus, which is an important issue, because the condition may last for many weeks, endangering dental health. Trismus can also cause involuntary tongue biting, which may be very painful. Tetanus-induced trismus can be relieved safely by the use of botulinum toxin. The procedure is considered safe, given that the masseter and temporalis muscles are at some distance from the larynx; injection should be administered into the cricopharyngeal muscles to relieve dysphagia.

Botulinum toxin for the treatment of trismus and dysphagia should be considered at an early stage in tetanus, because it reduces the risk of aspiration and pneumonia, allowing dental care and food intake, and may contribute to a more favorable course of the disease. Painful neck rigidity can be relieved by botulinum toxin injections into the trapezius, splenius capitis, levator scapulae, and sternocleidomastoid muscles; vital structures, such as the carotid artery, are present near these muscles, so care must be taken to avoid spread of botulinum toxin to the larynx. No information is available on the use of botulinum toxin in generalized tetanus in which large truncal muscles are affected, such as the abdominal and erector spinae muscles.

Hyperactivity of abdominal muscles in Parkinson's disease and dystonia can be successfully treated by use of botulinum toxin. Back pain syndromes can also be treated with injection of botulinum toxin into several levels of the erector spinae muscles in the L1–L5 area. Botulinum toxin is helpful in reducing the need of muscle relaxants in the treatment of tetanus that affects consciousness and the long-lasting effect of botulinum toxins (>3 months).

Difficulty of treating all affected muscle groups in generalized tetanus with botulinum toxin is one of the disadvantages. Even so, botulinum toxin should be considered in generalized tetanus, in which the rigidity of certain muscle groups may pose a special therapeutic challenge and threat to life. The botulinum toxin has a slow onset of action, and gradual increase in effect over 1–3 weeks necessitates simultaneous treatment with other muscle-relaxing drugs. It is important to monitor patients closely because of the possibility of overdosing which manifests days after injection of botulinum toxin. Especially in generalized tetanus, the main obstacle to the use of botulinum toxin for tetanus may prove to be the cost of treatment, in which large doses may be needed to reduce rigidity and spasms of large muscles.

SUMMARY

Tetanus toxin, which is produced by *C. tetani*, is the cause of tetanus symptoms. It is transported axonally to the spinal cord and/or brainstem after taken up into terminals of lower motor neurons where vesicular release of inhibitory neurotransmitters becomes blocked leading to disinhibition of lower motor neurons. Muscle rigidity and spasms occur, often manifesting as trismus/lockjaw, dysphagia, opisthotonos, or rigidity and spasms of respiratory, laryngeal, and abdominal muscles, which may cause respiratory failure. Botulinum toxin may reduce tetanus symptoms as botulinum toxin largely remains in lower motor neuron terminals, inhibiting acetylcholine release and muscle activity. Botulinum toxin can be injected into the masseter and temporalis muscles to treat the trismus. Botulinum toxin treatment should be started early in the course of tetanus to reduce the risk of pulmonary aspiration, involuntary tongue biting, anorexia, and dental caries. Botulinum toxin treatment can be helpful in other muscle group involvement.

Use of botulinum toxin for the treatment of muscle rigidity and spasms in tetanus has limited clinical experience. However, from a few published reports it would seem that such treatment is useful. The treatment of trismus with botulinum toxin is probably a fairly safe procedure, since injection into the masseter and temporalis muscles can be achieved without endangering the neighboring vital structures.

189
CHAPTER

Dengue Fever

Sahanya Ramesh Shetty, Neeraj Mangla

INTRODUCTION

Dengue fever is a vector-borne disease comprising fever, joint pain, skin rashes, headache, nausea, vomiting, and abdominal pain. The causative organism is dengue virus DENV, with serotypes 1–4 isolated in India and the vector is *Aedes aegypti*. Dengue fever poses a major threat to public health, especially in tropical and subtropical parts of India and worldwide. The other arboviral diseases in India include Japanese encephalitis, West Nile virus, chikungunya fever, Crimean–Congo hemorrhagic fever, and Kyasanur forest disease.

EPIDEMIOLOGY

The first case of dengue fever was reported in 1780 in Madras (now Chennai) and the first outbreak in 1963 in Calcutta (now Kolkata). Following this outbreak, many such outbreaks have been reported in different parts of India. There has been a significant rise in the total number of dengue-positive cases ever since. In the beginning of 2000, southern states, such as Maharashtra, Karnataka, Tamil Nadu, and Puducherry, and Northern States, such as Delhi, Rajasthan, Haryana, Punjab, and Chandigarh, were declared endemic areas for dengue.

On the global front, there has been an increase of 30-fold of the total number of dengue cases over the past five decades. Dengue is responsible for an estimated 50 million infections annually, and it is endemic in over 100 countries. In Southeast Asia, dengue outbreaks were recorded as early as in late 1940s, and it has been identified as a hyperendemic region for decades with the highest reported incidences. 87% of the total population in Southeast Asian countries are at a potential risk of dengue. In comparison to other Asian countries, India did not have widespread cases of dengue until the 1990s.

MODES OF TRANSMISSION

The development of dengue cases in India is dependent on various factors, such as unplanned urbanization, overcrowding, rising population, living in unsanitary conditions, decreased access to clean drinking water, storage of water in large tanks and containers for domestic and commercial use, changes in environment factors, interactions between host and pathogen, and immunological factors. In India, both *A. aegypti* and *A. albopictus* are adept vectors for dengue virus.

Temperature and precipitation: Temperature plays an ideal role for providing favorable conditions for breeding of mosquito and transmission of disease. In regions of warm temperatures and higher humidity, there is a decrease in the incubation period of dengue virus within the vector and during blood-feeding intervals. This leads to a faster process of replication of virus and intensity of transmission. However, the relation between virus transmission and weather is varied across different geographical conditions and socioeconomic conditions. Precipitation provides the mosquito an adequate source of breeding ground and habitat for larvae and pupae.

Urban region: Unlike the rural areas, drier regions, such as cities with a large population density, are prone to be infected by the dengue virus. Due to overcrowding in small areas of accommodation, there is always a tendency to store water in unprotected reservoirs inside or near their households. This may also be seen in areas with limited supply or limited hours of supply water. This leads to collection of water over a long period of time. This source of water attracts *A. aegypti,* which is anthropophilic and therefore increases the chances of transmission.

Inadequate vector control measures: Adequate vector control measures should be undertaken in endemic areas, especially during early monsoon and late monsoon phases. Failure to accommodate such activities within societies, districts, or parts of the city can benefit the transmission of dengue virus further. The lifespan of *A. aegypti* survives best between 16° and –30°C and a humidity of 60–80%. Altitude is a limiting factor for the mosquito as it is distributed between the sea level and 1,000 ft above the sea level. Since its anthrophilic, they have a high tendency to rest in and around cool shady places. Breeding is mostly seen in domestic man-made water receptacles in and around households, construction sites, and factories; natural

habitats are tree holes, leaf axils, and coconut shells. Other sites include unused tires, flowerpots, and desert coolers.

Dengue fever is a complex pathological condition dependent upon three important factors and their relationship between them:

1. *Host*: Man and mosquito
2. *Agent*: Dengue virus
3. *Environment*: Abiotic and biotic factors

TRANSMISSION

Dengue virus (DENV): It is a single-stranded RNA virus consisting of four serotypes DEN1 to DEN4. These serotypes are closely related and belong to the genus *Flavivirus* of family *Flaviviridae*.

Vector

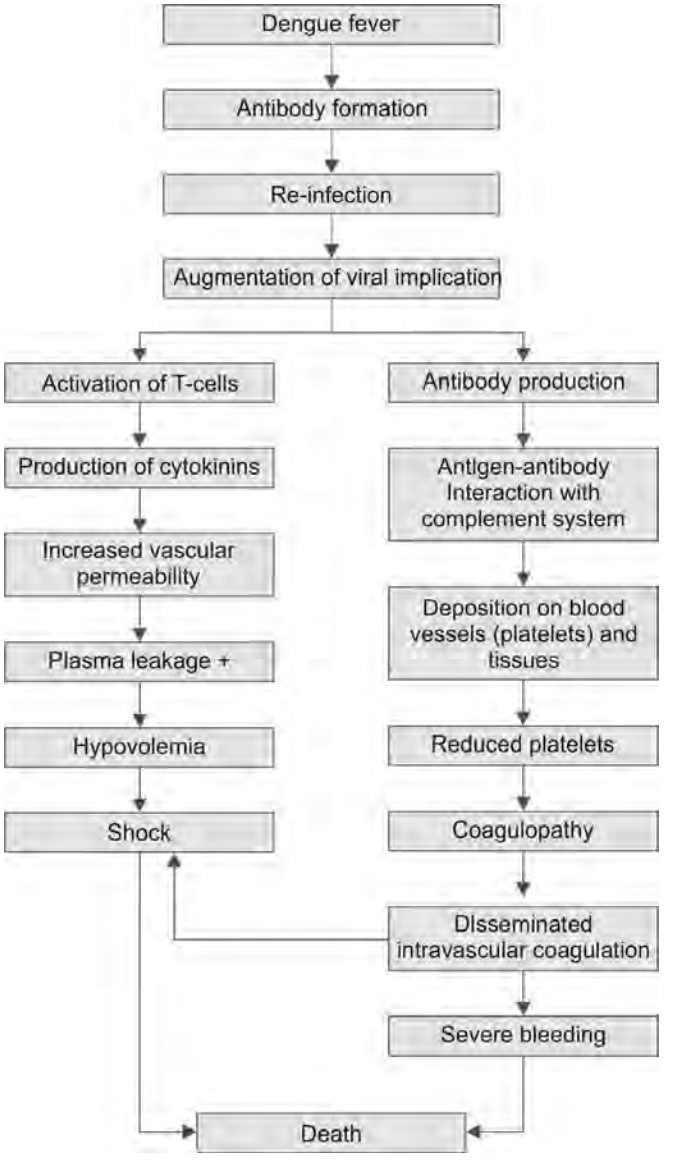
The bite of a female *Aedes* mosquito causes the infestation of DEN virus from mosquito to human. *A. aegypti* is the most potent vector, whereas other species, such as *A. albopictus*, *A. polynesiensis*, and *A. niveus* are secondary vectors. In urban areas of India, *A. aegypti* is the main vector while in some areas of Southern India, *A. albopictus* is a potent vector. A female *Aedes* mosquito lays its eggs on the damp surface just above the water line. The lifecycle of the aquatic stage of the mosquito involving the time taken from hatching to emergence as an adult can be as short as 7 days. The eggs can survive without water up to a year. At low temperatures, it may require several weeks for them to emerge. The average adult survival of *Aedes* mosquito is 15 days. In rainy season or late monsoon, the risk of transmission is higher and survival increases. To get one food meal, the mosquito must feed on several persons. Hence, the infection is transmitted to several persons at a time.

IMMUNOPATHOGENESIS

The infection starts primarily with dengue fever. The severity of infection goes uphill by subsequent infections by different serotypes progressing toward dengue hemorrhagic fever (DHF) or dengue shock syndrome (DSS). The clinical picture of DHF/DSS is much more severe and life threatening compared to dengue fever. The prognosis of DHF and DSS includes sudden-onset shock, capillary leakage, and hemorrhagic thrombocytopenia occurring at the time of active symptoms of fever (**Flowchart 1**).

CLINICAL PICTURE

After an incubation period of 4–10 days, primary infections may be subclinical or asymptomatic and can produce a spectrum of clinical manifestations. It will provide lifelong immunity to the infecting serotype. The individual infected with the infection is protected from the illness with a different serotype after 2–3 months from the onset of primary infection; however, there is no cross protective immunity in long term. Infection carried over to the next progeny of mosquitoes through eggs, called as transovarian transmission, is a more complicated form of transmission. DEN1 and DEN2 serotypes are widespread in India.



FLOWCHART 1: Pathogenesis of dengue fever.

CLINICAL MANIFESTATIONS

Dengue fever has an acute and sudden onset. It comprises three phases: (1) Febrile, (2) Critical, and (3) Recovery.

Febrile Phase

- It lasts for 2–7 days with the development of high-grade fever suddenly. It is accompanied by facial flushing, skin erythema, generalized body ache, myalgia, retro-orbital pain, arthralgia, rash, hemorrhagic manifestations, such as petechiae and mucosal membrane bleeding, and headache.
- Other symptoms include sore throat, anorexia, nausea, and vomiting which are common.
- *Uncommon symptoms*: Women in childbearing age may develop massive vaginal bleeding. Gastrointestinal bleeding, hematemesis, or melena can also be present.
- A positive tourniquet test is indicative of dengue fever.

- Liver and spleen may be enlarged after a few days of primary infection.
- The earliest manifestation in complete blood count is a decreased count of white blood cells which shows a higher possibility of dengue fever.
- It is an initial phase and too early to have a definite diagnosis of dengue fever, and one must pay careful consideration to rule out differential diagnosis of febrile illness. In addition, it is a precedent of hemorrhagic fever and DSS.

Tourniquet test: The test is performed by inflating a blood pressure cuff up to a midpoint between systolic and diastolic pressure for 5 minutes. A positive test is indicated by the presence of 10 or more petechiae per 2.5 cm^2 of area over the surface of skin. In DHF, the test is usually positive with the presence of 20 petechiae or more. However, in DSS, it may be negative or mildly positive during the heightened period of shock. In the event of a negative result, repeated tests must be taken to ensure confirmation of diagnosis. This is clearly a clinical finding and must be correlated with hematological values. In early stages of DSS/DHF, a timely diagnosis of the ailment has helped in reducing fatality risks and in aiding recovery to an immunocompetent system.

Critical Phase

- At 3–7th day from the onset of symptoms, there is an increased permeability of capillaries along with raised hematocrit levels. There is a drop in temperature of fever between 37.5 and 38°C and less.
- The leakage from capillaries is predominant and usually lasts for 24–48 hours. It is a denotable fact that plasma leakage follows as a result of a decreased level of white blood cells and platelets levels. This stage decides the prognosis of the patient. In case vascular permeability improves, there is a subsequent improvement in the immune system of the patient. This decreases the chances of further progression of leucopenia and thrombocytopenia. However, patients with increased leakage within capillaries tend to worsen and symptoms deteriorate due to loss of plasma volume.
- *Other clinical features are*: depending upon the degree of leakage from capillaries and the vigorous fluid therapy, it is likely to lead to pleural effusion and or ascites. Chest X-ray and USG of abdomen should be done to confirm the diagnosis. Note that the increase of hematocrit from baseline of >20% is directly related to the severity of plasma leakage. This may lead to shock progressively with warning signs and critical loss of plasma volume. There is a change of body temperature to subnormal (signs of hypothermia). The risks of prolonged symptoms of shock lead to decreased perfusion to vital organs and tissues. This leads to progressive organ impairment, metabolic acidosis, and disseminated intravascular coagulation. The progressive stages involve further decrease in plasma volume. In addition to the existing symptoms and the succession of these events, the white blood cells will increase in patients with severe hemorrhage and bleeding. This is contrary to leucopenia that was present in the febrile phase.
- Warning signs include abdominal pain and tenderness, persistent vomiting, fluid accumulation, signs of mucosal bleed, lethargy, restlessness, and hepatomegaly (liver enlargement > 2 cm). Laboratory findings include an increase in hematocrit along with decreased platelet count < 1,00,000/mm^3.
- Other organ involvement leads to severe hepatitis, encephalitis, or myocarditis.
- Cases with active signs of warning can be treated with adequate fluid resuscitation.

Recovery Phase

Once the patient has crossed the 24–48-hour critical phase, the physiological response involves a gradual re-absorption of fluid from the extravascular compartment in the next 48–72 hours. The patient's condition improves, appetite returns to normal, gastrointestinal symptoms resolve, and diuresis ensues.

Characteristic appearance of multiple petechial rashes over upper and lower extremities, back, neck, and chest are also seen. In the first 24–48 hours from the onset of symptoms, patients present with an erythematous macular rash all over the extremities, torso, and back. These rashes blanch upon applying pressure and may present only for a transient period. About 2–3 days after defervescence, the convalescent rash may appear. These are generalized petechial rashes and do not blanch upon applying pressure. They are surrounded by thin, round islets of normal skin, appearing like "isles of white in the sea of red." These rashes disappear after the recovery of symptoms, usually after 7 days. Other symptoms include bradycardia, electrocardiogram eliciting changes in cardiac activity, and pruritis.

On the resolving phase of symptoms, it is evident that the white blood cell count increases much faster when compared to platelet count. The hematocrit levels may be low due to the dilution effect as a result of the reabsorbed fluid. Respiratory distress may be aggravated due to pleural effusion and ascites along with excessive fluid intervention. In the recovery and/or critical phase, the degree of excessive fluid administered can lead to pulmonary edema or congestive heart failure.

SEVERE DENGUE

The clinical features are progressively life threatening with a prolonged critical phase. Depending upon the condition of the patient and progression of symptoms, the presence of one or more of the following is defined as severe dengue:

- Plasma leak from capillaries into the extra-vascular compartment—rise in hematocrit count that may progress to shock
- Signs of respiratory distress secondary to fluid overload
- Fluid overload in pulmonary or gastrointestinal system—pleural effusion/ascites
- Signs of bleeding due to thrombocytopenia
- Decreased adequate perfusion leading to severe organ impairment

The increased permeability of vascular blood vessels increases hypovolemia and progresses to shock. This begins around defervescence, during the 3–7th day of illness. One must look out for the warning signs as they are a precedent of shock. In the initial phase of shock, due to the loss of plasma volume to leakage, there is a compensatory system that maintains normal blood pressure with tachycardia and vasoconstriction, especially in the peripheries. This leads to decreased skin perfusion and capillary refill time. This leads to cold and clammy extremities. Due to the increased vasoconstriction, the diastolic pressure rises toward a normal systolic pressure. This results to a narrow pulse pressure. One must not be fooled by reading a normal systolic pressure as progression into

TABLE 1: Hemodynamic status in hypotensive shock.

Parameters	*Stable circulation*	*Compensated shock*	*Hypotensive shock*
Hypotensive shock	Clear, lucid	Clear, lucid	Altered mental status
Capillary refill time	Brisk <3 sec	Prolonged >2 sec	Delayed further, mottled skin
Extremities	Warm and pink extremities	Cool peripheries	Cold, clammy extremities
Peripheral blood volume	Good volume	Weak and thread	Feeble or absent
Heart rate	Normal	Tachycardia	• Severe tachycardia • Bradycardia in late shock
Blood pressure	Normal blood pressure	• Normal systolic pressure but increased diastolic pressure • Narrow pulse pressure • Postural hypotension	• Narrow pulse pressure <20 mm Hg • Hypotension • Unrecordable blood pressure
Respiratory rate	Normal	Tachypnea	• Metabolic acidosis • Hyperpnea • Kussmaul breathing

later stages of shock will lead to abrupt disappearance of both pressures. The clinical appearance of the patient appears to be lucid and often remains conscious. It is a combination of hypoxia and hypotensive states that leads to multiorgan failure.

Hypotension is defined as systolic blood pressure (SBP) of <90 mm Hg or mean arterial blood pressure (MAP) of <70 mm Hg or a systolic blood pressure decrease of >40 mm Hg. In children up to 10 years of age, the 5th percentile of SBP is calculated by the formula 70 + [(age in years) × 2] mm Hg (**Table 1**).

The patient progressively leads to shock if the pulse pressure is ≤20 mm Hg in children and/or in the presence of signs of poor capillary perfusion. The signs of poor capillary perfusion include delayed capillary refill time, cold or clammy extremities, and tachycardia. The pulse pressure of ≤20 mm Hg indicates a severe form of shock. It is evidently present that hypotension is usually present in later stages of shock associated with severe bleeding. In cases of severe dengue, as discussed in pathophysiology of dengue fever, coagulation disorders may present due to thrombocytopenia. However, it may not lead to bleeding in all cases. It leads to bleeding only in the presence of severe shock along with thrombocytopenia, acidosis, and hypoxia further leading to multiorgan failure and advanced disseminated intravascular coagulation. In some cases, ingestion of aspirin, ibuprofen, or corticosteroids may cause bleeding without precedent prolonged shock or hypotension.

Other manifestations include acute liver failure, cardiomyopathy, encephalitis, and encephalopathy, even present in the absence of severe plasma leakage or shock.

Fatality risk is higher when the clinical condition of the patient progresses to later stages of shock. This can be avoided if the patient is diagnosed and treated at an earlier stage.

A person should be considered for severe dengue with a history of fever for 3–7 days and living in endemic areas along with one or more of the following findings (**Table 2**):

- *Increased hematocrit*: Note that the higher the rise of level from baseline, the greater the severity of the disease
- Signs of respiratory distress to rule out pleural effusion or ascites

TABLE 2: Grading for dengue fever and dengue hemorrhagic fever based on severity of symptoms

Grade	*Signs/Symptoms*	*Laboratory findings*
Dengue fever (DF)	High-grade fever onset 3–7 days, retro-orbital pain, myalgia, arthralgia	Leucopenia, thrombocytopenia
DHF-I	Above symptoms + positive tourniquet test + plasma leakage	• Thrombocytopenia <100,000/mm^3 • Hematocrit 20% or more
DHF-II	Above symptoms + signs of bleeding from skin and IV sites + epistaxis, black tarry stools, mucosal bleeding (gums) + abdominal pain	• Thrombocytopenia <100,000/mm^3 • Hematocrit 20% or more
DHF-III	Above symptoms + weak, rapid pulse + narrow pulse pressure ≤20 mm Hg + high diastolic pressure + hypotension + cold extremities + altered sensorium (restlessness, lucid, confused)	• Thrombocytopenia <100,000/mm^3 • Hematocrit > 20%
DHF-IV	• Profound shock • Unrecordable blood pressure • Feeble pulse • Decreased pulse blood volume	• Thrombocytopenia <100,000/mm^3 • Hematocrit >20%

(DHF: dengue hemorrhagic fever)

- *Capillary compromise or signs of shock*: Tachycardia, cold clammy extremities, delayed capillary refill time >3 seconds, feeble pulse pressure or unrecordable blood pressure in later stages of shock
- *Signs of bleeding*: In mucosal membranes, ears, nose, and massive vaginal bleeding in woman of childbearing age
- *Altered level of consciousness*: Unresponsive, lucid, lethargy, coma, or convulsions
- *Severe gastrointestinal symptoms*: Persistent vomiting, intense abdominal pain, signs of jaundice
- *Signs of organ impairment*: Acute liver failure, acute renal failure, encephalopathy or encephalitis, or unusual symptoms such as cardiomyopathy

STEP-WISE APPROACH TO TREATMENT

1. *Initial assessment*:
   - History
   - Physical examination
   - Investigation
2. Diagnosis
3. Management: In pertinence with the severity of the clinical condition of the patient, management of the patient can be divided into:
   - *Group A*: Stable, may be discharged
   - *Group B*: Requiring hospital admission and intervention
   - *Group C*: Emergency resuscitation and intensive care stay

Initial Assessment

History

A complete and discreet history covers all areas of concerns and doubts. It aids in ruling out other differential diagnoses with a similar onset of febrile illness. It comprises:

- Onset and duration of first symptom
- Associated symptoms
- Frequency of symptoms within 24 hours
- Aggravating or relieving factors
- History of outside food consumption or travel to an endemic area
- Look out for warning signs
- *Change in mental sensorium*: Signs of dizziness, decreased level of consciousness, confusion
- History of trauma, fall from height, intoxication levels
- *Coexisting medical ailments*: Obesity, diabetes mellitus, pregnancy, hypertension
- History of last meal
- Check for decreased urine output and frequency since the onset of symptoms
- History of recent adventurous sports such as trekking, camping in forests, swimming in waterfall (rule out typhus, malaria, leptospirosis)
- *Recent unprotected sexual intercourse*: Rule out acute HIV seroconversion illness
- History of past medical and surgical interventions
- *Current medication history*: Use of aspirin, clopidogrel, heparin, warfarin

Physical Examination

It includes:

- *Head-to-toe examination*: Hydration status, signs of pallor, icterus, clubbing, cyanosis, lymphadenopathy, and pedal edema
- *Change in mental sensorium*: Signs of dizziness, decreased level of consciousness, confusion
- Assessment of hemodynamic status
- Signs of tachypnea, dyspnea, acidotic breathing
- Signs for abdominal tenderness, location of tenderness, rule out hepatomegaly, splenomegaly, signs of ascites
- *Signs of petechial rashes*: Over the upper and lower limbs, abdomen, chest,
- *Signs of bleeding*: Over mucosal membranes, ear, nose, throat, excessive vaginal bleeding in women
- *Tourniquet test*: Can be repeated in previously negative reading
- *Changes in hemodynamic status*: Look for signs of hypotensive shock

Investigation

- *Complete blood count with peripheral smear*: Hematocrit count is evaluated at the initial hours of febrile phase to maintain as baseline, in order to compare with in subsequent testing. An increased level of hematocrit count with a parallel decrease in platelet levels is an early indication of the critical phase of dengue fever.
- *Additional tests*: Arterial blood gas analysis in cases of sudden breathlessness, dyspnea on exertion, chest discomfort, desaturation status, liver function test, random blood glucose, serum electrolytes, serum urea, serum creatinine, bicarbonate levels, lactate count, cardiac enzymes, urine routine, and examination
- *Radiological studies*: Chest X-ray, ultrasound abdomen/CT abdomen

Dengue fever should be differentiated from other diseases (**Table 3**) and those presenting with similar features, such as fever and rashes.

DIAGNOSIS

Early diagnosis of febrile illness can prevent the progression to a more severe and critical phase of the disease and eventually in some cases death. During the initial 5 days of illness, viral isolation in cell cultures and nucleic acid amplification test (NAAT) can be done to confirm dengue. It can also be confirmed by virus antigen by enzyme-linked immunosorbent assay (ELISA) or rapid tests. Virus isolation requires a higher level of expertise and infrastructure and maybe expensive. In order to cultivate virus, it is ideal to cool and preserve the viability of virus after collection of samples from the patient and delivery to the laboratory. It usually requires several days for confirmation of virus cultivation whereas nucleic acid amplification detection assays can be used to detect dengue within 24–48 hours. Both virus isolation and NAAT need to be maintained at adequate quality assurance, controlled procedures, and done by experienced technicians. The NS1 antigen test can be done with antigen detection kits. Results from dengue NS1 can be obtained as early as an hour. After the

TABLE 3: Differential diagnosis of dengue fever.

Flu-like symptoms	*+/– Rash*	*Infectious diseases*	*Malignancy*	*Clinical features*
• Chikungunya • Influenza • Measles • HIV seroconversion illness • Mononucleosis	• Rubella • Measles • Scarlet fever • Meningococcal infection	• Malaria • Acute gastroenteritis • Leptospirosis • Typhus • Typhoid • Viral hepatitis • Bacterial sepsis • Septic shock	Acute leukemia	• Diabetic ketoacidosis • Lactic acidosis • Leukopenia ± thrombocytopenia • Platelet disorders • Renal failure • Respiratory distress (Kussmaul breathing) • SLE • *Acute abdomen*: Acute appendicitis, acute cholecystitis, perforated viscus

(SLE: systemic lupus erythematosus)

initial 5 days, there is a decrease in antigens and appearance of viruses may have disappeared. The NS1 antigen may be present in some cases. For serology, decreased or absence of immunoglobulin M (IgM) in response to a febrile phase affects diagnostic ability. A fourfold increase or a higher increase in antibody levels by IgG ELISA or by hemagglutination inhibition (HI) testing is indicative of an acute flavivirus infection.

MANAGEMENT

Group A (Patient Stable, may be Discharged)

- This includes patients who are able to take oral fluids in order to maintain adequate hydration and are able to void urine every 6 hours. Additionally, patients with no warning signs and with a decrease in frequency of vomiting, diarrhea, or fever episodes are included in this group. It also includes patients who are ambulatory and are not severely dehydrated. They need to be evaluated serially until the critical phase is over with complete blood count to monitor white blood cells and platelet count. In the event of a stable hematocrit and adequate hydration status, the patient can be sent home for rest and adequate oral rehydration with fluids is recommended.
- Oral fluids can be increased with oral rehydration solution (ORS), fruit juices, and electrolyte-rich water with sugar. One must be aware of possible hyperglycemia due to physiological stress in the febrile phase.
- Tablet paracetamol 500 mg for high fever is adequate at an interval of 6 hours. In order to reduce body temperature, tepid sponging can be done. Avoid use of acetylsalicylic acid (aspirin), ibuprofen, and nonsteroidal anti-inflammatory drugs (NSAIDs) as these may aggravate risks of bleeding with underlying thrombocytopenia.
- The patient and family need to be counseled regarding signs and symptoms of bleeding, rashes, severe abdominal pain, persistent vomiting, deterioration of mental status, cold clammy extremities, lethargy, irritability, restlessness, black stools, coffee ground vomiting, and decreased urine output. The patient should be monitored at home by family members for increased frequency of symptoms, temperature pattern, volume of intake fluids, urine output, and warning signs and reviewed after 4 days in the hospital. If any of the symptoms arise, the patient should be brought back to the hospital for critical intervention.

Group B (Patient Requiring Hospital Admission and Intervention)

This group includes patients who are in need of in-hospital management for close observation and approach to a critical phase. Coexisting medical conditions, such as pregnancy, diabetes mellitus, old age, infancy, renal failure, and immunosuppressed individuals, such as those chronic hemolytic disease and HIV, make the treatment more complicated and require careful close observation within the hospital. In the event of one or more signs of warning symptoms, the treatment module should be initiated at the earliest.

- *An initial hematocrit level must be obtained before starting fluid therapy*. Start with isotonic fluid solutions such as 0.9% saline, Ringer's lactate, or Hartmann's solution at 5–7 mL/kg/h for the first 1–2 hours. Then reduce it at a rate of 3–5 mL/kg/h for the next 2–4 hours and further maintain at 2–3 mL/kg/h or less according to the clinical response of the patient. Reassess the hydration status of the patient every half hourly in order to rule out early signs of pleural effusion or fluid overload. Repeat hematocrit level and watch for increase in levels despite fluid therapy. If the hematocrit level remains the same with minimal increase, continue with the same rate at 2–3 mL/kg/h for the next 2–4 hours. In case of increased hematocrit levels, increase the rate of fluid administration to 5–10 mL/kg/h for 1–2 hours. Repeat the hematocrit levels every 2 hourly and adjust the rate of fluid therapy accordingly.
- Maintain a minimum intravenous fluid in order to maintain an adequate urine output at 0.5 mL/kg/h. Initial fluid therapy is required during the initial 24–48 hours in order to replenish the loss of blood volume. The intravenous fluid should be tapered according to a decrease in the hematocrit level, stable hemodynamic status, and adequate urine output.
- Constant monitoring should be done for all patients until the critical phase is over. Parameters that need constant monitoring include vital signs and peripheral perfusion every 1–4 hours, urine output every 4–6 hours, and

hematocrit levels before and after fluid replacement and then every 6–12 hours. According to the hemodynamic status of the patient, serial investigations, such as liver function test, renal function test, and coagulation levels, should be done.
- *For correction in serum electrolyte imbalances*: Start sodium bicarbonate at 1–2 mEq/kg
- *Dengue patient without warning signs*: Encourage oral fluids in the absence of persistent vomiting. In the absence of oral tolerance, start intravenous fluids of 0.9% saline or Ringer's lactate.

Maintenance fluid can be calculated by using the Holliday–Segar formula: 4 mL/kg/h for the first 10-kg body weight + 2 mL/kg/h for the next 10-kg body weight + 1 mL/kg/h for subsequent body weight.

Group C (Emergency Resuscitation and Intensive Care Stay)

- It includes a patient requiring emergency and critical care intervention in the event of severe plasma leakage or respiratory distress due to fluid overload, severe hemorrhage, and organ impairment. Initial resuscitation with fluid is the sole essential requirement. The choice of fluid should be isotonic and volume should be sufficient to maintain adequate and effective circulation during the critical phase of plasma leak. It should be avoided by replacement with isotonic crystalloid solution or colloid solutions in hypotensive shock. During aggressive resuscitation, careful consideration to look out for hyperchloremic acidosis is evident in use of 0.9% saline and is often confused with lactic acidosis with prolonged shock.
- Blood grouping and matching should be done in the event of possible blood transfusion in patients with severe bleeding and decreased platelet count.
- Fluid resuscitation should be not confused with simple fluid administration. Resuscitation is defined as administration of large volume of fluids in boluses for a limited amount of time and close monitoring for signs of fluid overload and pulmonary edema. Ideal resuscitation with isotonic fluids should aim to restore central and peripheral circulation with decrease in tachycardia, improving blood pressure, pulse volume, decreased capillary refill time, and warm pink extremities. Hemodynamic status with a stable conscious level, decreasing metabolic acidosis, and urine output at ≥0.5 mL/kg/h would be expected after fluid resuscitation.

COMPLICATIONS IN SEVERE DENGUE

Electrolyte imbalances: These mostly occur due to excessive vomiting and diarrhea or due to use of hypotonic solutions for fluid therapy for resuscitation and treatment of dehydration. Hyponatremia, hypokalemia, metabolic acidosis, hyperkalemia, and hypercalcemia are most commonly present.

In the presence or absence of diabetes mellitus, hypoglycemia or hyperglycemia can occur.

Treat the underlying diseases, including nosocomial infections or coinfections resulting to high-grade fever.

Supportive and adjuvant treatment: It includes vasopressors and inotropes if required to prevent life-threatening hypotension and/or while endotracheal intubation. Treatment of organ impairment, such as encephalopathy or encephalitis, should be done. Renal replacement therapy and/or continuous venovenous hemodialysis can be initiated in adverse cases.

COMPLICATION: COMPENSATORY SHOCK

Initiate fluid resuscitation at the rate of 5–10 mL/kg/h with isotonic crystalloid solution (**Flowchart 2**). Reassess the condition of the patient and note the deterioration of symptoms. If the symptoms are resolving, intravenous fluids can be gradually decreased to 5–7 mL/kg/h for the next 1–2 hours. Further, on improvement of the patient's condition, the rate of fluid administered can be decreased to 2–3 mL/kg/h for the next 3–4 hours. Depending upon the patient's response, the maintenance rate can be continued for the next 24 hours.

However, if the patient's condition does not improve after initial fluid resuscitation, re-evaluate the hematocrit levels after bolus fluid is administered. In the event of persistent increased hematocrit levels of >50%, the second bolus fluid can be administered at 10–20 mL/kg/h for 1 hour. If there is improvement in hemodynamic status, a decreased rate at 7–10 mL/kg/h can be given for the next 1–2 hours. Further, it can be gradually tapered on improvement of vital signs and reduction of symptoms. In case of a decrease in hematocrit levels below the initial baseline hematocrit, it is indicative of bleeding. Preparation for possible blood transfusion must be done and transfusion should be started after cross checking with the serum blood count. In case of bleeding, serial administration of isotonic crystalloid or colloid solutions may need to be given for the next 24–48 hours.

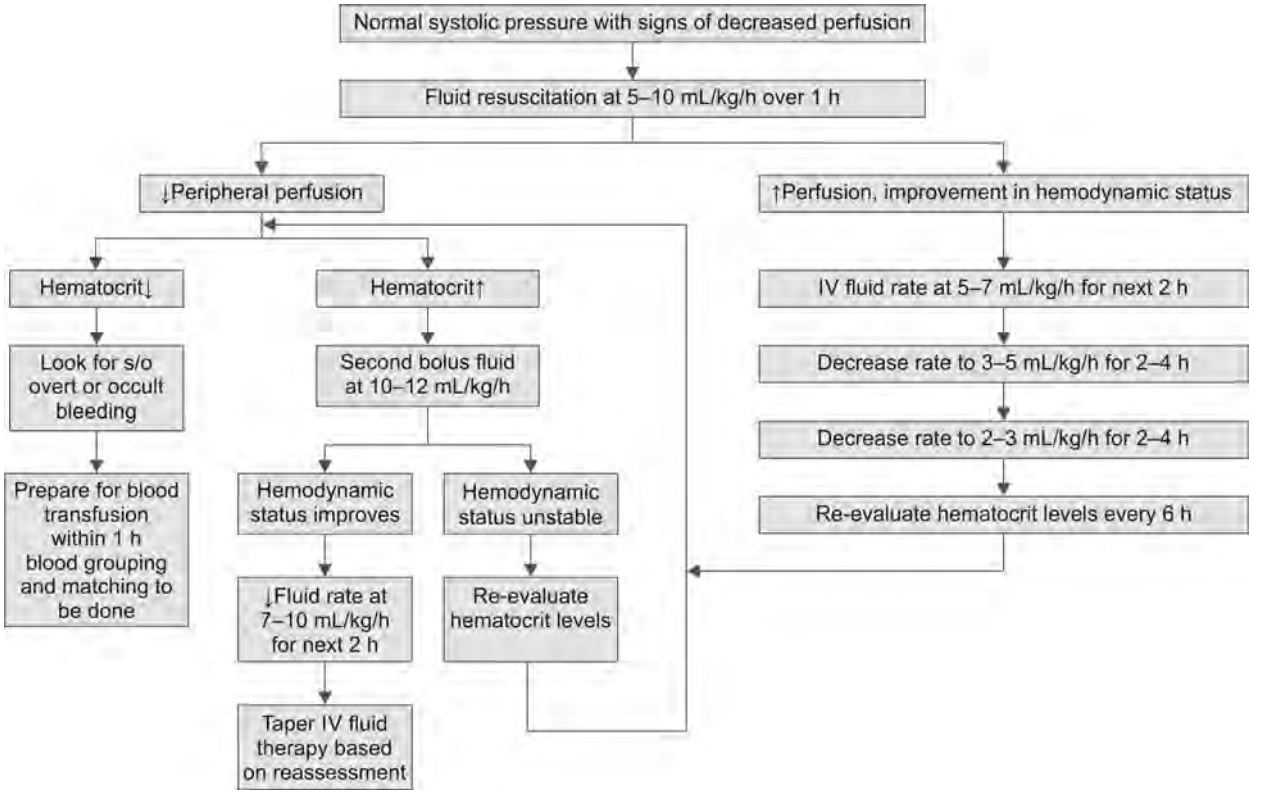
COMPLICATION: HYPOTENSIVE SHOCK

A more vigorous fluid therapy must be initiated for hypotensive shock (**Flowchart 3**). Fluid resuscitation with crystalloid or colloid solution at 20 mL/kg as bolus dose must be administered as fast as possible. This is to ensure that excessive plasma leakage can be reversed and the patient can be reverted from shock at the earliest.

In the event of improvement, follow with intravenous fluid administration at 10 mL/kg/h for the next 1 hour. Continue with crystalloid infusion and reduce the rate to 5–7 mL/kg/h for the next 1–2 hours. Then reduce to 3–5 mL/kg/h for the next 2–4 hours and then to 2–3 mL/kg/h or less maintained for the next 24–48 hours. In the event of unstable hemodynamic vitals, re-evaluate hematocrit levels and compare the results with the previous hematocrit prior to bolus administration. If the hematocrit level is below 40% in children and adult female, and below 45% in adult males, it indicates an underlying bleeding within the systemic circulation. The need for blood cross match and transfusion is evident and should be started as soon as possible.

If hematocrit is higher than baseline levels, shift to colloid solution IV fluids at a rate of 10–20 mL/kg as a second bolus over 30 minutes to 1 hour. Reassess the patient after the second bolus; if vitals improve, decrease the rate of IV fluids to 7–10 mL/kg/h for 1–2 hours. Change back to crystalloid solution later and reduce the rate of fluid administration gradually as mentioned above in the event of improving the patient's condition.

In the event of an unstable condition, repeat hematocrit levels. If the hematocrit reduces compared to the previous



Normal systolic pressure with signs of decreased perfusion
Fluid resuscitation at 5–10 mL/kg/h over 1 h
↓Peripheral perfusion
↑Perfusion, improvement in hemodynamic status
Hematocrit↓
Hematocrit↑
IV fluid rate at 5–7 mL/kg/h for next 2 h
Look for s/o overt or occult bleeding
Second bolus fluid at 10–12 mL/kg/h
Decrease rate to 3–5 mL/kg/h for 2–4 h
Decrease rate to 2–3 mL/kg/h for 2–4 h
Prepare for blood transfusion within 1 h blood grouping and matching to be done
Hemodynamic status improves
Hemodynamic status unstable
Re-evaluate hematocrit levels every 6 h
↓Fluid rate at 7–10 mL/kg/h for next 2 h
Re-evaluate hematocrit levels
Taper IV fluid therapy based on reassessment

FLOWCHART 2: Depicting fluid therapy in compensatory shock.

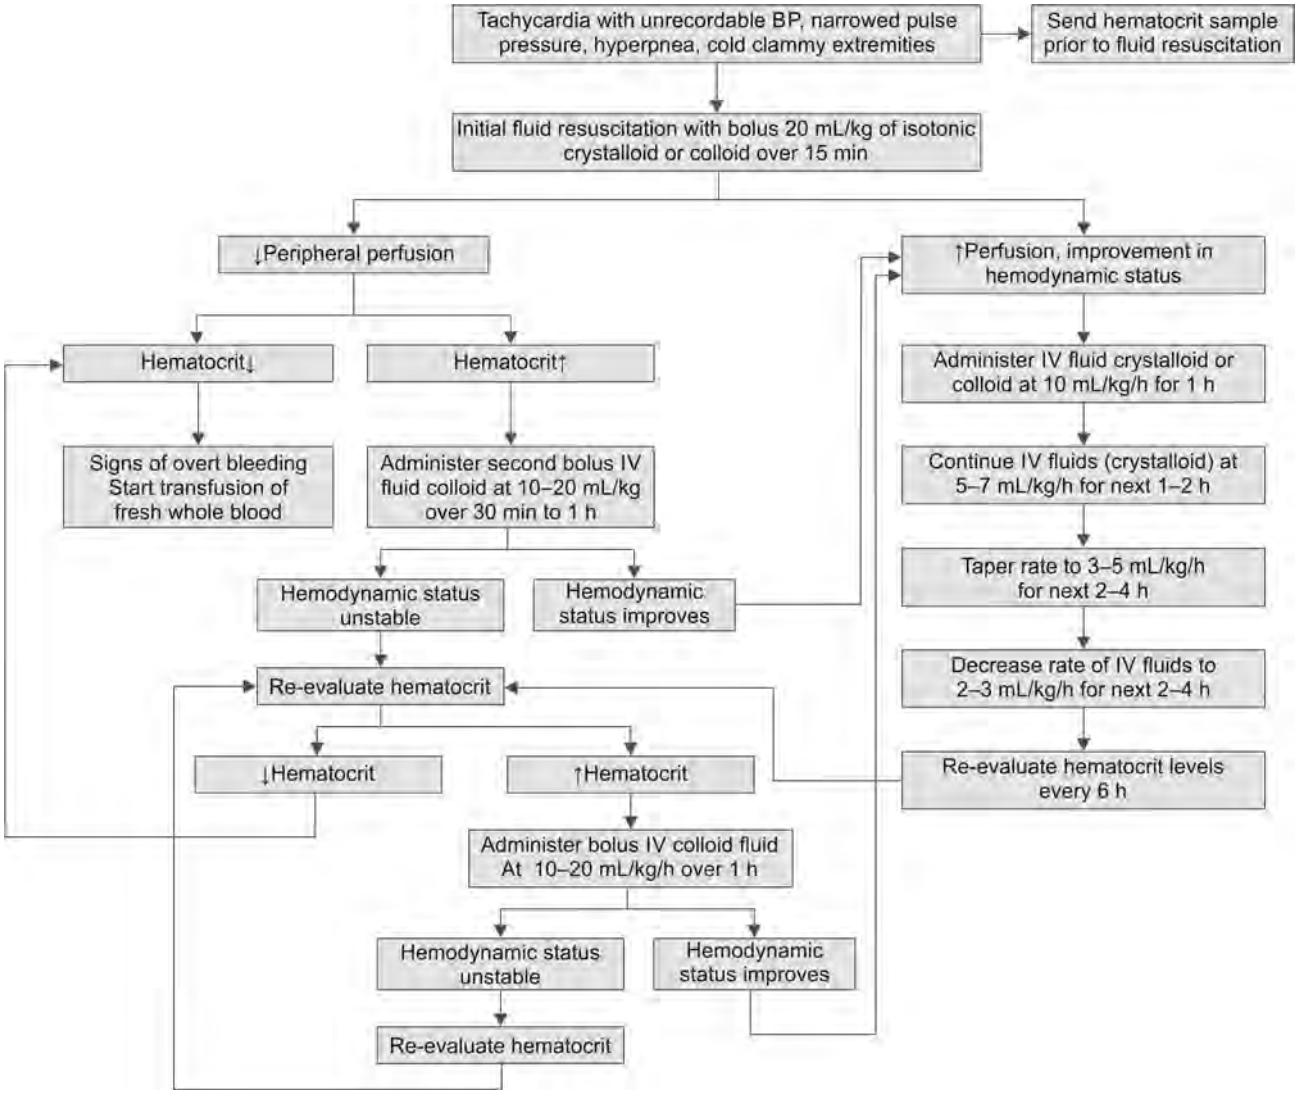
result, it indicates bleeding and requires immediate blood transfusion. If the hematocrit level increases to >50%, continue colloidal solution at 10–20 mL/kg infusion over 1 hour. After the bolus dose, decrease the rate of IV fluid to 7–10 mL/kg/h for the next 1–2 hours. Shift to crystalloid solution IV fluid and taper the rate of administration with respect to the patient's response.

Over the next 24 hours, serial doses of bolus IV fluid may be required depending upon the patient's response. Titrated doses need to be administered over the first 24 hours. In cases of severe dengue, the patient needs to be admitted to a high dependency unit or intensive care unit for intervention and constant monitoring until the critical phase is over and signs of shock are resolved.

A detailed input and output fluid chart should be maintained. Monitor vital signs and peripheral perfusion every 15–30 minutes during the critical phase and every 1 hour once the patient is out of shock phase. It is evident that vigorous fluid administration leads to increased risks of fluid overload and therefore needs more careful and regular monitoring in order to ensure adequate fluid replacement. In cases of severe dengue, acquire an arterial line as soon as possible in order to measure arterial blood pressure. Blood pressure measured by cuff may not be accurate in hypotensive shock. The arterial line can provide more accurate pressure readings and easier access to obtain a frequent sample of blood. ECG is taken to monitor cardiac activity changes and serial ECG to compare improvement or deterioration of the patient. Urinary catheterization should be done to monitor constant urine output, ideally at 0.5 mL/kg/h. Until the patient is stable, the hematocrit level should be evaluated prior and after bolus fluid administration and then every 4–6 hours. In addition, arterial or venous blood gas analysis should be done as soon as patient treatment begins. Evaluate bicarbonate, lactic acid levels, and total pCO_2 every 30 minutes in the initial critical phase until the patient's condition is stable. Random blood glucose should be checked before fluid resuscitation and repeat as indicated. Other investigations such as renal function test, liver function test, and coagulation profile prior to fluid resuscitation and after 1 hour of fluid resuscitation should be done.

The hematocrit level can be used as a guide to treatment along with changes in the patient's vital signs including peripheral extremities, pulse pressure, blood pressure (systolic and diastolic), heart rate, respiratory rate, and capillary refill time. An event of rising hematocrit along with unstable vital signs including narrow pulse pressure indicates active plasma leakage and can be treated well with a second dose of bolus replacement. An event of rising or persistently high hematocrit along with stable vital signs and adequate urine output does not require a more aggressive approach of fluid resuscitation and requires close monitoring of hematocrit levels for the next 24 hours. Hematocrit levels are more likely to reduce to baseline within 24 hours.

An event of decreased hematocrit levels with unstable vital signs including narrow pulse pressure, tachypnea, tachycardia, metabolic acidosis, decreased or no urine output shows an increased risk of bleeding, and blood transfusion should be initiated immediately. However, in an event of a hematocrit level with normal vital signs and adequate urine output is an indication of decreased plasma leakage and reabsorption of extravasated fluids. In this case, IV fluids must be decreased and finally stopped in order to prevent fluid overload and pulmonary edema.



Tachycardia with unrecordable BP, narrowed pulse pressure, hyperpnea, cold clammy extremities
Send hematocrit sample prior to fluid resuscitation
Initial fluid resuscitation with bolus 20 mL/kg of isotonic crystalloid or colloid over 15 min
↓Peripheral perfusion
↑Perfusion, improvement in hemodynamic status
Hematocrit↓
Hematocrit↑
Administer IV fluid crystalloid or colloid at 10 mL/kg/h for 1 h
Signs of overt bleeding Start transfusion of fresh whole blood
Administer second bolus IV fluid colloid at 10–20 mL/kg over 30 min to 1 h
Continue IV fluids (crystalloid) at 5–7 mL/kg/h for next 1–2 h
Hemodynamic status unstable
Hemodynamic status improves
Taper rate to 3–5 mL/kg/h for next 2–4 h
Re-evaluate hematocrit
Decrease rate of IV fluids to 2–3 mL/kg/h for next 2–4 h
↓Hematocrit
↑Hematocrit
Re-evaluate hematocrit levels every 6 h
Administer bolus IV colloid fluid At 10–20 mL/kg/h over 1 h
Hemodynamic status unstable
Hemodynamic status improves
Re-evaluate hematocrit

FLOWCHART 3: Fluid therapy in hypotensive shock.

HEMORRHAGIC COMPLICATIONS

Minor bleeding may occur in mucosa in any patient with dengue and recovers during the recovery phase. However, in patients with severe thrombocytopenia, bed rest and trauma should be avoided to prevent any bleeding. Careful consideration should be given in acquiring venous access and catheterization during this phase. Avoid use of intramuscular treatments for hematomas. In addition, in order to treat severe thrombocytopenia, there is no effective correlation with the use of prophylactic blood transfusion and is not indicated. In case of severe bleeding, it is more overtly present in the gastrointestinal tract and vagina in adult females. Patient with increased risk of bleeding are mentioned below.

- Persistent prolonged shock
- *Associated organ impairment*: Renal failure, liver failure
- Persistent metabolic acidosis
- Administration of nonsteroidal inflammatory agents
- *Underlying conditions*: Peptic ulcer disease
- Anticoagulant therapy
- Recent history or active complaints of trauma
- Hemolytic conditions are at risk of acute hemolysis with hemoglobinuria

Precursors to Bleeding

- Reduced level of hematocrit along with unstable hemodynamic state even after fluid resuscitation
- Refractory shock—not responding to consecutive fluid resuscitation at 40–50 mL/kg
- Persistent and overt bleeding with unstable hemodynamic status, with or without a decrease in hematocrit
- Hypotensive shock with a normal or low hematocrit level prior to fluid resuscitation
- Worsening metabolic acidosis with or without normal systolic blood pressure
- Persistent acidosis with or without abdominal tenderness and distension

Transfusion of blood should be initiated at the earliest; however, careful consideration should be taken to prevent acute fluid overload. A decreased level of hematocrit <30% is not indicated for blood transfusion as bleeding is a postplasma leakage phenomenon in the presence of prolonged shock. During the plasma leak phase, hematocrit levels exceed to 45% or more prior to onset of bleeding. When bleeding starts, hematocrit levels drop from these high levels to low and critically low hematocrit levels. Hence, the hematocrit levels may not be reduced due to plasma leak.

Treatment of Hemorrhagic Complications

Initial blood transfusion at 5–10 mL/kg of fresh packed red cells or 10–20 mL/kg of fresh whole blood at an appropriate rate should be started. Stored blood contains lower levels of 2,3-diphosphoglycerate (2,3-DPG) which decrease the oxygen-releasing capacity of hemoglobin that causes functional tissue hypoxia. An ideal clinical response includes improvement in hemodynamic status and acid–base balance. Repeat blood transfusion is considered in patients with continued signs of bleeding or no rise in hematocrit after the first blood transfusion. Insertion of a nasogastric tube (NG) should be performed with caution as severe bleeding may lead to occlusion of airway. A lubricant must be applied over the NG tube vigorously in order to prevent trauma. Central venous catheterization must be done under USG guided by experienced personnel.

COMPLICATION: FLUID OVERLOAD

In cases of severe dengue, fluid overload causes pleural effusions bilaterally and/or ascites is the main predisposing factor for acute respiratory syndrome. Acute pulmonary edema and severe persistent metabolic acidosis from severe shock are the other factors predisposing to acute respiratory distress syndrome (ARDS). Factors leading to fluid overload are aggressive administration of IV fluids; incorrect use of hypotonic solution in place of isotonic solutions; use of large volumes of intravenous fluid in patients with no severe bleeding; inappropriate transfusion of fresh frozen plasma, platelet concentrates, and cryoprecipitate; and intravenous fluids continued beyond the resolved plasma leakage phase (after defervescence). Primary comorbid diseases include congenital or ischemic heart disease and chronic lung or renal disorders.

Clinical Features

- *Respiratory insufficiency*: Due to fluid overload, leads to acute respiratory distress, difficulty in breathing
- *Tachypnea*: Increased respiratory rate
- Wheezing >> crepitations
- *Abdominal distension*: Ascites
- Raised jugular venous pressure
- *Signs of pulmonary edema*: Cough with pink or frothy sputum
- Crepitations
- Cyanosis
- *Signs of irreversible shock*: In heart failure with predisposing hypovolemia

Investigations

- *Chest X-ray*:
  - Pleural effusion
  - Cardiomegaly
  - Upward displacing of diaphragm—due to ascites
  - Varying degrees of bat's wing appearance
  - Kerley B lines
- ECG—detection of arrythmias, ischemic changes
- Arterial blood gas analysis
- *ECHO-2D*: In order to elicit regional wall abnormality, presence of clots, vegetations, hypokinesia, ventricular hypertrophy
- Cardiac enzymes

Management

In order to relieve respiratory distress, oxygen therapy should be started immediately. Intravenous fluids must be stopped to allow redistribution of fluid into the intravascular space from pleural and peritoneal cavities. This enables dieresis and reverts pleural effusion, thereby decreasing ongoing respiratory distress. Fluids can be stopped when signs of decreased or nil plasma leakage is evident with stable hemodynamic vitals including systolic blood pressure, normal pulse pressure, and adequate peripheral perfusion. Fluid therapy can be stopped when hematocrit levels decrease to baseline with good pulse volume, adequate urine output, and no signs of fever for 24–48 hours.

- IV fluids can be stopped if the patient is maintaining normal blood pressure, pulse pressure, and hematocrit levels after 24–48 hours. If required, oral or intravenous furosemide can be started at 0.1–0.5 mg/kg/dose once or twice daily or an infusion of 0.1 mg/kg/h. Evaluate serum potassium levels and treat any abnormalities mainly ongoing hypokalemia.
- In case a patient is maintaining stable vitals during the first 24–48 hours, it is advisable to regulate the intravenous fluids according to the patient's response. Gradual and timely tapering of fluids must be followed. Avoid use of diuretics during this period as they cause decrease in intravascular volume.
- Patients with unstable vitals and persistent decreased hematocrit levels elicit signs of occult bleeding. Immediately start fresh whole blood transfusion at an adequate rate.
- Patients with unstable vital signs and elevated hematocrit levels should obtain small doses of bolus of colloid fluid solution.

SUMMARY

Over the past 50 years the world has seen large increases in the rates of dengue fever. Dengue fever is a mosquito-borne infection caused by the dengue virus commonly a disease of the tropics and subtropics geographic area and many cases are diagnosed among returning travelers in all areas of the world. Symptoms include fever, headache, muscle and joint pains, and a characteristic skin rash. Sometimes the disease may progress into life-threatening dengue hemorrhagic fever, which manifests as bleeding, thrombocytopenia, and leakage of blood plasma, or into dengue shock syndrome, in which life-threatening hypotension occurs.

Most cases can be managed by supportive therapy with oral rehydration and close follow-up. Judicious use of intravenous fluids is required to maintain perfusion and sufficient urinary output. Dengue may progress to severe disease requiring blood transfusions and admission for intensive care. Prevention currently depends upon reducing the habitat of the vector; *Aedes aegypti*, and avoiding its bite. Habitat reduction involves decreasing mosquitoes access to stagnant bodies of water or, if that is not possible, applying insecticide. While efforts are being made to develop a vaccine.

190
CHAPTER

Malaria

Sahanya Ramesh Shetty, Neeraj Mangla, Devendra Richhariya

INTRODUCTION

Malaria is a parasitic infection that is preventable and treatable. In some cases, severe malaria progresses into cerebral malaria and sometimes death. Malaria is a clinical condition affecting the immune system causing hemolytic changes in systemic circulation. Malaria has been a major disease affecting large sections of society for a long time. Reference to protozoan infections can be traced back to writings from Hippocrates and numerous mythological and biblical passages. The main objective of treatment includes the removal of the parasite from the patient's blood rapidly and effectively. This will further help in prevention of progression of the disease and its severity. Complete cure is not determined; however, early prevention and diagnosis can provide aid in recovery and complete remission. Some critical cases, due to lack of medical care attained, may progress to uncomplicated malaria and to severe disease or death. In chronic states of long-standing malaria, due to prevalent malarial transmission around, malaria-related anemia develops. Although treatment is definitive and clear, malaria has been a cause of serious concern among developing and developed countries.

INCIDENCE

According to the World Health Organization (WHO) studies, there has been a global decline from 71 to 57 cases at risk per 1,000 population at risk during the period of 2010–2018. Between 2014 and 2018, the rate of decline slowed down dramatically reducing to 57 cases per 1,000 population at risk in 2014 and remained at a stagnant level till 2018. However, the Southeast Asian region has shown a fall in incident rate from 17 cases of disease per 1,000 population at risk in 2010 to 5 cases in 2018. This accounted for a total of 70% decrease in the number of malarial cases per 1,000 population. In the African region, the case incidence decreased from 294 in 2010 to 229 in 2018, with a 22% reduction. In the region of Americas, a rise was observed during this period due to increase in malaria transmission in the Bolivarian Republic of Venezuela. During 2015 and 2018, there were only 30 countries which were endemic. This also marked a reduction in case incidence by a large number and progressing to a reduction of 40% or more by 2020. Of the four subtypes, *Plasmodium falciparum* is the most prevalent parasite for malaria in African region, accounting for 99.7% of estimated malarial cases in 2018. In the South-eastern Region, it accounted for 50% of the total malaria cases, 71% in the Eastern Mediterranean Region, and 65% in the Western Pacific Region. In the South-east Asian region, when compared on the global front, there is a huge *Plasmodium vivax* burden with majority being in India at 47%. In the American region, it accounts for 75% cases.

CAUSATIVE AGENT, TYPES, AND LIFE CYCLE

Malaria is caused by protozoa of the genus *Plasmodium*. *Vector*: Mode of transmission is by the bite of a female mosquito of the genus *Anopheles* on humans. It comprises four species that affect the human population:

1. *P. falciparum*
2. *P. vivax*
3. *P. ovale*
4. *P. malariae*

Among the four species of *Plasmodium*, *P. falciparum* and *P. vivax* account for the majority of the cases, of which *P. falciparum* leads to causation of the most severe form of the disease.

Life Cycle

The life cycle of *Plasmodium* incudes two host (mosquito and human) and various stages.

Infective: The uninucleate, lancet-shaped sporozoite (~1 × 7 μm). Sporozoites are produced as a result of sexual reproduction in the midgut of vector *Anopheles* mosquitoes and migrate to the salivary gland. During a blood meal of an infected *Anopheles* mosquito, there is transmission of sporozoites from the saliva of vector to the small blood vessels of the human. On entering the systemic circulation of human (second host), there is uptake of protozoans to liver parenchymal cells. This occurs within 30 minutes of inoculation. After the uptake, the parasite develops into a multinucleate spherical schizont within the liver, comprising 2,000–40,000 uninucleate merozoites. This process is called exoerythrocytic schizogony (liver phase). This period takes 5–21 days and is dependent on the type of *Plasmodium*.

In *P. vivax* and *P. ovale*, the maturation phase can take up to 1–2 years and at this time dormant parasites are called hypnozoites. The life cycle of *Plasmodium* is summarized in **Flowchart 1**. Microscopic features of early trophoblast (*vivax and falciparum*) and mature stages of *vivax and falciparum* are shown in **Figures 1A** and **B**.

PATHOPHYSIOLOGY

The inevitable nature of the mature schizonts results in their eruption and release of large numbers of merozoites into systemic circulation. When the merozoites enter the blood stream, they infect the red cells. There is a development or maturation of merozoites into either an erythrocytic stage schizont or a spherical or banana-shaped uninucleate gametocyte. This mature erythrocytic schizont contains few merozoites. This schizont further ruptures and releases merozoites that further infect other erythrocytes. This enables to determine a time period between the release of merozoites and further infestation of erythrocytes and can help in classic periodicity of fever in malaria. The spherical or banana-shaped gametocyte presents the sexual stage of *Plasmodium*. It is highly infectious when mosquitoes ingest it during their blood meal. During the cycle within the mosquito, gametocytes develop into females (macrogametes) and males (microgametes). They further mature after 2–3 weeks into sporozoites that are infectious to human. It can be concluded that the time interval between development of sporozoites and infection of a mosquito must be 2–3 weeks and that is essential for the mosquito to be alive to infect.

CLINICAL FEATURES

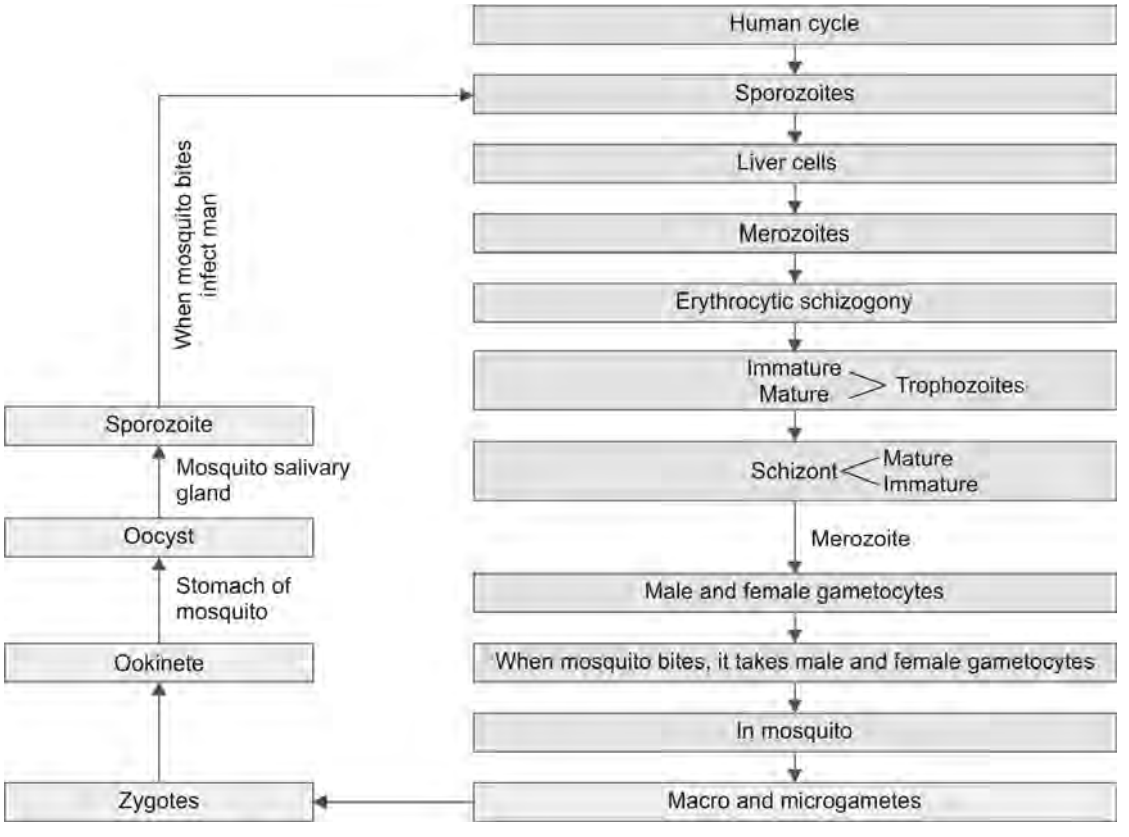
Nonspecific: Lack of sense of well-being, headache, fatigue, abdominal discomfort, muscle ache, nausea, vomiting, and orthostatic hypotension.

Classic malaria paroxysm: Fever spikes with chills and rigors at a regular interval (often >40°C). Other than fever, there are many clinical features such as mild anemia and splenic enlargement (splenic enlargement is common in otherwise healthy people living in malaria-endemic areas; it reflects repeated infection). Mild jaundice common in uncomplicated malaria resolves in 1–3 weeks.

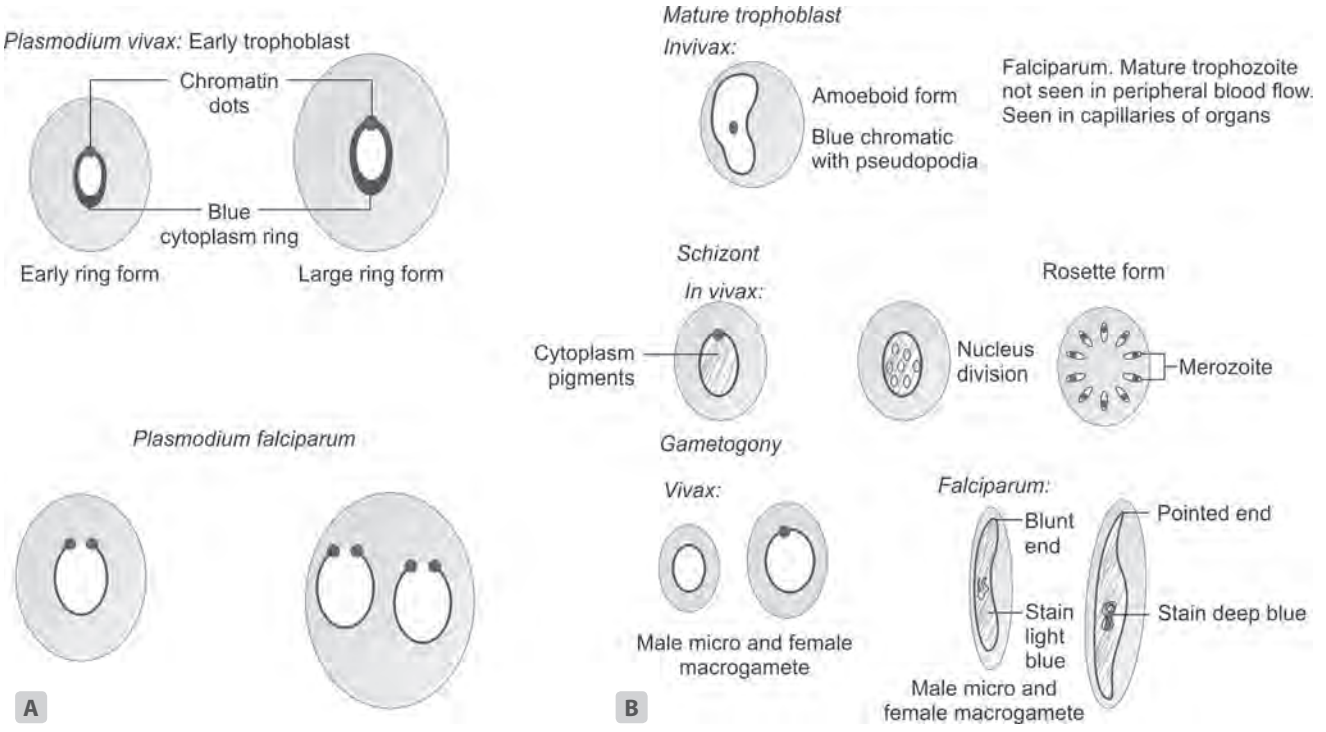
Severe falciparum malaria: Criteria for defining severe malaria are: unarousable coma (cerebral malaria), acidosis, severe normochromic normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome (ARDS), hypoglycemia, hypotension, shock, disseminated intravascular coagulation (DIC), convulsion, hemoglobinuria, others (hyperparasitemia-parasitemia >5%), jaundice (serum bilirubin >3 mg/dL). Clinical features of malaria are summarized in **Table 1**.

INVESTIGATION AND DIAGNOSIS

A large spectrum of diseases are present in differential diagnosis of febrile illness. One must always consider the possibility of malaria in patients with a history of travel even if the patient has been on prophylaxis for malaria. This can help reduce the morbidity and mortality rates in patients with



FLOWCHART 1: Life cycle of *Plasmodium*.



FIGS. 1A AND B: (A) Microscopic features of early trophoblast (*vivax* and *falciparum*); (B) Mature stages of *vivax* and *falciparum*.

TABLE 1: Clinical features of malaria.

Type of malaria	*Uncomplicated malaria*	*Severe malaria*	*Malaria relapses*
	Classical (but rarely observed) malaria attack lasts for 6–10 h	Severe malaria is a medical emergency and should be treated urgently and aggressively. It occurs when infections are complicated by serious organ failures or abnormalities in the patient's blood or metabolism	In *P. vivax* and *P. ovale* infections, patients having recovered from the first episode of illness may suffer several additional attacks ("relapses") after months or even years without symptoms. Relapses occur because *P. vivax* and *P. ovale* have dormant liver stage parasites ("hypnozoites") that may reactivate. Treatment to reduce the chance of such relapses is available and should follow treatment of the first attack
Stages of febrile illness	• A cold stage (sensation of cold, shivering) • A hot stage (fever, headaches, vomiting, seizures in young children) • Finally a sweating stage (sweats, return to normal temperature, tiredness)		
Clinical presentation	• Fever • Chills • Sweats • Headaches • Nausea and vomiting • Body aches • General malaise	Cerebral malaria, with abnormal behavior, impairment of consciousness, seizures, coma, or other neurologic abnormalities	Neurologic defects may occasionally persist following cerebral malaria, especially in children. Such defects include trouble with movements (ataxia), palsies, speech difficulties, deafness, and blindness

Continued

Continued

Type of malaria	*Uncomplicated malaria*	*Severe malaria*	*Malaria relapses*
Physical findings	• Elevated temperatures • Perspiration • Weakness • Enlarged spleen • Mild jaundice • Enlargement of the liver • Increased respiratory rate	• Cerebral malaria, with abnormal behavior, impairment of consciousness, seizures, coma, or other neurologic abnormalities • *Severe anemia* due to hemolysis (destruction of the red blood cells) • *Hemoglobinuria* (hemoglobin in the urine) due to hemolysis • *Acute respiratory distress syndrome* (ARDS), an inflammatory reaction in the lungs that inhibits oxygen exchange, which may occur even after the parasite counts have decreased in response to treatment • *Abnormalities in blood coagulation* • *Low blood pressure* caused by cardiovascular collapse • *Acute kidney injury* • *Hyperparasitemia*, where more than 5% of the red blood cells are infected by malaria parasites • *Metabolic acidosis* (excessive acidity in the blood and tissue fluids), often in association with hypoglycemia • *Hypoglycemia* (low blood glucose). Hypoglycemia may also occur in pregnant women with uncomplicated malaria or after treatment with quinine	• Recurrent infections with *P. falciparum* may result in severe anemia • Malaria during pregnancy (especially *P. falciparum*) may cause severe disease in the mother and may lead to premature delivery or delivery of a low birth weight baby • On rare occasions, *P. vivax* malaria can cause rupture of the spleen • *Nephrotic syndrome* (a chronic, severe kidney disease) can result from chronic or repeated infections with *P. malariae* • *Hyper-reactive malarial splenomegaly* (also called "tropical splenomegaly syndrome") occurs infrequently and is attributed to an abnormal immune response to repeated malarial infections. The disease is marked by a very enlarged spleen and liver, abnormal immunologic findings, anemia, and a susceptibility to other infections (such as skin or respiratory infections)
Diagnosis	Demonstration of parasites in the blood, usually by microscopy. Additional laboratory findings may include mild anemia, mild decrease in blood platelets (thrombocytopenia), elevation of bilirubin, and elevation of aminotransferases		

a decreased immune response, such as children, pregnant women, or patients undergoing chemotherapy. Complete history and primary evaluation are essential to determine the source or route of transmission. *There is often a confusion between P. knowlesi and P. falciparum or P. malariae* at different stages. Clinical correlation is helpful in these stages as *P. malariae* infection is not generally severe and may cause only uncomplicated malaria. However, *P. falciparum* and *P. knowlesi* are determinants of severe malaria. According to updates from the National Vector Borne Disease Control Programme (NVBDCP), India, it is recommended to start the first loading dose of chloroquine only for the areas where neither microscopy nor rapid drug test is available for the first 24 hours.

Diagnosis of malaria is based on clinical suspicion and laboratory confirmation of parasitemia and microscopic examination of peripheral blood smear (PBS). Confirmation is done by thin and thick film (more reliable when parasitemia is very low). Nothing is found better than direct examination of smear, but it is time consuming, needs infrastructure, and single negative PBS cannot rule out malaria. To improve the measures for diagnosing malaria, various rapid diagnostic testing are available for malaria (**Table 2**).

TABLE 2: Rapid diagnostic tests for malaria.

Microscopic methods	• Acridine orange staining • QBC testing
Molecular methods	• DNA and rRNA probes • Polymerase chain reaction (PCR)
Antigen detection	• HRP2 antigen detection • Parasite F test • Parasite LDH detection
Other methods	• Immunochromatographic test

(HRP2: histidine-rich protein 2; LDH: lactate dehydrogenase; PCR: polymerase chain reaction; QBC: quantitative buffy coat)

TREATMENT OF UNCOMPLICATED MALARIA

Mostly early intervention and treatment have proven to improve the prognosis of the patient (**Table 3**).

P. vivax: Chloroquine for 3 days followed by primaquine (PQ) for 2 weeks. PQ is contraindicated in infants, patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, and pregnant women. Ask patients to watch out for dark-colored urine or hematuria, discoloration of peripheries, and any signs of cyanosis. In such events, primaquine must be withheld.

Treatment of *P. vivax* Malaria

The drug schedule for treatment of *P. vivax* malaria is as follows:

- *Chloroquine*: 25 mg/kg body weight divided over 3 days, i.e., 10 mg/kg on day 1, 10 mg/kg on day 2, and 5 mg/kg on day 3.
- *Primaquine*: 0.25 mg/kg body weight daily for 14 days. PQ is contraindicated in infants, pregnant women, and individuals with G6PD deficiency. A 14-day regimen of PQ should be given under supervision.

Treatment of *Plasmodium falciparum*

Treatment involves a combination of artesunate (AS) for 3 days with sulfadoxine–pyrimethamine (SP) for 1 day. In addition, a single dose of PQ is added on day 2.

Artemisinin-based combination therapy with sulfadoxine–pyrimethamine (ACT-SP): Artesunate (AS), available as 50-mg tablet, is given for 3 days, and SP tablets, containing 500-mg sulfadoxine and 25-mg pyrimethamine, are given for 1 day. In addition, PQ large tablets should be given on the second day. ACT-SP—AS 4 mg/kg body weight daily for 3 days plus sulfadoxine (25 mg/kg body weight) and pyrimethamine 1.25 mg/kg body weight on the first day.

Pregnant women with uncomplicated *P. falciparum* should be treated as follows:

- *First trimester*: Quinine—quinine salt 10 mg/kg, three times daily for 7 days; pregnant female should eat regularly, to avoid hypoglycemia while on quinine treatment. Artesunate-based combination therapy is not to be given in the first trimester of pregnancy.
- *Second and third trimesters*: Artesunate-based combination therapy is indicative.

Note: PQ is contraindicated in pregnant woman. In cases where timely diagnosis of malaria and/or rapid diagnostic testing, suspected cases of malaria are to be treated with a course of chloroquine, until confirmatory reports are awaited. In the North-Eastern states of India, it is recommended to use co-formulation of tablet artemether 20 mg and lumefantrine 120 mg as per the age-specific dose schedule. It is recommended to use the co-formulated tablet of artemether (20 mg) and lumefantrine (120 mg) (ACT-AL) as per the age-specific dose schedule.

Treatment of Mixed Infections

P. vivax + *P. falciparum cases*: All mixed infections should be treated with a full course of ACT and PQ 0.25 mg/kg body weight daily for 14 days. In the north-eastern states, treat with age-specific ACT-AL for 3 days + PQ 0.25 mg/kg body weight daily for 14 days. In other states: ACT-SP for 3 days + PQ 0.25 mg/kg body weight daily for 14 days.

Treatment of P. ovale and P. malariae: In India, these species are very rarely found in few places. *P. ovale* should be treated as *P. vivax*, and *P. malariae* should be treated as *P. falciparum*.

Treatment of mixed infections: All cases of mixed infection are to be treated as *P. falciparum* as per the drug policy applicable in the area plus PQ for 14 days.

TABLE 3: Summary of treatment of malaria.

Drug-sensitive malaria		
	Oral treatment for uncomplicated malaria	Parenteral treatment for severe malaria
Chloroquine	10-mg base/kg followed by 5 mg/kg at 12, 24, 36 hours. Total 25 mg/kg. Add primaquine 0.25 mg/kg or 15 mg/day for 14 days for radical cure	3.5 mg/base/kg IM or subcutaneously every 6 h. Total dose 25 mg/kg
Sulfadoxine– pyrimethamine	• 20 mg/kg sulfadoxine, 1 mg/kg pyrimethamine (single oral dose—three tablets) • 1 tablet = 500 mg sulfadoxine + 25 mg pyrimethamine	
Drugs-resistant malaria		
Mefloquine	15 mg/kg single dose, second dose 10 mg/kg	
Quinine	10 mg/kg every 8 hourly with tetracycline 4 mg/kg QID or doxycycline 3 mg/kg OD for 7 days	20 mg/kg IV loading dose over 4 h followed by 10 mg/kg over 2–8 hours every 8 hourly
Artesunate	In combination with total 25 mg of mefloquine per kg, give a total of 10–12 mg/kg in divided doses over 3–5 days	2.4 mg/kg IM or IV followed by 1 mg/kg. Artesunic acid 1 ampoule = 60 mg dissolved in 5% dextrose given by IV/IM bolus
Artemether	Orally the same regimen as artesunate	3.2 mg/kg IM. Then 1.6 mg/kg daily, not to be given IV (1 ampoule = 80 mg)
Halofantrine	8 mg/kg repeated at 6 and 12 h, repeat regimen 1 week later in an immunodeficient patient	

Drug Resistance

Drug resistance is the ability of a parasite stain to survive or multiply despite administration and absorption of drugs given in the doses equal to or higher than those recommended but in the limit of the tolerance of the subject.

WHO Grading of Drug Resistance

- Sensitive—clearance of parasitemia within 7 days of initiation of therapy.
- Low grade—clearance of parasitemia with recrudescence.
- High grade (R-I)—75% but <100% parasites are clear within 7 days of initiation of therapy.
  High grade (R-II)—parasite count does not fall by >75%.

Drug failure: Absence of drug action after administration of a normally effective dose caused by improper ingestion or deficient absorption or unusual rate of rapid excretion.

RADICAL TREATMENT

Radical treatment: Radical treatment is primaquine administration to all confirmed cases of malaria. Tissue schizonticidal activity of primaquine therapy (a 2-week therapy in *P. vivax* malaria) completely cures the infection in the host and thereby prevents relapses. A single dose of primaquine destroys the gametocytes in *P. falciparum* malaria, thereby preventing the spread of the infection into the mosquito.

All proven cases of malaria (a 2-week course in *P. vivax* malaria and a single dose in *P. falciparum* malaria) should be given primaquine. In the event of uncomplicated cases of *P. falciparum* and *P. vivax* malaria, it is preferred to follow treatment per orally. Hence, it is imperative that primaquine is started in all proven cases of malaria. It is advisable to maintain a 2-week course for *P. vivax* malaria and a single-dose therapy in *P. falciparum* malaria.

CHEMOPROPHYLAXIS TO TRAVELERS

Travelers who are planning to visit a malaria-endemic area should start taking an antimalarial drug 1 week before departure and continue for 4 weeks after leaving the endemic area. Recommended prophylactic drugs depend on the knowledge of the local pattern of *Plasmodium* drug sensitivity. Chemoprophylaxis is never entirely reliable. Malaria should be taken into consideration as a differential diagnosis of fever in a patient who has traveled to an endemic area and even if he/she has been taking prophylaxis. Mefloquine remains the prophylactic agent of choice. Doxycycline (can be used in <8 years and in pregnant women) and atovaquone + proguanil combination are used as an alternative to mefloquine. Chloroquine remains the drug of choice in preventing drug-sensitive malaria. It is safe in pregnancy also. Pregnant women should avoid traveling to an endemic area (chloroquine or proguanil or intermittent SP):

- Chloroquine—300-mg base (500 mg salt) orally once a week
- Mefloquine—228-mg base (250 mg salt) orally once a week
- Doxycycline—100 mg orally once a day
- Primaquine—start only after testing G6PD deficiency 15 mg base daily for 14 days
- Atovaquone + proguanil 250/100 mg once daily
- Pyrimethamine-sulfadoxine—in areas of chloroquine-resistant malaria. Three tablets single dose (75 mg + 1,500 mg).

TREATMENT OF SEVERE MALARIA

Severe malaria is considered an emergency, and treatment should be started as per the severity and associated complications which can be best decided by the treating physicians. A blood smear sample should be taken. Give a parenteral dose of artemisinin derivative or quinine in suspected severe/cerebral malaria cases before admitting or referring patients, and send the case sheet, details of treatment history, and blood slide with the patient to the higher center. Parenteral artemisinin derivatives or quinine should be used irrespective of the chloroquine-resistance status of the area with one of the options given in **Box 1**. After parenteral artemisinin therapy, patients should receive a full course of oral artesunin-based combination therapy for 3 days. After parenteral quinine therapy, the patient should continue with oral quinine 10 mg/kg body weight three times a day for 7 days plus doxycycline 3 mg/kg

BOX 1: Treatment of severe malaria.

Initial parenteral treatment for at least 48 hours: Choose one of the following four options:

1. *Quinine*: 20-mg quinine salt/kg body weight on admission (IV infusion or divided IM injection) followed by a maintenance dose of 10 mg/kg 8 hourly; the infusion rate should not exceed 5 mg/kg/h. Loading dose of 20 mg/kg should not be given, if the patient has already received quinine
2. *Artesunate*: 2.4 mg/kg IV or IM given on admission (time = 0), then at 12 h and 24 h, then once a day or
3. *Artemether*: 3.2 mg/kg IM given on admission, then 1.6 mg/kg per day or
4. *Arteether*: 150 mg daily IM for 3 days in adults only (not recommended for children)

Supportive treatment:

- Plasma exchange
- Measure blood sugar every 4–6 hourly
- Parasite count and hematocrit every 6–12 hourly
- Blood transfusion
- Management of fluid balance

Follow-up treatment, when the patient can take oral medication following parenteral treatment:

- Quinine 10 mg/kg three times a day with doxycycline 100 mg once a day or clindamycin in pregnant women and children under 8 years of age, to complete 7 days of treatment
- Full oral course of area-specific ACT
- *In north-eastern states*: Age-specific ACT-AL for 3 days + PQ single dose on the second day
- *In other states*: Treat with ACT-SP for 3 days + PQ single dose on the second day

(ACT-AL: co-formulated tablet of artemether and lumefantrine; ACT-SP: artemisinin-based combination therapy with sulfadoxine–pyrimethamine; PQ: primaquine)

body weight once a day or clindamycin 10 mg/kg body weight 12-hourly for 7 days (doxycycline is contraindicated in pregnant women and children under 8 years of age). Pregnant women (any trimester) of severe malaria can be treated with artemisinin derivatives (do not have a risk of hypoglycemia like quinine). Continue with parenteral treatment for a minimum of 48 hours and then switch to oral therapy (if the patient accepts orally). Mefloquine is associated with neuropsychiatric complications and should be avoided in cerebral malaria.

CHRONIC COMPLICATIONS OF MALARIA

Tropical splenomegaly (Hyperreactive malarial splenomegaly)—chronic and repeated malaria infection causes splenomegaly and hepatomegaly, and the patient presents with abdominal mass and dragging sensation of abdomen. Sharp abdominal pain is suggestive of peri-splenitis. Anemia and pancytopenia in blood picture is significant findings. The patient is vulnerable to respiratory and skin infections.

Quartan malaria nephropathy—chronic and repeated malaria infection by *P. malariae* gives rise to an immune complex-mediated injury to renal glomeruli and histologically presents as focal and segmental glomerulonephritis with a slit in the capillary basement membrane.

Burkitt's lymphoma and Epstein–Barr virus (EBV) infection—immunosuppression induced by malaria infection may give rise to infections of lymphoma virus. Burkitt's lymphoma is strongly associated with EBV infection.

CEREBRAL MALARIA

Cerebral malaria is a manifestation of severe falciparum malaria. The condition is described in *P. vivax* or mixed infection of *P. falciparum* and *P. vivax*. Incidences are increasing in India in the areas (northeast region, Gujarat, Andaman, and Rajasthan) where chloroquine-resistant malaria is highly prevalent. Three benign forms of malaria—*vivax*, *ovale*, and *malariae*—invade only old red cells and reticulocytes and are able to produce parasitemia not >2%. On the other hand, *falciparum* invades/infects erythrocytes of all ages. A high level of parasitemia and a large number of merozoites are released to infect hepatocytes. In *falciparum* malaria, only younger ring forms are present in peripheral blood. Other stages of life cycle remain sequestrated in the internal organ of body (escape the host defense mechanism). Thus, severe and complicated malaria is produced only by *P. falciparum*.

Criteria for Diagnosing Cerebral Malaria

Unarousable coma after exclusion of encephalitis and bacterial meningitis: Persistence of coma for >6 hours after generalized seizure and confirmation of *P. falciparum* parasitemia, along with the presence of features of severe malaria, such as severe normocytic anemia, hemoglobin < 9 g, parasitemia > 10,000/μ, renal failure, pulmonary edema, circulatory collapse, DIC, metabolic acidosis, and hemoglobinuria. Partial or generalized tonic-clonic seizures (GTCS) are common. Whenever cerebral malaria is suspected, confirm with parasitological diagnosis. Cerebral malaria can be suspected even if PBS is negative. Presence of malaria pigments in monocytes is a useful indicator of diagnosis of malaria, especially in the absence of peripheral parasitemia and in an anemic child. In a patient with severe *falciparum* malaria, >2% of total erythrocytes are parasitized.

Neuro-ophthalmological Signs in Cerebral Malaria

Disorders of conjugate gaze nystagmus are common findings. Papilledema is rare. Corneal and conjunctival reflexes remain intact. Pupils are symmetrical and react to light. Motor system examination findings—upper motor signs, increase in muscle tone and deep tendon reflexes, and presence of patellar and ankle clonus—are observed. In advanced stages, opisthotonos posturing may be observed; posturing may be decerebrate or decorticate. Deep breathing hypoventilation with extensor posturing with periodic respiration features is suggestive of transtentorial herniation. Other commonly associated conditions are summarized in **Box 2**. The mortality rate for severe malaria and cerebral malaria is high (15–20%); deep coma is an important indicator for adverse prognosis. Other prognostic indicators are given in **Table 4**. The patients who survived developed long-standing neurological sequelae and postmalaria neurological syndrome (**Table 5**).

BOX 2: Common associated conditions with severe and cerebral malaria and suggested antimalarial drugs.

Commonly associated conditions:

- Hypoglycemia
- Raised intracranial pressure
- Anemia
- Lactic acidosis
- Hypoxia
- Renal failure
- Bleeding disorders
- Chest infections
- Gram negative sepsis

Associated systemic complications and their management:

- Blood transfusion/blood products for anemia, coagulopathy
- Correction of hypovolemia for shock
- Paracetamol sponging fanning for hyperpyrexia
- Dialysis for renal failure
- Bolus glucose followed by infusion for persistent hypoglycemia
- Fluid and electrolyte maintenance
- Fluid restriction and diuretics for pulmonary edema

Suggested antimalarial and doses:

- *Quinine*: 20 mg/kg bolus infusion over 4–6 h followed by 10 mg/kg IV (over 6 h) every 8 hourly
- *Artesunate*: 2.4 mg/kg IV or IM given on admission (time = 0), then at 12 and 24 h, then once a day
- *Artemether*: 3.2 mg/kg IM given on admission, then 1.6 mg/kg per day for 6 days
- *Quinidine*: 10 mg/kg IV over 1 hour followed by 0.1 mg/kg/min IV with ECG monitoring

TABLE 4: Poor prognostic indicators or cerebral malaria.	
Clinical indicators of poor prognosis	• Deep coma • Repeated convulsion • Absent corneal reflexes • Decerebrate rigidity • Organ dysfunction • Retinal hemorrhage • Age < 3 years
Laboratory indicators of poor prognosis	• Parasitemia > 5% • Peripheral schizonts • Leukocytosis • PCV < 20% • Anemia < 7 g • Hypoglycemia < 40 mg • BUN > 60 mg/dL • Total bilirubin > 2.5 • Aminotransferases >3 times

(BUN: blood urea nitrogen; PCV: pneumococcal conjugate vaccine)

TABLE 5: Neurologic sequelae of cerebral malaria.	
Neurologic sequelae	• Hemiplegia • Cortical blindness • Aphasia • Ataxia • Tremors • Hearing defect • Repeated convulsion • Behavioral abnormalities • Spastic quadriplegia
Postmalarial neurologic syndrome	• Acute confusional state or psychosis • Generalized seizures • Action and/or postural tremors • Delayed and self-limiting cerebral ataxia • Severe steroid-responsive encephalopathy • Motor aphasia • Generalized myoclonus • Cerebral ataxia

SUMMARY

Malaria has been a cause of serious concern among developing and developed countries. It has been a major disease affecting large sections of society for a long time. Malaria is a parasitic infection that is preventable and treatable. Treatment is definitive and clear. The main objective of treatment includes the removal of the parasite from the patient's blood rapidly and effectively. This will further help in prevention of progression of the disease and its severity. Early prevention and diagnosis can provide aid in recovery and complete remission. Clinically, malaria damages the immune system. In some cases, severe malaria progresses into cerebral malaria and sometimes death. In some cases, it may progress to severe categories due to lack of medical care and may progress to complicated malaria and to severe disease or death. In chronic states of long-standing malaria, due to prevalent malarial transmission around, malaria-related anemia can develop.

191
CHAPTER

Tuberculosis

Suman Thakur, Vivek Chauhan

INTRODUCTION

Tuberculosis (TB) tops the list of infections that cause death and is also listed among top 10 causes of death worldwide. More than one-third of the world's population has had TB infection, but disease and death occurs disproportionately in those who are immunocompromised and at extremes of the age spectrum. Rest of the infected but immunocompetent population harbors TB in dormant or latent form for many years. TB can produce disease in any organ of the body and thus has innumerous manifestations. In emergency room (ER), TB can present with acute or chronic manifestations involving almost any organ or system. Therefore, in high-burden countries like India, TB always remains a possibility, either primary or an underlying cause, in all patients. An intelligent and focused investigation often reveals the underlying infection by TB and the newer diagnostic methods have made it possible to diagnose TB in a matter of few hours. If treated before it causes significant damage to the organs or systems, it is curable but the emergence of resistance in TB bacillus to the first- and second-line drugs is a great cause of concern throughout the world.

ETIOLOGY/CAUSES

The agent causing TB is *Mycobacterium tuberculosis* (*Mtb*) an acid-fast bacillus (**Box 1**) and humans are the only natural host for *Mtb*. It is an obligate aerobe and survives in humans by disseminating and then lying dormant in organs with high blood flow and oxygen concentration such as lungs, renal cortices, meninges, vertebrae, and epiphyses of long bones for many years.

BOX 1: Etiological agent for tuberculosis.

Etiological agent: Tuberculosis
Domain: Bacteria
Phylum: Actinobacteria
Class: Actinobacteria
Order: Actinomycetales
Family: Mycobacteriaceae
Genus: Mycobacterium
Species: Mycobacterium tuberculosis

PATHOPHYSIOLOGY

Mycobacterium tuberculosis has developed mechanisms to survive within humans by evading the immune response and lie dormant in humans waiting patiently for decades for an opportunity to overcome the immune system and then spread to the other human hosts. *Mtb* enters the macrophages and alters its functions to survive and replicate inside macrophages. The natural history of TB in humans has four phases; replication, dissemination, latency, and reactivation.

In most humans, the cell-mediated immunity quickly controls the replicating *Mtb* and surrounds them forming "granulomas" or "tubercles". Some of the *Mtb* reach local lymph nodes where also they get surrounded by immune cells. The caseation, necrosis, and calcification is called *"Ghon foci"* while the area of primary scarring and calcification along with the calcified hilar lymph nodes produces what is called the *"Ghon complex"*.

Spread is initiated when *Mtb* proliferates in lungs leading to liquefactive necrosis as a result of immune cells trying to contain the *Mtb*. The liquefied material from lungs escapes to the environment in the form of tiny cough droplets containing *Mtb*. Inhalation of infected droplets may establish *Mtb* in the new susceptible hosts. The liquefactive necrosis in various organs can occur either during primary infection called primary TB or when *Mtb* reactivates after a latent period of dormancy called secondary TB.

CLINICAL PRESENTATION

Mycobacterium tuberculosis can get disseminated widely through infected macrophages and thus can produce disease in any organ or system. Still, the most common organ to develop disease is the lungs because of their higher oxygen content and blood flow. The classical presentation is pulmonary TB (PTB) presenting with prolonged fever (evening rise), productive cough, hemoptysis, night sweats, weight loss, fatigue, and malaise.

TABLE 1: Common extrapulmonary tuberculosis.	
Effusions	Pleural, ascitic, joint, and pericardial
Neurological	Meninges, brain parenchyma, and spinal cord
Musculoskeletal	Bones, joints, muscles, and vertebrae
Urogenital	Kidneys, ureters, bladder, and genital organs
Abdominal	Intestinal, peritoneal, esophageal, mesenteric, and hepatobiliary
Lymphatic	Lymph nodes, splenic, bone marrow, thymic ophthalmological, otorhinolaryngeal, and dermatological

Equally important is the common extrapulmonary tuberculosis (EPTB) presenting as **Table 1**. The clinical presentation of EPTB will be organ specific. The EPTB patients are mostly noncontagious, still they have a high morbidity and mortality and are more likely to present with varied complications in the ER. Early recognition and treatment of classical PTB is important from public health perspective, but diagnosis and treatment of EPTB is also important from the patient's perspective.

Features of Concern (Red Flags)

Although TB requires prompt treatment in all patients, but the following are particularly aggressive presentations of TB where a delay in diagnosis can lead to quick loss of life or organs:

Meningoencephalitis (severe new-onset headache and altered sensorium), vertebrospinal (paraparesis), pericarditis (chest pain, elevated jugular pressure, and hypotension), endocarditis (murmurs and continuous high grade fever), and miliary TB (multiple organ dysfunction), PTB with destroyed lungs (hemoptysis and respiratory failure), and ocular TB (loss of vision).

EVALUATION

History

Salient features in history suggestive of TB include any one or more of the following: Cough persisting for >2 weeks, pyrexia of unknown origin >1 week, any episode of hemoptysis, night sweats, and weight loss. Patients with EPTB will have organ-specific complaints and are often missed in initial analysis. Genital TB in females is an important cause of primary infertility. "Night cries" are typically reported in vertebral TB. The tone of paravertebral muscles decreases during sleep and the resulting movement of vertebrae causes intense pain at night. A high index of suspicion and careful examination followed by focused investigation often reveals the underlying diagnosis of EPTB.

Physical Examination

Whenever a diagnosis of PTB is considered, it is advisable to avoid close contact during examination. Patient should be given a triple layer mask and focused examination to record the vitals and provision of necessary supportive care is needed. EPTB is mostly noncontagious and detailed examination should be done. Elicitation of signs in neurotuberculosis helps localize the lesion in brain, meninges, or spinal cord. Similarly bone and joint TB.

Interpretation of Findings

Some specific physical examination findings that should prompt workup for EPTB include matted cervical lymph nodes (more common in young), unilateral pleural effusion (all ages), ascites (in young), meningitis (all ages), blackish discoloration of skin suggestive of adrenal TB, nonhealing ulcers on skin and mucosa (all ages), abdominal lump (intestinal or mesenteric TB), boggy swelling below umbilicus (psoas abscess), vertebral tenderness with deformity (vertebral TB), blurry vision with red eye or headache (ocular TB), and muffled heart sounds with raised jugular venous pressure (pericardial TB).

INVESTIGATIONS

Diagnosis of Pulmonary Tuberculosis

Since PTB is the most common form and is also responsible for spread of TB in community, it should be diagnosed and treated promptly. Properly collected sputum is used for diagnosis.

Ziehl–Neelsen (ZN) staining is the cheapest method to diagnose TB with the help of an acid-fast stain and a microscope. ZN staining has low sensitivity if bacillary load is <10,000/mL in the sample, so may come false negative in cases that have intermittent shedding of bacilli.

Better staining methods include fluorescent stain (auramine-rhodamine) to detect *Mtb* under fluorescent microscope and is easier to screen large number of samples in a shorter time. Fluorescent microscopy is a better screening tool but can give false positives, so all fluorescence positive samples should be confirmed using ZN staining, culture, or nucleic acid amplification methods.

Cartridge-based nucleic acid amplification tests (CBNAATs) have been developed and are in wide use. They have very high sensitivity and low turnaround time of 2 hours. CBNAAT results are positive at a bacillary load of 131 bacilli/mL. CBNAAT is better than microscopy as it gives diagnosis of TB and rifampicin resistance in the same process and it also has higher sensitivity at low bacillary loads.

Culture methods are the gold standard for diagnosis of TB as they can come positive at 10–100 bacilli/mL, but the turnaround time for cultures is high. Solid cultures show *Mtb* growth at 6–8 weeks and liquid cultures show *Mtb* growth earliest at 12–18 days. Cultures must be done in all cases as they help us in doing drug sensitivity analysis and diagnose drug resistant TB.

Chest X-ray

Some patients of PTB do not shed bacilli but have clinical symptoms and lesions on chest X-ray suggestive of PTB. Findings on chest X-ray that have high likelihood of PTB include cavitary lesions that are most common in upper lobes (**Fig. 1**), but can occur anywhere in the lungs and military TB showing small <3 mm nodules in all lung fields. Chest X-ray showing fibrosis in upper lobes suggest old healed PTB.

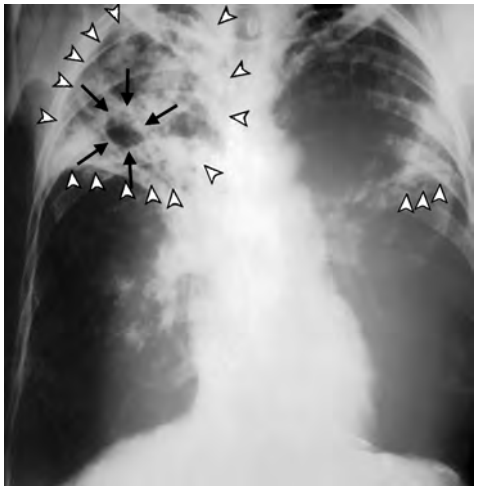

FIG. 1: Chest X-ray showing typical lesions (cavity) in pulmonary tuberculosis involving upper lobes.

Diagnosis of Extrapulmonary Tuberculosis

The samples used for diagnosis of EPTB depend on the site and organ involvement and thus include pus, lymph node aspirate, effusions, tissue, cerebrospinal fluid, urine, synovial fluid, gastric aspirate, and bone marrow.

The methods used to diagnose EPTB are similar to PTB and include ZN staining, fluorescent staining, CBNAAT, and cultures. Since the bacillary load in EPTB samples is not high, CBNAAT has been recommended to be performed in all EPTB samples for a quick diagnosis. CBNAAT can be performed in all samples except urine and blood.

Histopathology

Diagnosis can also be established by examining tissue samples under microscope and presence of caseous necrosis and granulomas on histopathology is highly suggestive of TB.

Imaging in Extrapulmonary Tuberculosis

Radiological investigations such as computed tomography and magnetic resonance imaging has a big role in establishing the diagnosis in many forms of EPTB where bacillary load is less and obtaining sample is not easy, e.g., genitourinary TB, intestinal TB, mesenteric TB, bony TB, suspected tuberculomas, and pericardial effusion.

Adenosine Deaminase in Effusion

If history is suggestive of TB and other causes of effusion are ruled out, presence of elevated levels of adenosine deaminase (ADA) in from pleural or pericardial effusion, ascites, or cerebrospinal fluid is used by many clinicians to establish a diagnosis of EPTB in absence of a definitive diagnosis.

Diagnosis of Latent Tuberculosis

Skin test called *Mantoux test* where we inject 0.1 mL of purified protein derivative intradermally in the forearm and the result is read after 48 and 72 hours by measuring the skin induration at the test site. Induration size of >10 mm is taken as a positive result for Mantoux test, but individuals who have received Bacillus Calmette–Guérin (BCG) immunization for TB prevention are also expected to have positive test. In absence of BCG and active TB, a positive Mantoux test is suggestive of latent TB.

Tuberculosis and Human Immunodeficiency Virus

All patients diagnosed with TB must be worked up for HIV infection. The immune system in HIV-infected individuals does not mount adequate response to TB infection and therefore, the manifestations in these individuals are atypical, e.g., cavitary form of reactivation TB in HIV depends on the CD4 levels and patients with low CD4 levels can have normal chest X-rays with reactivation TB. The Mantoux test is taken as positive at >5 mm induration in HIV-positive patients.

Diabetes and Tuberculosis

All patients of TB must be worked up for diabetes mellitus which is a condition where immune system becomes weak and can lead to reactivation of latent TB.

TREATMENT

Treatment of TB depends upon whether the *Mtb* bacillus is drug sensitive or drug resistant. The drug sensitive forms of *Mtb* infection are treatable using four *primary drugs, i.e., rifampicin (R), isoniazid (H), ethambutol (E), and pyrazinamide (Z)* in a fixed dose combination given on a daily basis for first 2 months followed by rifampicin and isoniazid for next 4 months.

New Case of Tuberculosis

For PTB and most forms of EPTB, 6-month combination therapy 2 (HRZE) + 4 (HRE) of antitubercular [antituberculous treatment (ATT)] drugs is curative unless the *Mtb* is drug resistant. The sputum is tested for presence of *Mtb* at 2 months and at 6 months.

Previously Treated Tuberculosis

Patients who have taken ATT for >1 month in the past and are now diagnosed again with TB. Regimen for treatment of previously treated TB is 2 (HRZES) + 1 (HRZE) + 5 (HRE).

Classification of Resistant Tuberculosis

- *Monodrug-resistant (MR) TB*: Resistance to one of the four first-line drugs H, R, Z, and E
- *Polydrug-resistant (PDR) TB*: Resistance to only one of R or H plus one of Z or E
- *Multidrug-resistant (MDR)TB*: Resistance to both R and H
- *Extensive drug-resistance (XDR):* Resistance to R and H and one of the fluoroquinolones and one of the second-line injectable drugs

If the sputum is found to be resistant to rifampicin at the time of diagnosis using CBNAAT, the sample is then tested using line probe assay (LPA) to detect resistance for both rifampicin and isoniazid. Simultaneously cultures should be established to test sensitivity for second-line drugs. Cultures take few weeks to compete, but LPA can be obtained within hours and can confirm MDR TB.

Treatment of MDR TB includes 6–9 months of intensive phase with injectable kanamycin and oral levofloxacin, ethambutol, pyrazinamide, ethionamide, and cycloserine

followed by 18-month continuation phase with oral levofloxacin, ethambutol, ethionamide, and cycloserine.

Treatment of XDR TB includes 6–12 months of injectable capreomycin, oral moxifloxacin, linezolid, para aminosalicylate, clofazimine, high-dose isoniazid, and co-amoxiclav. The injectables are stopped and 18-month continuation phase contains all other oral drugs.

Bedaquiline and delamanid are new drugs added for drug-resistant TB and have been shown to effectively reduce the total duration of therapy in them.

Additional steroids are needed in some forms of TB, e.g., TB meningitis and pericardial TB.

DISPOSITION

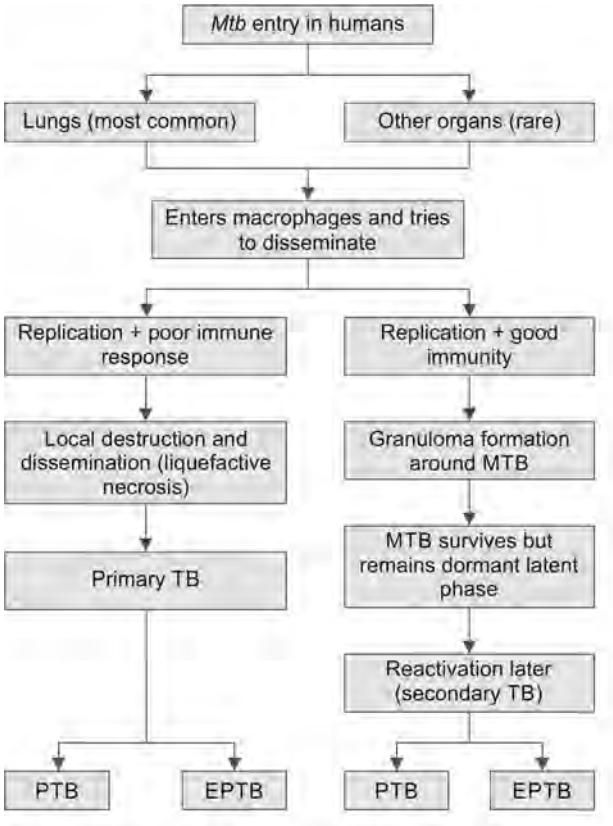
The patients of TB can be diagnosed by two methods:

1. First is by proving the diagnoses using microbiological methods (ZN staining, fluorescent staining, CBNAAT, or culture)
2. Second is clinically diagnosed TB where microbiological diagnosis could not be established. Clinical diagnosis can be based upon history, physical examination, blood investigations, and radiological investigations.

The patients are put on appropriate treatment and then discharged once their condition is stabilized. The duration of ATT should be extended to total 9 months in TB meningitis.

SUMMARY

Tuberculosis is caused by *Mtb* and it is the number one infectious cause of death worldwide. Humans are the only natural host for *Mtb* and its survival mechanism has helped *Mtb* to establish infection in one-fourth of the human population worldwide. In most humans, the infection does not result in disease but the bacillus replicates and disseminates to various organs before the immunity checks its multiplication. The bacillus evades sterilization by the immune system by lying inactive or dormant in multiple organs called latent TB. Later in life when immunity becomes weak, the reactivation TB may occur. To come out of the infected host into the environment, the most common mechanism used by *Mtb* is cough and therefore, lungs are the most commonly infected organs in TB. Liquefactive necrosis in lungs causes cavity formation and the contents of the liquefied parenchyma are expelled out of lungs in cough. These coughed out droplets contain enough bacilli to infect surrounding susceptible hosts. *Mtb* also gets established in various organs during its primary infection which results in EPTB. Almost all organs can show damage due to *Mtb* and is called EPTB. EPTB is an important cause of morbidity and mortality among ER patients. The diagnosis is made after careful history, focused examination, and intelligent investigation. Various methods widely used to detect *Mtb* in human samples include ZN staining, fluorescence microscopy, CBNAAT, and *Mtb* cultures. CBNAAT can detect rifampicin resistance along with the presence of *Mtb* in the samples. LPA can detect rifampicin and isoniazid resistance. To detect resistance to other drugs, we use *Mtb* culture methods but it is takes weeks to months for this process. Diagnosis of TB is not always possible to confirm by microbiological methods and many cases are diagnosed based upon history, physical examination, and investigations like radiology. Once detected the patients should be promptly started on ATT to make them noninfectious. Steroids may be given in addition to the patients of meningitis and pericarditis. The treatment regimen for MDR TB includes one injectable and numerous other second-line drugs and is prolonged for 2–3 years. Newer drugs like bedaquiline and delamanid has reduced the total duration of treatment for up to 1 year in MDR TB. Organ-specific involvements in EPTB need special consideration and red flag signs must be remembered while working in ER so that the diagnosis of TB in life or organ threatening presentations is not missed. **Flowchart 1** summarizes tubercular infection.



Mtb entry in humans
Lungs (most common)
Other organs (rare)
Enters macrophages and tries to disseminate
Replication + poor immune response
Replication + good immunity
Local destruction and dissemination (liquefactive necrosis)
Granuloma formation around MTB
Primary TB
MTB survives but remains dormant latent phase
Reactivation later (secondary TB)
PTB
EPTB
PTB
EPTB
• Diagnosis: Clinical, ZN staining, CBNAAT, and culture or biopsy
• Treatment: Combination chemotherapy
• New case: 6 months 2 HRZE + 4 HRE
• Previously treated case: 2 (HRZES) + 1 (HRZE) + 5 (HRE)

(CBNAAT: cartridge-based nucleic acid amplification test; EPTB: extrapulmonary tuberculosis; MTB: *Mycobacterium tuberculosis*; PTB: pulmonary tuberculosis; TB: tuberculosis; ZN: Ziehl–Neelsen)

FLOWCHART 1: Summary of tuberculosis infection.

CHAPTER

Rabies

Ashok Mishra

INTRODUCTION

Management of animal bite cases is mandatory to protect against the risk of rabies which is an acute fatal encephalomyelitis caused by a ribonucleic acid (RNA) virus under the genus *Lyssavirus* and family Rhabdoviridae. It is the most important viral zoonosis of warm-blooded animals such as dogs, cats, and jackals recognized today because of its global distribution, incidence, veterinary, and human health costs and extremely high-case fatality rate.

Most of the mortality due to rabies is from Asia and Africa with 56% of the deaths estimated to occur in Asia and 44% in Africa. Human rabies is mainly caused by dog bites and annual incidence of bite in India is 1.7%. Human rabies is endemic in India. According to a recent the World Health Organization (WHO) estimate, globally 55,000 deaths occur every year; of these, 20,000 (36%) occur in India. In India, there are 17.4 million exposures to animal bites each year. Rabies is transmitted to man usually by bites or licks of rabid animals.

Rabies now features among the 17 identified neglected tropical diseases (NTDs) by the WHO. The acute viral infection is characterized by inflammation of the central nervous system (CNS). When the disease occurs in man, the most characteristic symptom is fear of water (hydrophobia) which develops due to painful spasms of the muscles of deglutition. Rabies is an extremely dangerous disease with a frequently long incubation period, highly distressing symptoms, and as a rule, a lethal outcome. The violent symptoms associated with the illness and usual inevitability of death make it one of the most terrifying diseases.

Rabies or hydrophobia is probably the oldest recorded infection of mankind. Even today it is as frightening a disease as it was in the past. Sushrut, the famous Indian physician observed this condition in dogs, foxes, etc., which manifests as a state of confusion, drooping of tail and lower jaw, and profuse salivation. He emphasized that this condition was fatal, once clinical symptoms became apparent.

Dr Louis Pasteur in 1885 developed the first antirabies vaccine which was first administered on July 6, 1885 to Joseph Meister, the young boy who had been severely bitten 14 times by a rabid dog. After Jenner and his concept of protection against smallpox, rabies vaccine was the third vaccine developed in history, long before recognition of the nature of viruses.

CURRENT SCENARIO

September 28 is being observed as World Rabies Day. This viral disease which is almost invariably fatal kills 50,000–70,000 people per year. Around the world, rabies kills around 100 children every day because they cannot afford the vaccine. In Africa and Asia alone, the disease threatens 3.3 billion people—just under half the world's population.

More than 99% of all human deaths from rabies occur in the developing world, and rabies still remains a neglected disease throughout most of Asia. Asia accounts for >90% of all rabies deaths with nearly 31,500 deaths and 40–60% of all animal bites occurring in children under 14 years. Dog bites are the primary source of human infection in all rabies endemic countries in the region and account for 96% of human rabies cases. The annual incidence of suspect bites from rabid dogs is 6.5 per million humans in Asia. India, Bangladesh, and Myanmar are high rabies endemic among the Southeast Asian countries. The estimated number of human rabies deaths in Asia is approximately 30,000–40,000 annually (20,000 in India, 2,000 in Bangladesh, and remainder in the rest of Asia).

In India, about 15 million people are bitten by animals, mostly dogs (91.5%) every year and need postexposure prophylaxis (PEP). The incidence of animal bites in 17.4 per 1,000 population. A person in bitten every 2 seconds and someone dies from rabies every 30 minutes. Cats are the second most common source of human rabies exposures in Asia and virus samples collected from Asian rabid cats and other domestic animals revealed only canine street virus strains.

Causative Agent

The causative agent (*Lyssavirus* type 1) is a very small (size 120 × 80 nm), bullet shaped, i.e., round at one end and flat at another, neurotropic RNA-containing virus (**Fig. 1**). The virus is present in the saliva of rabid animals, in the saliva of human rabies patients, and also in the urine in low titers. Upon biting, scratching or licking on broken skin and intact mucous membrane, the virus enters the body, multiplies locally in the tissues and muscles, and then travels to brain at the speed of 3–10 mm/h via neurotropic nerves. There it affects the brainstem function, causing hydrophobia (fear of water), aerophobia (fear of breeze), and/or photophobia (fear of light)

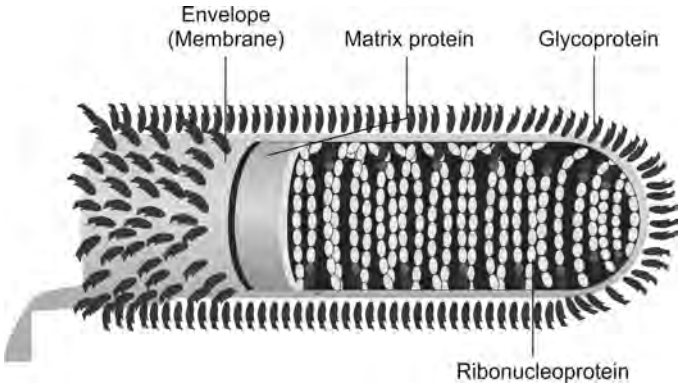

FIG. 1: *Lyssavirus* type 1—causative agent of rabies.

and finally resulting in respiratory paralysis and death. Virus is highly resistant against cold, dryness, and decay, and can remain infectious for weeks in dead bodies.

The virus recovered from naturally occurring cases of rabies is called "street virus". It is pathogenic for all mammals and shows a long variable incubation period (20–60 days in dogs). Serial brain-to-brain passage of the street virus in rabbits modifies the virus such that its incubation period is progressively reduced until it becomes constant between 4 and 6 days. Virus isolated at this stage is called a "fixed virus''. A fixed strain of virus is one that has a short, fixed, and reproducible incubation period (4–6 days) when injected intracerebrally into suitable animals. It does not form Negri bodies. The fixed virus is used in the preparation of antirabies vaccine.

Reservoirs of Infection

Rabies exists in three epidemiological forms.

1. *Urban rabies*: The transfer of infection from wildlife to domestic dogs results in the creation of urban cycle while is maintained by dog and is responsible for 99% of human cases in India. Cats can also be the source of human infection.
2. *Wildlife rabies*: Wildlife or sylvatic rabies is perpetuated by the jackal, fox, hyena, etc. In South Africa, the disease is enzootic in the mongoose. These animals maintain a cycle among themselves and transmit the infection to dogs and domestic animals. Man may contract rabies through intrusion into this wildlife cycle of rabies.
3. *Bat rabies*: In some Latin American countries such as Brazil, Venezuela, Mexico, Trinidad, Tobago, and parts of USA, the vampire bat is an important host and vector of rabies. They can transmit rabies to animals and humans. This form of rabies is responsible for killing hundreds of thousands of cattle annually. Humans are affected while sleeping outdoors. Recently, rabid bats have been found in Germany, Denmark, and Holland but not reported in India. Rabies virus is probably transmitted between vampire bats by either bite or aerosol.

Source of Infection

The source of infection for man is the saliva of rabid animals. In dogs and cats, the virus may be present in the saliva for 3–4 days (occasionally 5–6 days) before the onset of clinical symptoms and during the course of illness till death. Only half of rabid animals have virus in saliva so the probability of getting rabies following the bite of a rabid canine is 50%.

Carrier States

In rare cases, carrier states have also been reported where the animal although apparently healthy, has transmitted the disease.

Host Factors

All warm-blooded animals including man are susceptible to rabies. Incidence of rabies is maximum in children aged <15 years. Bites around head and neck are most dangerous. Veterinary workers, animal handlers, forest staff, hunters, field naturalists, and laboratory staff working with rabies virus are much more vulnerable for exposure to rabies virus.

Mode of Transmission

- *Animal bites*: In India, most of the human rabies cases occur due to bite of a rabid dog. There is also possibility of contracting rabies through the bites of cats, monkey, horses, sheep, goat, etc. As a prerequisite to transmission, the saliva of the biting animal must contain the virus at the time of bite.
- *Licks*: Licks on abraded skin and mucosa (abraded or unabraded) can transmit the disease. In rare instances, the disease may be transmitted through bone splinter or other object contaminated with saliva of a rabid animal.
- *Aerosols*: Aerosol (respiratory) transmission can occur in two ways, either in caves harboring rabid vampire bats or in the laboratory where aerosols created during homogenization of infected animal brains can infect laboratory workers.
- *Person-to-person*: Man-to-man transmission although rare, is possible either through bite by a hydrophobia patient or through corneal or organ transplants.

Incubation Period

The incubation period in man is highly variable, commonly 3–8 weeks following exposure (may be up to 3 months). But it may vary from 4 days to many years.

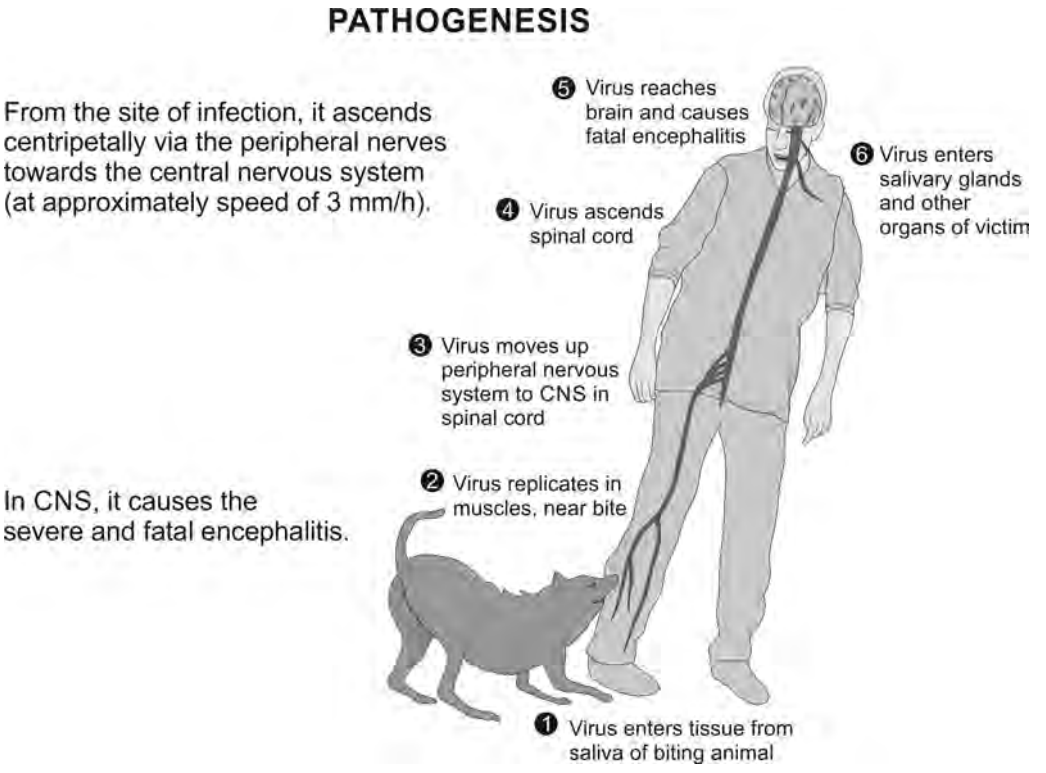
The incubation period depends on number of factors: (i) site of the bite, (ii) severity of the bite, (iii) number of wounds, (iv) amount of virus injected, i.e., virus inoculum, (v) species of the biting animal, (vi) protection provided by clothing, and (vii) treatment undertaken, if any.

In general, incubation period is shorter in severe bites, bites on head and neck region, upper extremities, and also bites by wild animals. In no other communicable disease, the incubation period is not so variable and dependent on so many factors as in rabies.

PATHOGENESIS

The live virus, once introduced through the epidermis or mucous membrane, multiplies and ascends centripetally up the peripheral nerves to the CNS resulting in generalized encephalomyelitis (**Fig. 2**). Once the virus reaches the CNS, it multiplies exclusively in the grey matter and then spreads centrifugally along autonomic nerves to other tissues including salivary glands and cornea.

The pathognomonic lesion is an intracytoplasmic eosinophilic inclusion body commonly known as Negri bodies. These Negri bodies are seen only with infection of



PATHOGENESIS
From the site of infection, it ascends centripetally via the peripheral nerves towards the central nervous system (at approximately speed of 3 mm/h).
In CNS, it causes the severe and fatal encephalitis.
5 Virus reaches brain and causes fatal encephalitis
6 Virus enters salivary glands and other organs of victim
4 Virus ascends spinal cord
3 Virus moves up peripheral nervous system to CNS in spinal cord
2 Virus replicates in muscles, near bite
1 Virus enters tissue from saliva of biting animal

(CNS: central nervous system)

FIG. 2: Pathogenesis of rabies.

"street virus" and not with "fixed virus". So far the virus has not been isolated from the blood of rabies patients and hence, the hematogenous route of spread is ruled out. In rabies, there is no initial viremia and the virus is not accessible to the normal immune mechanism of the body. The viremia or the stimulation of the normal immune mechanism is only during the end stages of the fatal disease therefore the role of naturally acquired infection is practically nonexistent.

CLINICAL PRESENTATION

Rabies in man is known as hydrophobia in general. The disease can be divided into different stages:

- *Prodromal stage*: The disease begins with prodromal symptoms such as fever, headache, myalgia, sore throat, and vomiting. There is pain and tingling or numbness at the site of bite in about 80% of cases. It is the most important complaint at this time and is related to the multiplication of virus at the local site. This stage may last for 3–4 days.
- *Stage of acute encephalitis*: This stage is characterized by excessive motor activity and agitated behavior. There is widespread excitation and stimulation of nervous system involving the sensory, the motor, the sympathetic, and the mental systems. There are symptoms of confusion, hallucination, muscle spasms, and convulsions. There is exaggerated sensitivity to noise, light, touch, or currents of air. Autonomic symptoms such as increased perspiration, salivation, lacrimation, pupillary dilatation, and hypotension are present. Hypoxia and hyperventilation progress to hypoventilation and repeated apnea.
- *Stage of brainstem dysfunction*: Now the characteristic symptom of hydrophobia appears which is pathognomonic of rabies and is absent in animals. This fear of water is due to painful, violent, involuntary contraction of diaphragm, respiratory, laryngeal and pharyngeal muscles, and initiated by swallowing of liquids. Progressively, even the sight, smell, or sound of liquids can precipitate spasm of muscles of deglutition. More than 80% patients succumb to the disease during this stage. Death is due to respiratory arrest, convulsions, or choking. Rest of the patients may progress to next stage.
- *Stage of paralysis*: Paralytic symptoms can occur at any time during the course of illness. Now the muscle spasms cease and there is apathy, stupor, coma, and generalized flaccidity. Death occurs due to hypoxia or heart failure. Occasionally, rabies may present as Guillain–Barré type of ascending paralysis. This may be seen with bite of a vampire bat or in patients who have received PEP against the disease.
- *Death*: Once the symptoms develop, the disease is fatal and the patient dies within two weeks. There are no quarantine restrictions for a rabies patient. However, since the saliva, urine or tears, etc., may contain the virus, all the persons coming in contact should be immunized against rabies. Transmission from man to man, though uncommon is possible.

DIAGNOSIS

The clinical diagnosis can be possible on the basis of classical signs and symptoms. Hydrophobia is pathognomonic of rabies. There is history of animal bite.

Laboratory Diagnosis

The laboratory tests are not routinely done for the management of animal bite cases, as these are not cost effective for

management purposes and have limited availability in specific centers of big cities. Several biological samples such as saliva, cerebrospinal fluid (CSF), skin biopsies containing hair follicles collected at the nape of neck, extracted hair follicles, tears, and urine can be used. Positive results of viral RNA in samples should be confirmed by sequencing to avoid false positives. Sensitivity of testing only one skin biopsy/patient is ≥98% but by collecting and testing three serial daily saliva samples per patient, it is possible to achieve maximal, i.e., 100% sensitivity. Fluorescent antibody test is a very reliable test nowadays and can establish the diagnosis within a few hours. If the brain is negative, by this test a person need not be treated. Fluorescent antibody titers in clinical rabies are >1:10,000 which help to differentiate between rabies and vaccine reaction.

Rabies-specific Enzyme-linked Immunosorbent Assay Technique

Enzyme-linked immunosorbent assay (ELISA) techniques for detection of rabies antigen or antirabies immunoglobulin G (IgG) are rapid, easy to use, and safe. Fluorescent antibody test can be performed on corneal impressions. After 7–10 days of illness, virus neutralizing antibodies appear in the serum and CSF which can be measured by the rapid fluorescent focus inhibition test (RFFIT) or ELISA. Histopathologically, the necrosed ganglia, demyelinated cord sheaths, glial proliferation, and Negri body inclusions are typical feature for a specific encephalomyelitis due to rabies.

Differential Diagnosis

Before the appearance of hydrophobia and in those cases where it does not manifest, rabies needs to be differentiated from other clinical conditions such as tetanus (lockjaw), encephalitis, hysteria, acute polyneuritis, poliomyelitis, and belladonna poisoning.

Rabies in Dogs

Two clinical forms of manifestation are known in dogs:

1. *Furious rabies*: Dog behaves abnormally and becomes very restless. Gradually it becomes dangerously aggressive with a tendency to bite objects, animals, and man indiscriminately and without provocation. There is profuse salivation due to paralysis of muscles of deglutition and tone of bark changes due to partial paralysis of vocal cords. Generalized convulsions followed by muscular incoordination and paralysis of muscles of trunk and extremities are seen at the terminal phase of illness.
2. *Dumb rabies*: It is characterized by predominantly paralytic clinical features. The excitation phase, if present, tends to be very short. Progressive paralysis starts with head and neck region. Animal has difficulty in swallowing. The dog withdraws itself from being disturbed and lapses into a stage of sleepiness and dies in about 3 days.

Once the symptoms of rabies develop in an animal, it rarely survives more than a week.

Observation of an animal for 10 days from the day of biting for signs of rabies is applicable for dogs and cats only and not for other domestic or wild animals. The rationale for observation is that if these animals are having infective saliva with rabies virus, they will show signs of disease in the next 3–5 days and die subsequently in another 3–5 days.

MANAGEMENT OF HUMAN RABIES (HYDROPHOBIA)

Although no specific treatment for rabies is available, a case has to be managed according to following procedure. The patient should be sedated and kept in a quiet room, with shades drawn on windows. No external stimuli such as noise and bright light should be present which may lead to convulsions. Patient should be treated symptomatically and proper hydration and diuresis should be maintained. Intensive respiratory and cardiac therapy is given. The nursing attendants and all persons coming in contact with the patient should be adequately protected as these patients are potentially infectious. The intensive care and nursing support are a must for rabies patients and there are seven cases of human rabies on record who survived this dreaded disease.

PREVENTION OF HUMAN RABIES

Postexposure Prophylaxis for Rabies

Human rabies is essentially a fatal disease once the clinical signs develop, although 100% preventable. Rabies PEP consists of thorough wound care along with administration of modern antirabies vaccine and rabies immunoglobulin (RIG). This is highly effective if carried out systematically and diligently. If a person has received pre-exposure prophylaxis (PrEP), then it eliminates the need for RIG in case of an exposure. The key to survival is administration of PEP as soon as possible. A patient with category III exposure needs thorough wound cleansing and a first dose of vaccine along with RIG on the day of bite or day of reporting (**Table 1**). The vaccination is done according to one of the WHO approved schedules to achieve a serum antibody titer of >0.5 IU/mL which is considered acceptable according to WHO. In case of any confusion regarding exposure it is always better to give over-treatment rather than under-treatment for prevention of rabies.

Assessment of Exposure and Observation Period

Immunization must be initiated immediately after every bite. Observation of dog/cat for signs of rabies for at least 10 days is important as well as valid. We can modify the treatment regimen (from postexposure to pre-exposure) if the dog/cat survives 10 days of observation.

We start the modern antirabies vaccine [cell culture vaccine (CCV)] according to the WHO schedule on the day of bite by dog/cat or as soon as the patient reports. That is considered day "0". Then the vaccine is given on day "3" and "7" as per schedule. If the dog/cat is alive and normal till the 10th day, then the remaining doses are not given. Alternatively, after giving the first and second doses on days "0" and "3", the third dose of day "7" may be deferred if the dog/cat is healthy on day 7. It is further deferred to day 14 if the dog/cat is alive and healthy for 10 days. Then the patient is given the option of converting the present postbite/postexposure vaccination into a modified preventive/pre-exposure vaccination by giving the third dose of vaccine either on day 21 or day 28. As three doses confer immunity for a duration of 1 year, so it is advisable to give a booster dose after 1 year. Thus, we convert the postexposure schedule to pre-exposure schedule. It is further emphasized

TABLE 1: Postexposure prophylaxis in rabies.

Categories	Nature of contact	Recommended treatment	
		Unknown, sick, proven, and wild animal	Healthy animal
I	Touching or feeding animals, licks on intact skin no mucous membrane exposure	None	None
II	Nibbling of uncovered skin, minor scratches, or abrasions without bleeding	• Modern tissue culture • Rabies vaccine	• Modern tissue culture • Rabies vaccine
III	Single or multiple transdermal bites or scratches, contamination of mucous membrane or broken skin with saliva from animal licks, exposure due to direct contact with bats	• Modern tissue culture • Rabies vaccine and rabies immunoglobulin (RIG)	• Modern tissue culture • Rabies vaccine and RIG

- Start pre-exposure vaccination particularly in children and others likely to have repeated animal contact, and are at a risk of dog bites
- Start full treatment on first day and discontinue vaccine if animal is alive and well on day 10, or if it has been found rabies negative on reliable laboratory examination. Encourage patient to return for another dose of vaccine on day 21, so that a full pre-exposure series has been completed
- If there is significant delay in presentation or if the patient is immunosuppressed, it may be appropriate to double the first dose of vaccine. Administration of two ampoules of vaccine, one in each arm, on day 0

that the observation period of 10 days is valid for dogs and cats only and not for any other animals because of the variability in the period of infectivity in other animals saliva.

Wound Care and Treatment

Proper wound care is a very important step as it may bring down the risk of infection to the extent of 50–70%. This step is however, often neglected. Our objective is to reduce the virus deposited at the site of bite as much as possible. The wound treatment must be done immediately or as early as possible after the bite. The steps are as follows:

- Gentle washing of the wound using a detergent soap, preferably under running tap water for at least 10 minutes.
- Application of household antiseptics like povidone-iodine, 40–70% alcohol or 0.01% aqueous solution of iodine can be done.
- In some extensive deep wounds the exploration of wound followed by debridement, removal of dirt and dead tissue may be required in a hospital setting and sometimes under anesthesia.
- *Suturing must be generally avoided as a rule*, as it may lead to the risk of inoculation of virus deep into the wound. However, if it cannot be avoided, it should be done as late as possible, from several hours up to 1 or 2 days. The suturing should be loose and minimum possible stitches should be given. Before the suturing equine rabies immunoglobulin (ERIG) or human rabies immunoglobulin (HRIG) should be infiltrated into the wound.
- *Generally animal bite wound should not be dressed or bandaged* and if unavoidable, it should be loose and not occlusive.
- Proper tetanus prophylaxis and wherever necessary, systemic antibiotics to prevent wound sepsis should be given.
- The use of any local applicant or irritant such as turmeric, neem, red chilli, lime, plant juices, coffee powder, coin, etc., should be discouraged or avoided as these will propel the virus deeper into the wound causing nerve infection, encephalitis, and death.

MODERN ANTIRABIES VACCINE

The vaccine against rabies is a liquid or dried preparation of fixed virus inactivated by a suitable method. In India, mainly three types of modern CCVs are available which are:

1. Human diploid cell vaccine (HDCV)
2. Purified chick embryo cell vaccine (PCECV)
3. Purified vero cell rabies vaccine (PVRV)

Dose

About 1 mL intramuscular (IM) for HDCV and PCECV and 0.5 mL IM for PVRV irrespective of age of person.

All CCV can be stored at 2–8°C and never to be stored in freezer compartment.

Indications

All cases of animal bites irrespective of severity of exposure require the same number of injections and dose per injection. The category III requires simultaneous administration of RIGs.

Site for IM Injection

The deltoid region is ideal site for injection (anterolateral aspect of mid-thigh in young children). Gluteal region is not recommended due to the amount of fat present there which retards the absorption of vaccine and interferes with the optimal antibody production and immune response. The use of modern, inactivated, and purified CCV with a potency of at

least 2.5 IU per single IM dose should be done according to one of the following WHO schedules:

- *Intramuscular schedule*: The most widely used is WHO Essen Schedule on day 0, 3, 7, 14, and 28 with an optional dose on day 90. *Abbreviated Multisite IM Schedule* (Zagreb Schedule), i.e., the 2-1-1 regimen (one dose of CCV IM in right arm and one in left arm on day 0, one dose on day 7 and one dose on day 21), although WHO approved is, however, not approved by Drug Controller General of India and hence should not be used in our country.
- *Intradermal (ID) schedule*: This schedule has been recommended by the WHO to reduce the cost of postexposure treatment with CCV. This has been approved by the Government of India also. This should only be used where adequately trained staff is present well versed in technique and maintenance of cold chain and storage of supplies. The regimen currently in use is known as the updated Thai Red Cross Schedule. In this schedule one dose of vaccine in a volume of 0.1 mL is given intradermally at two different lymphatic drainage sites, usually the right and left upper arms, on day 0, 3, 7, and 28. This updated Thai Red Cross Schedule (2-2-2-0-2) has been adopted in India.

It is important to know that the IM dose of PVRV is 0.5 mL and that of PCECV is 1 mL. Still as per the recommendations of the WHO, the ID dosage of all rabies vaccines uniformly is 0.1 mL.

Regarding adverse effects, properly prepared CCV have not been associated with any serious adverse effects. Some people may complain of localized edema and redness, sore arm, headache, nausea, malaise, and fever.

Switch over from one CCV to other is not encouraged as good immune response is best achieved with same brand/type of vaccine. However in case of nonavailability of same type/brand switch over can be done.

RABIES IMMUNOGLOBULIN FOR PASSIVE IMMUNIZATION

The RIGs or antirabies serum (ARS) are readymade antirabies antibodies providing passive immunity and immediate protection. Even the best of modern vaccines take 10–14 days to elicit the protective antibody titer of >0.5 IU/mL of serum and therefore RIGs cover this vulnerable period in category III exposure.

The combination of antirabies vaccine and RIG is almost 100% effective "at prevention" of clinical symptoms and disease; however, attempts to use vaccine or RIG after the onset of symptoms have not been successful. Some salient points related with use of RIG should always be kept in mind. These are:

- RIG should be administered in all individuals with category III exposure and in those with category II exposure who are immunodeficient.
- RIG is administered only once and as soon as possible after the initiation of PEP. RIG is not indicated beyond the seventh day after the first antirabies vaccine dose.
- The dose of human RIG is 20 IU/kg body weight and for equine RIG, 40 IU/kg body weight.
- All of the RIG, or as much as anatomically possible, should be administered into or around the wound site/s.
- Remaining RIG, if any, should be injected IM at a site distant from the site of vaccine administration. RIG may be diluted to a volume sufficient for all wounds to be effectively and safely infiltrated. There are no scientific grounds for performing a skin sensitivity test prior to ERIG administration. So it is not mandatory.

Rabies immunoglobulin should be immediately given after exposure to inhibit viral spread because vaccination needs time to induce a humoral response. RIG can be diluted with normal saline whenever the calculated dose (20 IU/kg body weight for HRIG subject to a maximum of 1,500 IU and 40 IU/kg body weight for ERIG subject to a maximum of 3,000 IU) is inadequate to infiltrate all wounds without previous dilution. However, the overall dose of HRIG or ERIG should not be increased because it may interfere with vaccination and may lead to reduced rate of seroconversion.

SPECIFIC SITUATIONS

Pre-exposure Prophylaxis

It is recommended for high-risk groups such as laboratory staff handling the rabies virus and infected material, physicians and paramedics attending the hydrophobia cases, veterinarians, animal handlers and catchers, wildlife wardens, pet owners, and travelers from rabies-free to rabies-endemic areas.

Pre-exposure prophylaxis should consist of three 1 mL IM or 0.1 mL ID doses of CCV, one dose each given on day 0, 7, and 28 with one booster after 1 year. Persons in high-risk group should have their neutralizing antibody titers checked every 6 months. If it is <0.5 IU/mL, a booster dose of vaccine should be given. These persons after successful PrEP, if get exposed to rabies virus irrespective of time interval between previous vaccination and re-exposure require only two booster doses of CCV on day 0 and 3 without any RIG, whatever be the category of exposure or bite.

Re-exposure Following Pre-exposure or Post-exposure Prophylaxis

In case of re-exposure anytime, if a person has previously received complete PrEP of three doses with one booster after 1 year or PEP of five doses with a potent CCV, should be given only two booster doses, IM or ID on days 0 and 3 but no RIG is necessary in them (WHO, 2002).

Pregnancy and Lactation

There are no contraindications regarding the use of modern CCV for PEP during pregnancy and lactation.

Extremes of Age

The dose of CCV is not dependent on age and weight. The dose is exactly the same from pediatric to geriatric age group.

If a dog is vaccinated against rabies, it cannot suffer from or transmit the disease. But in view of questionable maintenance of cold chain it is very difficult to say that a vaccinated dog is immune against rabies unless it is confirmed by a serological test. However, a modern tissue culture vaccine of adequate potency, if given regularly to dog following strict schedule should prove to be sufficiently protective.

Indications for Doubling the First Dose of Cell Culture Vaccine

In some situations it becomes necessary and appropriate to double the first dose of antirabies CCV, whatever route or schedule is used. These are:

- In patients with underlying chronic disease (e.g., liver cirrhosis)
- In patients who are severely malnourished
- In patients reporting for treatment after a delay of 48 hours or more
- In patients who are congenitally immunodeficient or suffering from acquired immunodeficiency syndrome
- In patients taking immunosuppressive drugs (including corticosteroids, antimalarials, and anticancer drugs)
- In patients with very high degree of exposure or extensive wounds, i.e., on head, neck, face, hands, genitals, etc., following bites by suspect or proven rabid animals or by wild animals such as fox, jackal, and mongoose
- In patients where RIG is indicated but unavailable

CONTROL OF RABIES

As the major source of infection is dog, the control of dog population along with their mass immunization in the shortest possible time remains the most logical approach for the control of this dreaded disease. A canine rabies control program has been launched by the ministry of agriculture. This type of program should incorporate three basic elements:

1. Epidemiological surveillance
2. Control of dog population
3. Mass immunization of dogs

Mass immunization may be considered by giving primary vaccination at 3 months of age and booster 1 year later and then every year. Nowadays, safe oral vaccines have become available and can be used for mass immunization. Oral immunization can cover 75% of dog population. Oral vaccination of wild animals with attenuated as well as recombinant vaccines by using "oral vaccine baits" has successfully reduced and controlled wildlife rabies in foxes in some countries of Europe such as Germany and Switzerland and also in Canada.

Health Education

Health education of public regarding prevention and control of rabies and management of animal bite is crucial to save lives. It is a real tragedy that this disease which is 100% preventable is still a major cause of mortality in developing countries.

Consumption of raw milk of any suspected rabid animal (cow, buffalo, goat, etc.) shall be considered and treated as category III exposure. Boiling of milk destroys the rabies virus.

Proper cooking of meat destroys the virus but raw meat can transmit the virus.

If a person presents after a considerable delay of weeks to months with a history of animal bite, it is mandatory to give complete course of postexposure treatment including infiltration of wound site with RIG in view of the 100% mortality with this disease. It may be appropriate to double the first dose of vaccine.

SUMMARY

- The saliva of rabies patients contains rabies virus and is infective, hence in case of suspicion about contact with saliva of a rabies patient during kissing the contact requires rabies postexposure vaccination. If ulcers are present in the mouth, then immunoglobulins should be advised by IM route.
- Rabies virus is present in the semen and to some extent in vaginal secretions. In some male patients, priapism and in both male and female patients increased libido may be observed. Hence to the healthy contact, a complete course of postexposure vaccination should be given. If abrasion on penis or vagina, RIG is to be given by IM route.
- There have been some instances of failure even after complete course of antirabies treatment. During discussions at WHO and other expert committee meetings it was found that the efficacy and immunogenicity of modern CCV were never in doubt but failures were either due to delay in getting vaccination or RIG was not used or there was already immunosuppression in patients.
- There is no contraindication of giving antirabies vaccine along with Expanded Program of Immunization (EPI)/ pediatric vaccines in case of postexposure vaccination; however, an interval of 3–4 weeks between the two types of vaccines is advisable in case of PrEP.
- Modern antiretroviral (ARV) can be safely given to children having chickenpox, measles, or any other eruptive fevers.
- If during antirabies vaccination any dose is missed, then patient is counseled regarding strict adherence to schedule and schedule is completed as soon as possible.
- No dietary restrictions are required during vaccination but alcohol, tobacco, gutka, and smoking must be avoided.
- There is no single shot antirabies vaccine till date and a full course of antirabies vaccination does not guarantee or provide lifelong immunity against the disease.

Rabies is still a very dreadful as well as dreaded disease. Strict measures to control or eliminate the disease in domestic as well as wild animals must be taken if we are ever to achieve mastery over this deadly virus. In conclusion, cases of human rabies would be extremely rare if all patients knew whom to approach for treatment in case of bite, if antirabies vaccine and serum were readily available and if the postexposure treatment was strictly and diligently carried out following the guidelines.

193
CHAPTER

Skin and Soft Tissue Infections

Javier Saavedra Urbe, Devendra Richhariya

INTRODUCTION

Skin and soft tissue infections (SSTIs) are causes for common outpatient as well as emergency department (ED) visits. SSTIs are common form of infections presenting to ED which includes routine skin infections to rapidly life-threatening SSTIs. Abscess and purulent cellulitis, nonpurulent cellulitis, and necrotizing soft tissue infections (NSTIs) are the most important clinical types of SSTI in clinical practice. SSTIs can be classified as proposed by the Infectious Disease Society of America (IDSA) because it suggests a useful clinical diagnostic approach—in which the first step is to "look for pus" (**Flowchart 1**)—dividing SSTIs according to presence or absence of purulence. If there is purulence, the causative bacterium is likely *Staphylococcus aureus*. Performing good drainage, with an incision and drainage procedure is utmost importance along with antibiotics with activity against methicillin-resistant *S. aureus* (MRSA) are generally indicated. If there is no pus, then consider nonpurulent cellulitis and NSTIs. In nonpurulent cellulitis beta-lactam antibiotics (which do not cover MRSA) can be used as causative agents is β-hemolytic streptococcal species. If a necrotizing infection is suspected, broad-spectrum antibiotics should be administered because etiology may be polymicrobial. In addition to antibiotics, prompt surgical intervention is also indicated. Antibiotics recommended for major SSTIs are summarized in **Table 1**. SSTIs can also be classified on the basis of involvement of skin. Erysipelas is a form of nonpurulent cellulitis limited to the epidermis and impetigo is an infection that affects only the keratin cells of this layer. Furuncles are an infection originating in hair follicles that produce a localized subcutaneous abscess within the hypodermis. Carbuncles, which are a coalescence of multiple furuncles, tend to extend deeper into the hypodermis. Necrotizing fasciitis is an infection of the fascia is the connective tissue layer that lies below the hypodermis; SSTIs can also be classified on the basis of severity of local and systemic symptoms, and recommended management is summarized in **Table 2**.

MICROBIOLOGY

Staphylococcus aureus or one of the β-hemolytic streptococcal species is the major causative agent for community-onset SSTIs presenting to ED. However, in special circumstances after animal bites and water exposure, there are numerous other important pathogens that cause SSTIs. **Table 3** summarizes the special types of SSTI in which the bacteriology includes pathogens other than *S. aureus* and β-hemolytic streptococcal species.

Staphylococcus aureus is a gram-positive coccus that grows in clusters and is a part of the normal human microbiota. It is frequently found on the nasal mucosa, the skin (especially of the axilla and groin), and in the gastrointestinal tract. Classically *S. aureus* causes localized pus-producing lesions, such as furuncles, abscesses, and carbuncles. *S. aureus* has unique quality to survive on fomites; infection control measures should include disinfecting high-touch household surfaces and linen. Finally, the purulent nature of *S. aureus* infections seems to allow transmission from person to person by even brief direct contact with the draining lesion.

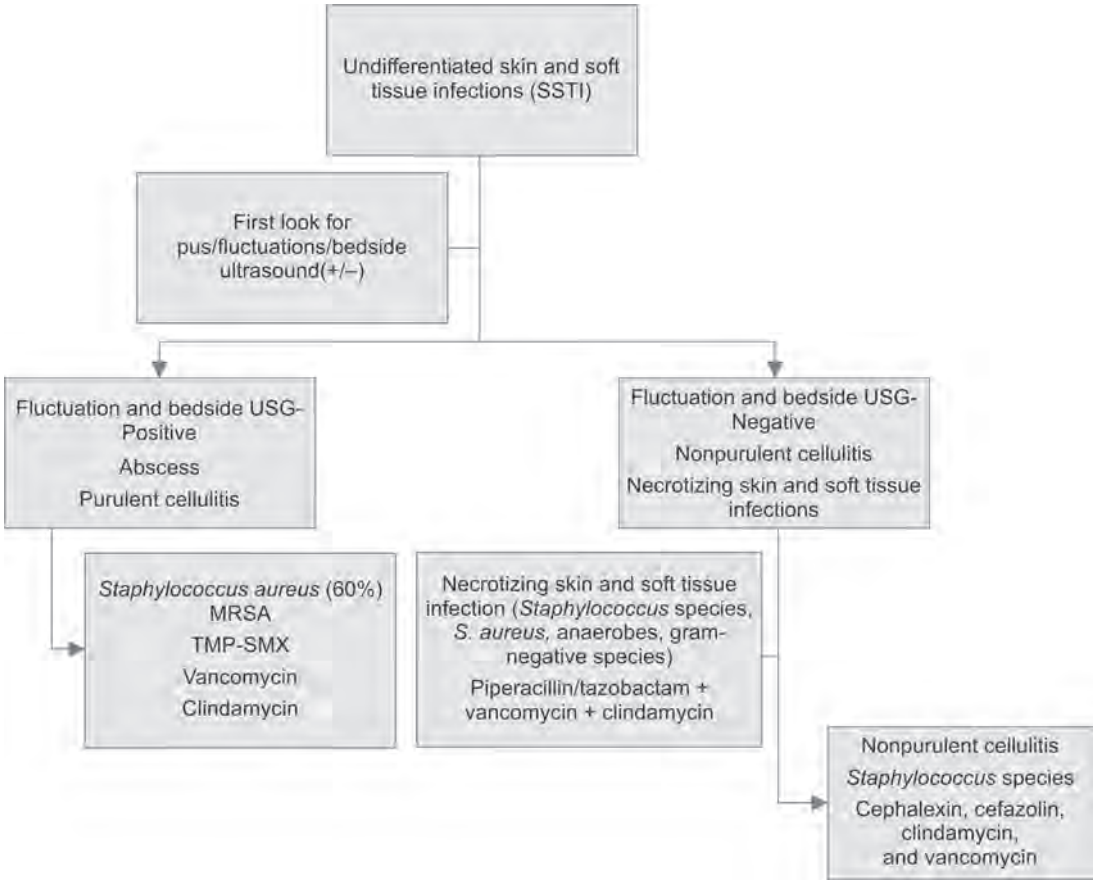
β-hemolytic Streptococcal Species

The β-hemolytic streptococci species are gram-positive cocci that grow in chains and are also part of the normal human skin microbiota. In contrast with *S. aureus*, a characteristics clinical feature of streptococcal SSTIs is lack of purulence. *Streptococcus pyogenes*, also known as group A *Streptococcus* (GAS), is the most common, but other species—groups G, D, and B are identified as etiologies of nonpurulent cellulitis. *S. pyogenes* is one of the preeminent human pathogens, responsible for a range of clinical infections including not only impetigo, lymphangitis, erysipelas, cellulitis, and necrotizing fasciitis, but also pharyngitis, scarlet fever, pneumonia, streptococcal toxic shock syndrome, and the notorious sequelae of infection, rheumatic fever, and glomerulonephritis.

IMPETIGO

Epidemiology and Microbiology

Impetigo is caused by both *S. aureus* and *S. pyogenes* after colonization of the unbroken skin. Colonization further leads to infection at an interval of approximately 10 days. Impetigo mostly occurs in children between ages 2 and 5 years, but may also occur in older children or adults. Poor hygiene and



(MRSA: methicillin-resistant *Staphylococcus aureus*; TMP-SMX: trimethoprim-sulfamethoxazole; USG: ultrasonography)

FLOWCHART 1: Clinical approach to undifferentiated skin and soft tissue infection.

TABLE 1: Antimicrobial therapy for purulent cellulitis, nonpurulent cellulitis, and necrotizing soft tissue infection.

Infections	***Antibiotics***	***Dosage (adult)***	***Comments***
Impetigo (*Staphylococcus* and *Streptococcus*)	• Mupirocin ointment • Cephalexin • Clindamycin • TPM-SMX	• Apply to lesion • 250 mg 6 hourly PO • 300–400 mg 6 hourly PO • 1–2 DS tablet 12 hourly PO	
Abscess and purulent cellulitis (MRSA and MSSA)	• Vancomycin • Clindamycin • Doxycycline • Linezolid	• 30 mg/kg/day in two divided doses IV • 600 mg every 8 hours IV or 450 mg qid PO • 100 mg 12 hourly PO • 600 mg every 12 hours IV or 600 mg bid PO	For penicillin allergic patients; parenteral drug of choice for MRSA
Nonpurulent cellulitis (beta-hemolytic *streptococcus* and MSSA	• Cephalexin • Cefazolin • Clindamycin • Nafcillin • Penicillin VK	• 500 mg every 6 hours PO • 1 g every 8 hours IV • 600–900 mg every 8 hours IV • 1–2 g every 4–6 hours IV • 250–500 mg every 6 hours PO	
Necrotizing soft tissue infection (GAS, *Clostridium* species, MRSA, gram-negative rods, and others)	• Piperacillin • Tazobactam • Aztreonam • Vancomycin + clindamycin	• 4.5 g every 6 hours IV • 2 g every 6 hours IV • 15–20 mg/kg IV every 12 hours IV • 600–900 mg every 8 hours IV	

(DS: double strength; GAS: group A *Streptococcus*; IV: intravenous; MRSA: methicillin-resistant *Staphylococcus aureus*; MSSA: methicillin-susceptible *Staphylococcus aureus*; TMP-SMX: trimethoprim-sulfamethoxazole)

TABLE 2: Severity classification of skin and soft tissue infections (SSTIs).		
Class	*Description*	*Management*
1	Afebrile and healthy, other than acute SSTI	If required, incision and drainage. If required, oral antimicrobials as an outpatient
2	Febrile and ill appearing, but no unstable comorbidities (e.g., diabetes) that may complicate or delay resolution	Can be treated with oral antibiotics or outpatient IV therapy and may require a short period of observation in hospital
3	Appear toxic and unwell (fever, tachycardia, tachypnea, and/or hypotension)	Likely to require inpatient treatment with parenteral antibiotics
4	Sepsis syndrome or life-threatening infection (e.g., necrotizing fasciitis)	Likely to require admission to intensive care facility for surgical assessment and parenteral antimicrobial agents

TABLE 3: Microbiology of special types of skin and soft tissue infections (SSTI).	
Conditions	***Possible pathogens***
Fresh or salt water exposure	*Vibrio vulnificus*, *Aeromonas hydrophila*, *Erysipelothrix rhusiopathiae*, *Mycobacterium marinum*, and others
Human bites	*Eikenella corrodens*, *Fusobacterium nucleatum*, *Streptococcus anginosus*, and *Staphylococcus aureus*
Cat bites	*Pasteurella multocida; Streptococcus* species, *S. aureus*, *Fusobacterium* species, *Bacteroides* species, and others; and *Bartonella henselae* (cat scratch disease)
Dog bites	*Pasteurella multocida; Streptococcus* species, *S. aureus*, *Fusobacterium* species; *Bacteroides* species; and *Capnocytophaga* (may cause overwhelming sepsis in susceptible patients)
Diabetic foot	*S. aureus* (including MRSA), β-hemolytic streptococcal species, *Pseudomonas aeruginosa*, *Enterococcus* species, *Escherichia coli*, other *Enterobacteriaceae* species, oral anaerobic species, *Bacteroides* species, and *Clostridium* species
Injection drug use	*S. aureus* (including MRSA), *Streptococcus* species, oral anaerobic species, *Clostridium perfringens*, *Clostridium sordellii*, and *Clostridium novyi*
Perirectal abscess	*S. aureus*, *Streptococcus* species, *E. coli*, other *Enterobacteriaceae* species, *Bacteroides fragilis*, and other anaerobic species

(MRSA: methicillin-resistant *Staphylococcus aureus*)

disruption of the epidermal layer by mosquito bites, abrasions, and eczema are the important risk factors for impetigo.

Clinical Features

There are two major types of impetigo: Nonbullous and bullous. Nonbullous impetigo is the more common form and presents as a yellowish crust on the face, arms, or legs. Impetigo begins with a papule, and then progresses to vesicle, and pustule surrounded by an area of erythema. Over a period of 4–6 days the pustule gives rise to the characteristic thick and golden crust. Sores may be pruritic, but not painful. Fever is rare, but regional lymphadenopathy may be present. Touching the sores may result in spread of the infection. Bullous impetigo is a staphylococcal disease common in children <2 years of age. Bullous impetigo clinically present as painless fluid-filled bullae, predominantly on the arms, legs, and trunks. After the bullae break, they may form yellow scabs. If infection extends to the dermis, ulcers covered with a crust or eschar develops. Poststreptococcal glomerulonephritis is a possible complication of streptococcal impetigo.

Diagnosis

The diagnosis of impetigo is made by visual recognition. For differentiating staphylococcal from streptococcal infection, Gram stain and culture may be used. Assays of antistreptolysin O are not useful in the diagnosis or management of impetigo. If poststreptococcal glomerulonephritis is suspected in any patient, assays of antistreptolysin O may be helpful.

Treatment and Prophylaxis

Impetigo treatment involves removing the crust and washing the affected area with soap and water followed by prescribing antibiotic. A topical antibiotic with reliable antistaphylococcal activity is useful. Mupirocin is the most widely recommended topical agent. For more widespread lesions cephalexin and dicloxacillin antibiotics may be used. Good personal hygiene can prevent the spread of impetigo to susceptible individuals.

ABSCESS

Epidemiology and Microbiology

Focal collections of pus located within the dermis and hypodermis are known as cutaneous abscesses and are clinically present as "painful, tender, and fluctuant red nodules, pustule, and surrounded by a rim of erythematous swelling". The definitions and terminology of common types of abscesses and other purulent infections are listed in **Table 4**.

Staphylococcus aureus is responsible for abscess in about 75% of cases, of which mostly MRSA predominates. Injection drug use (IDU)-related cutaneous abscesses may be polymicrobial and contain oral streptococci and anaerobes, because saliva is so often used to dissolve the drug and clean needles and syringes. Recurrent abscesses associated with injectable drug abusers; after shaving of legs, axilla, and pubic hair; and prior colonization of infection.

TABLE 4: Definitions—purulent skin and soft tissue infection.

Conditions	*Description*
Cutaneous abscess (skin abscess)	Subcutaneous collection of pus with a wide spectrum of size and severity
Folliculitis	Tiny, papular abscesses, inflammation and infection of hair follicles
Furuncle	Small, spontaneous, and cutaneous purulent abscess develop around a hair follicle, extending below the epidermis. Patients may be referred as a "spider bite" or commonly called as "boil"
Carbuncle	Multiple furuncles coalesce and of typically involving the deep subcutaneous tissues; base of the neck is common site
Paronychia	Abscess at the base of a finger or toe nail, trapped below the eponychial fold
Hidradenitis suppurativa	An often-inherited form of acute and chronic inflammation of sebaceous and apocrine glands that causes follicular occlusion; abscesses appear purulent but are sterile
Purulent cellulitis	Erythema, induration, and warmth that extends from a purulent focus

Clinical Features

Cutaneous abscesses are easily recognized by their visual appearance. The circular shape erythema, swelling, and induration often associated with a small point of necrosis or signs of spontaneous drainage. There may or may not be significant purulent cellulitis extending radially from the purulent focus (nonpurulent cellulitis, often circumferential around a limb). Fluctuance is a classic hallmark of abscesses; however, it is frequently absent in the early stages of formation and in the case of a deep subcutaneous abscess. In fact, minimal external signs appear of cutaneous abscesses where hypodermis is particularly thick, like the gluteal and thigh region.

Diagnosis

For a cutaneous abscess the first-line "diagnostic test" is palpation for fluctuance examination. When fluctuance is absent or difficult to localize emergency physician may take the help of ultrasound examination as an adjunct to the physical examination. Ultrasound examination findings of abscess cavities are hypoechoic or anechoic and acoustic enhancement deep to the pus collection. In addition, for deep or intramuscular abscesses, ultrasound examination can be invaluable in identifying the best location for incision. A computed tomography scan rarely required and may be used for deep subcutaneous or intramuscular abscesses and helpful to evaluate abscesses around the perineum (scrotum and rectum) and in the neck. Cultures are usually not necessary, because the bacteriology has been well-established and MRSA is endemic. For recurrent abscesses Gram staining and culture of the pus may be required.

Treatment and Prevention

Incision and drainage is strongly recommended for treatment of carbuncles, abscesses, and large furuncles. Incision and drainage traditionally involve a single linear incision followed by blunt dissection. Needle aspiration has been shown to be generally inferior to incision and drainage for drainage of cutaneous abscesses. However, on the face when cosmesis is a major consideration, needle aspiration may be preferred. Incision and drainage is routinely followed by irrigation of the abscess by some practitioners. After incision and drainage, packing the abscess cavity with one-quarter to one-half inch of gauze is another widely accepted routine practice. Antibiotics should be reserved for large or complicated abscesses, defined as those with fever or other systemic inflammatory response syndrome signs, >5 cm of surrounding cellulitis, or occurring in an immunocompromised host. After successful incision and drainage, hospitalization is not required but admission may be considered in the following situation.

- If abscesses drainage is done in the operating room,
- Significant surrounding cellulitis associated with fever requires parenteral antibiotics,
- Evidence of severe sepsis suggesting bacteremia, and
- Immunocompromised patients [including acquired immunodeficiency syndrome (AIDS), end-stage renal disease, and poorly controlled diabetes mellitus]

Discharge instructions aimed at reducing recurrences and spread of *S. aureus* within households. Discharge instructions after abscess incision and drainage should be given to patient are as follows:

- Keep draining wounds covered with a clean bandage.
- Wash hands frequently, especially after touching infected wounds or soiled bandages.
- Wash clothing that is contaminated by drainage.
- Do not share contaminated items such as towel, clothing, bedding, or razors.
- Clean contaminated environment surfaces with bleach, detergent, or disinfectant.

PURULENT CELLULITIS

Purulent cellulitis is associated with a purulent focus such as an abscess, a pustule, ulcer, or purulent wound and also known as culturable cellulitis. Causative pathogens for cellulitis with purulence are likely *S. aureus* with approximately 60% being MRSA. Oral trimethoprim-sulfamethoxazole (TMP-SMX) and intravenous vancomycin and clindamycin (oral or intravenous) are recommended antibiotics. It is very important for physicians to understand the distinction between purulent and nonpurulent cellulitis and the implications regarding etiology and antibiotic choice.

NONPURULENT CELLULITIS

Nonpurulent cellulitis typically occurs when there is a breakdown in the physical skin barrier, immune system, and/or circulatory system. Major risk factors include diabetes mellitus, obesity, venous insufficiency, impaired lymphatic drainage (e.g., trauma or prior surgery), IDU, and old age. Most cases of nonpurulent cellulitis are caused by β-hemolytic *Streptococcus* species includes not only *S. pyogenes*, but also

group C or G streptococci. Local pain, tenderness, swelling, and erythema are common clinical findings in nonpurulent cellulitis. Large areas of skin can be involved rapidly and associated with systemic manifestation such as fever, lymphangitis, or bacteremia. Carefully examine the lower extremities interdigital spaces between the toes for fissures or maceration, which may indicate a fungal coinfection requiring treatment.

ERYSIPYELAS

Erysipelas is a subtype of nonpurulent cellulitis limited to the epidermis. Erysipelas is an acute onset infection, clinically present as fever and mostly involve lower extremity with clear line of demarcation between involved and uninvolved tissue. Facial erysipelas may occur after streptococcal sore throat and classically has a brilliant salmon red color lesion and butterfly-shaped distribution.

Correct diagnosis of nonpurulent cellulitis can be challenging. It is identified as nonpurulent when it is actually purulent (and potentially caused by MRSA) and can lead to initiation of inappropriate treatment. In purulent cellulitis, fluctuance may be absent or underappreciated, especially early in the infection.

In addition, noninfectious processes are often misdiagnosed as cellulitis. Nonpurulent cellulitis should be distinguished from chronic venous insufficiency, gout, large local reactions, bee stings contact dermatitis, deep vein thrombosis, fungal infection, drug rash, vasculitis, malignancy (lymphangitis and carcinomatosis), and herpes zoster. The most important and life-threatening mimic of cellulitis is NSTI.

For diagnosis of cellulitis, imaging is not useful though point-of-care ultrasound examination can be used to evaluate undifferentiated erythema and swelling, such as deep vein thrombosis, superficial thrombophlebitis, bursitis, and acute arthritis (septic joint). Ultrasound findings in cellulitis give rise to a "cobblestone" appearance (subcutaneous edema, with hyperechoic fat lobules and adjacent hypoechoic interlobular septate). All patients with a soft tissue infection with signs of systemic toxicity (fever, hypotension, and tachycardia) should have blood cultures and laboratory tests (complete blood count with differential, serum chemistries, creatine phosphokinase, and C-reactive protein and lactate levels). Marked leukocytosis, hyponatremia, and elevated creatine phosphokinase should raise the concern for an NSTI.

Treatment and Prevention

Empiric antibiotic therapy must cover *Streptococcus* species for uncomplicated nonpurulent cellulitis. Staphylococcal coverage is not needed if there is no purulence. Options include cephalexin, dicloxacillin, clindamycin, and penicillin. For nonpurulent cellulitis with systemic signs of infection such as a high fever, intravenous antibiotics are indicated. Options include cefazolin, ceftriaxone, and clindamycin. In addition, if the patient is immunocompromised, e.g., poorly controlled diabetes, infected with the human immunodeficiency virus, and end-stage renal disease patients with cellulitis should generally hospitalized. In the setting of a traumatic wound and in patients with a history of MRSA infection or IDU, initial MRSA coverage should be considered (in the setting of cellulitis). Options for oral MRSA therapy include addition of TMP-SMX or doxycycline to the beta-lactam, or switching to clindamycin. Elevation of the extremity is considered an important component of cellulitis treatment. Interdigital fissures, scales, and maceration should be treated with a topical azole drug as this is an evidence of an underlying fungal infection. Other underlying predisposing conditions such as edema, eczema, venous insufficiency, diabetes mellitus, and obesity should be identified and treated accordingly.

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing fasciitis is the commonly used term but fasciitis represents only one aspect of NSTIs. NSTIs are rapidly spreading bacterial infection associated with necrosis of subcutaneous fat, muscle, and fascia. Necrotizing cellulitis, clostridial gas gangrene and myonecrosis, and spontaneous streptococcal myositis with streptococcal toxic shock are the subtypes of NSTIs. These infections are most difficult and high-stakes problems in emergency medicine require prompt surgical exploration and debridement for definitive diagnosis and cure. The diagnosis is on the basis of high suspicion, the patient is taken for surgical exploration and debridement for necrosis, patient survival chances may increase. If NSTIs are not suspected initially and patient condition not improved in spite of antibiotics and resuscitation, chances of survival become less. So management of these infections requires close teamwork and close association between emergency and with surgical team.

Epidemiology, Microbiology, and Pathophysiology

Necrotizing soft tissue infections are not very common. Globally the annual incidence ranges from 1.69 to 15.5 cases per 100,000 persons with mortality rates average 20–30% in the literature, but range widely depending on the pathogen(s) involved, underlying host factors, and how quickly the diagnosis is recognized. It is classically taught that NSTIs occur in the wake of devitalized tissue, such as in the postoperative or battlefield setting. Risk factors associated with NSTI are intravenous drug abusers, diabetic foot ulcers, peripheral vascular disease, malnourished, and alcoholic patient.

Necrotizing soft tissue infections are divided into two broad categories: (1) Polymicrobial infection (type I) and (2) Monomicrobial infection (type II). The proportion of cases that are polymicrobial can vary according to the study setting. Polymicrobial infections can include various bacteria, including streptococcal species, Enterobacteriaceae (gram-negative rods), clostridial species, nonclostridial anaerobes such as *Peptostreptococcus* species, *Staphylococcus* species. Monomicrobial infections classically are caused by GAS, previously called streptococcal gangrene. Any age-group and healthy individual may be affected by these infections. Monomicrobial NSTIs occur after exposure to salt water and fresh water, due to *Vibrio vulnificus* and *Aeromonas hydrophila*. *Clostridium perfringens* is found in both monomicrobial and polymicrobial infections. *Clostridium sordellii* NSTI occurs in individual with intravenous drug users and in the postpartum period. Additionally, community-associated MRSA (CA-MRSA) has been implicated as a cause of monomicrobial necrotizing fasciitis. Certain anatomic areas of the body are more prone for NSTIs like Fournier's gangrene is an NSTI of the

genitourinary region. Ludwig's angina is an NSTI that begins in the floor of the mouth. Both have the potential to spread rapidly along adjacent fascial planes. A summary of terms commonly encountered to categorize NSTI is listed in **Table 5**.

The pathophysiology of NSTIs differs depending on the etiologic pathogen. Bacteria or clostridial spores enter through the wound, inflammation, and necrosis spread from the skin and immediate subcutaneous tissue eventually to deeper muscle and fascia. When the inciting mechanism is the seeding of injured muscle by GAS bacteremia, inflammation, and necrosis spreads from the muscle (at which point pain and hypotension may be the only signs) to the skin, eventually producing visible necrosis and bullae. Vascular occlusion is a key component of NSTI pathophysiology. Virulence factors of *C. perfringens* and GAS produce exotoxins, contribute to lethality. *C. perfringens* alpha toxin causes platelet destruction, hemolysis, and increased capillary permeability, and produces massive circulatory collapse due to direct cardiotoxic effects. Streptococcal pyrogenic exotoxins, which compromise normal immune defenses, act as superantigens and trigger massive cytokine release ("cytokine storm") precipitate toxic shock syndrome. **Figure 1** presents a simplified taxonomy and pathophysiology of NSTI.

TABLE 5: Types of necrotizing soft tissue infections (NSTIs).

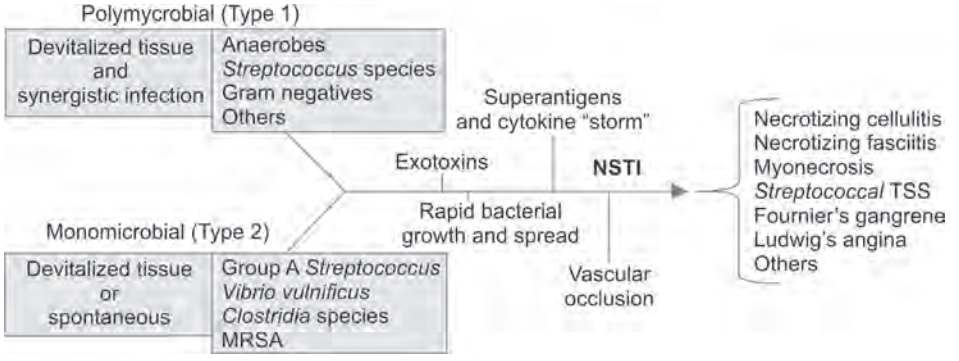
Type	*Description*
Gas gangrene	Associated with contamination of traumatic or surgical wounds by the toxin-producing anaerobe *Clostridium perfringens*, typically involves deep muscle tissue and spreads along facial planes
Fournier's gangrene	Typically, polymicrobial NSTI of the perianal and perineal region, more common in men
Ludwig's angina	Typically, polymicrobial odontogenic infection involving the floor of the mouth, with potential to spread via fascial planes to the neck and mediastinum
Type 1, polymicrobial	Polymicrobial (synergistic) infection, often involving oral and bowel flora. Includes Fournier's gangrene and Ludwig's angina
Type 2, monomicrobial	Typified by group A *Streptococcus* (GAS) and *Vibrio vulnificus*. GAS disease is classically associated with trivial injury and produces streptococcal toxic shock syndrome

Clinical Features

The presence of any of "hard findings" such as bullae, crepitus, necrosis, and cutaneous sensory deficit (from cutaneous nerve necrosis) on physical examination should be considered as NSTI until proven otherwise while the most common presenting signs and symptoms are nonspecific and include fever, pain, tenderness, local swelling, and erythema. In ED, diagnosing NSTIs are challenging as hard findings are absent in early stage of the disease. Massive "woody" soft tissue swelling, referred to as the Michelin Man sign, has been described, and likely is associated with *C. sordellii* and *C. novyi* infections among IDUs. Severe *C. sordellii* infections classically produce no fever. Gastrointestinal symptoms may predominate and be misleading early in cases of streptococcal toxic shock. Myositis may present as isolated and severe deep muscle pain; an elevated creatine phosphokinase, serum lactate, or small hemorrhagic bullae may be the first clues to a serious infection. Certain presentation in ED should raise the suspicion of NSTI. These include the following: diabetic foot infection; perineal infections, especially in men (Fournier's gangrene); odontogenic infections involving extension into the floor of the mouth (Ludwig's angina; any skin infection or poorly differentiated soft tissue complaint in an IDU; and unexplained, severe deep muscle pain).

Diagnosis

Laboratory testing may be useful in distinguishing NSTIs from other SSTIs, particularly from nonpurulent cellulitis. White blood cell count of >15.4/mm^3 and sodium of <135 mmol/L in the setting of a skin or soft tissue complaint should be considered an NSTI until proven otherwise. Elevated creatine phosphokinase can suggest infection involving deep muscle or fascia. Wong and colleagues derived the laboratory risk indicator for necrotizing fasciitis score based on laboratory tests including white blood cell count, sodium, and C-reactive protein. Moderate-to-high risk for NSTI is considered if score of 6 or higher (**Table 6**).



(MRSA: methicillin-resistant *Staphylococcus aureus*; NSTI: necrotizing soft tissue infection; TSS: toxic shock syndrome)

FIG. 1: Simplified taxonomy and pathophysiology.

TABLE 6: Laboratory risk indicator for necrotizing fasciitis score.

Laboratory parameters	*Range*	*Points*
C-reactive protein (mg/L)	≥150	4
White blood cell count (per mm^3)	15–25	1
	>25	2
Hemoglobin (g/dL)	11–13.5	1
	<11	2
Na (mmol/L)	<135	2
Creatinine (mg/dL)	>1.6	2
Glucose (mg/dL)	>180	1

Note: A score of >6 should prompt further evaluation (imaging) and surgical consultation.

Source: Wong CH, Khin LW, Heng KS, Tan KC, Low CO. The LRINEC (Laboratory Risk Indicator for Necrotizing Fasciitis) score: a tool for distinguishing necrotizing fasciitis from other soft tissue infections. Crit Care Med. 2004;32(7):1535-41.

Plain radiographs helpful in demonstrating the subcutaneous gas in a stippled pattern (25% of NSTIs). Initial imaging modality of choice in most cases of NSTI is computed tomography scanning. It can demarcate the extent of inflammation and identify asymmetric thickening of the deep fascia and fluid adjacent to fascia, and is more sensitive than plain radiography for detecting tissue gas. Hemodynamically unstable patients in ED can be evaluated by bedside ultrasound examination. Specific ultrasound findings in NSTI include tissue gas, irregular fascia thickening, and perifascial fluid. Surgical exploration and debridement remains the definitive diagnostic test for NSTI, as well as the definitive treatment. The gold standard is a constellation of surgical findings that includes nonbleeding tissue, nonadherent muscular fascia on blunt dissection, greyish appearance of the fascia, and so-called dishwater pus. A Gram stain of the surgical specimen should be performed and result can be used to guide empiric antibiotic treatment.

Treatment

Prompt surgical debridement is considered the cornerstone of effective treatment. Surgical treatment involves wide debridement down to bleeding, and repeated inspection and debridement during the hospitalization is often necessary. The most critical supportive care is early goal-directed treatment of sepsis, resuscitation with crystalloid fluid, tissue perfusion monitoring, use of norepinephrine, and pain management when indicated. Because the bacterial etiology is almost never known at the time, NSTI is first suspected in the ED. Broad empiric antimicrobial coverage (piperacillin/tazobactam, vancomycin, and clindamycin) is required, targeting GAS, *Clostridium* species, gram-negative bacteria, and MRSA. Survival is likely inversely correlated with how soon antibiotics are started, as it is in septic shock. For suspected *Aeromonas hydrophila*, the recommended treatment is doxycycline plus either ciprofloxacin or ceftriaxone, and for *Vibrio vulnificus* it is doxycycline plus either ceftriaxone or cefotaxime.

SUMMARY

Skin and soft tissue infections are among the most common infections encountered in the ED and emergency physicians should be expert in their diagnosis and management. The emergence of CA-MRSA at the turn of the millennium greatly increased the incidence of purulent SSTIs and forced a change in antibiotic treatment. The first step in approaching an undifferentiated skin infection should be carefully assessed for purulence, which generally indicates a staphylococcal (often MRSA) infection. Drainage is required for abscesses and adjuvant antibiotics active against MRSA provide additional benefit. Nonpurulent cellulitis can be reliably treated with beta-lactam antibiotics alone. Antibiotic choice is best guided by a hospital antibiogram. Potentially deadly NSTIs require prompt recognition and surgical treatment, yet they are difficult to diagnose. A prudent approach is to consider NSTI every time one encounters a diabetic foot infection, an infection involving the perineum or the floor of the mouth, a skin or soft tissue complaint in an IDU, or any patient with unexplained severe muscle compartment pain.

194
CHAPTER

Musculoskeletal Infections

Avdi S Tahiri, Artan Bejta

INTRODUCTION

Bone and joint infections are relatively uncommon cause of musculoskeletal complains among patients seeking care in emergency department (ED). Musculoskeletal infections such as osteomyelitis (OM) and septic arthritis can have long-term, devastating consequences for children and adolescents, if they are not diagnosed and promptly treated. The classic presentation for these infections is a child with fever and difficulty bearing weight or refused to walk. They management is challenging. Challenges include not only eradicating the infection but also managing other orthopedic complications such as joint destruction, bone loss, pathologic fracture, angular deformities, and limb length discrepancy. The importance of nutritional supplementation as an adjuvant treatment of these infections cannot be overemphasized. A systematic approach to OM, spondylodiscitis, spinal, epidural abscess, and antibiotic prophylaxis for an open fracture, septic arthritis, and periprosthetic joint infection (PJI) is essential in emergency department. For further evaluation and management lab investigations and radiology are also required.

OSTEOMYELITIS

Osteomyelitis (OM) is an infection of bone respectively inflammatory reaction of the bone due to infection most often bacterial in nature, is a rare but serious condition which included all parts of bone (bone marrow and periosteum) and all surrounding structures such as soft tissues and skin, thus as come to damaging all of these structures.

Epidemiology

The exact incidence is unknown. A study from Glasgow, Scotland, covering the period 1990–1999, suggests that it is less than three cases per 100,000 per year (Blyth et al. 2001). Incidence increase by age, especially over 60 years of age and diabetes-related OM.

Etiology and Causes

The causal organism in both adults and children is usually *Staphylococcus aureus* (found in over 70% of cases), and less often one of the other gram-positive cocci, such as the group A beta-hemolytic *Streptococcus* (*Streptococcus pyogenes*) which is found in chronic skin infections, as well as group B *Streptococcus* (especially in newborn babies) or the alpha-hemolytic diplococcus *S. pneumoniae*. But OM can be caused by other organisms as well. *Pseudomonas aeruginosa* often appears in patients using intravenous drugs. Immunocompromised patients are at risk for infection on one wide number of microorganisms such as mycobacteria and fungi (*Candida*) (**Table 1**).

TABLE 1: Organism involved in osteomyelitis.

Age group	***Most common organisms***
Newborns (younger than 4 months)	*S. aureus, Enterobacter* species, and group A and B *Streptococcus* species
Children (aged 4 months to 4 years)	*S. aureus*, group A *Streptococcus* species, *Kingella kingae*, and *Enterobacter* species
Children, adolescents (aged 4 years to adult)	*S. aureus* (80%), group A *Streptococcus* species, *H. influenzae*, and *Enterobacter* species
Adult	*S. aureus* and occasionally *Enterobacter* or *Streptococcus* species
Unusual osteomyelitis organism	
Organism	*Patient characteristic*
Salmonella	Sickle cell anemia patients (*S. aureus* is still most common)
Pseudomonas	IV drug use with AC or SC joint infection or puncture wound through rubber soled shoes
Bartonella	HIV/AIDS patient following cat scratch or bite
Fungal osteomyelitis	Immunosuppressed, long-term IV medications, or parentarel nutrition
Tuberculosis	Manifestations include Potts disease

(AC: acromioclavicular; AIDS: acquired immunodeficiency syndrome; HIV: human immunodeficiency virus; IV: intravenous; SC: sternoclavicular)

Risk Factors

Certain conditions and behaviors that weaken the immune system increase a patient's risk of OM, including diabetes mellitus (most cases of OM), sick cell disease, human immunodeficiency virus (HIV), acquired immunodeficiency syndrome (AIDS), rheumatoid arthritis, intravenous drugs use, alcoholism, long-term use of steroids, hemodialysis, poor blood supply, recent injuries, and bone surgery replacements.

Pathophysiology

Bacteria may reach the bone via the bloodstream by direct inoculum caused by, e.g., trauma or surgery or by direct spread from an adjacent soft tissue infection (diabetic foot ulcer or periodontal disease). Whatever the route of access, bacteria must be able to subsequently adhere to components of the bone matrix in order to start the infection. Hematogenous OM results either from the introduction of microorganism into the bloodstream (e.g., via intravenous drug use or infected central venous catheter) or an infection elsewhere has a primary focus [e.g., endocarditis] (**Fig. 1**). Patients with OM will often have one or more pathologic risk focus associated with these mechanisms. OM can be acute and chronic OM. An acute OM progresses over days or weeks and is characterized by inflammation of viable bone. Chronic OM evolves over weeks to months or even years and is distinguished by progression to osteonecrosis with the formation of sequestrum, often in the setting of recurrent of refractory infection. In children, the infection usually starts in the vascular metaphysis of a long bone, most often in the proximal tibia or in the distal or proximal ends of the femur. In adults, hematogenous infection accounts for only about 20% of cases of OM, mostly affecting the vertebrae.

Several classification systems exist to categorize OM. The Waldvogel classification system divides OM into the categories of hematogenous, contagious spread, and vascular insufficiency (mechanism of pathogenesis). Cierny–Mader staging system is based of status of disease process, not in etiology, chronically or other factors (**Table 2**). This classification is based by the extent of host anatomic involvement, physiological status, and comorbid factors than can have influence in clearance of infection successful antibiotic therapy and other treatments.

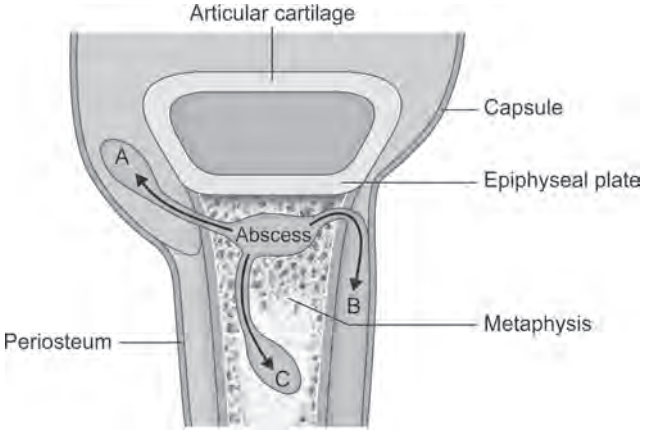

FIG. 1: The spread of pus from a metaphysical focus of osteomyelitis (A) directly into the joint, (B) into a subperiosteal abscess, and (C) into the medullary canal.

Clinical Presentation and Physical Examination

The most common anatomic locations of OM correlate with their mechanism of pathogenesis. Acute hematogenous OM occurs predominantly in children, with the metaphysis of long bones the most common location (e.g., femur and tibia). Contiguous spread is usually in lower extremities, especially in feet (diabetes and other vascular ulcers). Patients usually present within several days to weeks after the onset of symptoms. In addition to local sings of inflammation and infection, patients have sings of systemic illness, including fever, irritability, and lethargy. The subacute and chronic forms usually occur in adults. Generally, are secondary, to an open wound, most often an open wound injury to bone or surrounding soft tissue. Localized bone pain erythema and drainage around the affected area are frequently present. The cardinal sings of subacute and chronic OM include draining sinus tracts, deformity, instability and local sings of impaired vascularity, range of motion, and neurologic status. The incidence of deep musculoskeletal infection from open fractures has been reported to be as high as 23%. Other patients' factors such as altered neutrophil defense, humoral immunity, and cell-mediated immunity can increase the risk of OM. In diabetic and other patients with chronic wounds, certain physical exanimation findings specific to and highly suggestive of OM are easily identified at the bedside. Typical clinical findings include tenderness over the involved bone and decreased range of motion in adjacent joints.

Diagnosis

The diagnosis of OM is based primarily on the clinical findings, with data from the initial history, physical exanimation, laboratory testing, tissue sampling, and imagery. Due to non-specific constellation of sing and symptoms often associated with OM, emergency physicians must have a high index to suspicion for this disease.

Initial laboratory testing in ED should include a complete blood count (CBC), erythrocyte sedimentation, and C-reactive protein (CRP) at the minimum. Blood cultures are positive in up to one-half of children with acute OM. Patients with OM can have or not a leukocytosis. In OM of the extremities plane film and bone scintigraphy remain the primary investigative procedures.

Radiographic evidence of bone destruction by OM may not evident until approximately 2 weeks after the onset of

TABLE 2: Cierny–Mader classification of osteomyelitis.

Anatomic location	
Stage I	Medullary
Stage 2	Superficial
Stage 3	Localized
Stage 4	Diffuse
Host type	
Type A	Normal
Type BL	Locally compromised
Type BS	Systemically compromised
Type C	Treatment is worse to the patient than infection

infection. These radiologic tools help to rule out other potential pathology (e.g., fracture) and provide a baseline for future comparison. A bone abscess found during subacute or chronic stage of hematogenous OM is known as a Brodie's abscess. Computer tomography (CT) can demonstrate periosteal reaction, cortical/medullar bone destruction, and/or adjacent soft tissue infection in great detail.

Magnetic resonance imaging (MRI) can be extremely helpful in unclear situations. This imaging modality is particular useful when a patient is suspected of having an OM and discitis septic arthritis involving the axial skeleton and pelvis. MRI is the most sensitive (90%) and specific (83%) imaging modality available for diagnosing OM, often as early as 3–5 days after the initial onset of infection.

Histologic and microbiologic exanimation of bone is the gold standard for diagnosing OM. Cultures of sinus tract samples are not reliable for identifying causative organisms. Therefore, biopsy is advocated to determine the etiology of OM. Isolation of the infecting microorganism from bone followed by antibiotic susceptibility testing (antibiogram) are important in directing treatment.

Treatment

After the initial evaluation, staging, and establishment of microbial and susceptibilities, treatment includes antimicrobial therapy, debridement with management of dead space, and, if necessary, stabilization of bone. In the most patients with OM, early antibiotic therapy produces the best results. Eradicating a deep-seated infection of the bone can be difficult and successful treatment of OM often requires a combination of medical and surgical therapies. Emergency physician must determine first in caring of a patient with OM is to decide whether antibiotic therapy needs to be initiated ED or not. It depends on the hemodynamic condition of the patient. If the patient's condition appears stable, this allows us to wait a little time until the results of the bone biopsy comes and where we get an information about the type of antibiotic therapy which indicated by antibiogram. However, if the patient is unstable or has sing and symptoms of sepsis every antibiotic therapy is justified. In suspected cases for active OM, blood samples for blood culture should be taken before the antibiotic therapy.

Antibiotic Therapy

Acute hematogenous OM is best managed with careful evaluation of microbial etiology and susceptibilities and a 4–6-week course of appropriate antibiotic therapy. After cultures have been obtained, an empiric parenteral therapy regimen (nafcillin) plus ceftriaxone is initiated to cover clinically suspected organisms. Children with acute OM should receive 2 weeks of initial parenteral therapy before they are given an oral antibiotic therapy.

Chronic OM in adults is more refractory to therapy and is generally treated with antibiotics and surgical debridement. Depending on the type of chronic OM patient may be treated with parenteral antibiotic therapy for 2–6 weeks. Oral therapy using fluoroquinolone antibiotics for gram-negative organisms is presently being used in adults with OM. Other antibiotics that can used to gram-negative agents, such as *P. aeruginosa*, can be achieved with cefepime or meropenem. Gram-positive agents can be covered with vancomycin. Metronidazole can be used to anaerobic agents. Use of vancomycin in combination with piperacillin-tazobactam should be avoided due to risk of nephrotoxicity.

Debridement and Surgical Therapy

The indications for surgical treatment of OM will depend on many factors, including the anatomic location, duration of symptoms, mechanism of pathogenesis, and patient comorbidities. The quality of debridement is the most important and critical factor in successful management. After debridement with excision of bone, removing all infected soft tissues, it is necessary to obliterate the dead space created by the removal of tissue. Dead space management includes local free tissue transfers (e.g., flap coverage) and the use antibiotic impregnated beads. Soft tissue procedures have been developed to improve the local blood flow and antibiotic delivery.

Special Situations

Diabetes mellitus: Diabetes is a significant contributing factor in OM, particularly when patients have concomitant neurologic or vascular abnormalities. *P. aeruginosa* is most frequently isolated from these infections. Initial hospitalization to these patients for vascular supply, identify the agents, and debridement and drain tissue may be necessary.

Follow-up

During treatment, patients with OM should be followed closely for signs and symptoms of worsening infection. After the treatment, follow-up should be based on the response of therapy and the overall health of the patient.

SPONDYLODISCITIS (VERTEBRAL OSTEOMYELITIS)

Spondylodiscitis is an infectious inflammation that affects the vertebrae, vertebrae disk, and adjacent structures. Commonly referred as vertebral OM, spondylodiscitis has an annual incidence of 2.4–4.8 cases per 100,000 individuals. All ages can be affected, but the appearance mostly increases with age. Men are up to three times more than women; this is probably because of higher frequency of comorbidities in men. Spondylodiscitis is the most common complication of sepsis or local infection, usually in the form of an abscess. It usually affects two contiguous vertebrae and space between them. The most common site of infection is the lumbar spine (58%) followed by thoracic (30%) and cervical spine (11%).

Etiology

The main causative organisms are staphylococci and *Mycobacterium tuberculosis*, but potential organisms include a large number of bacteria (*Escherichia coli*, *P. aeruginosa*, and *Proteus mirabilis*), fungi, and rarely zoonosis. Spinal infections can be described etiologically as pyogenic, granulomatous tubercular, fungi, and parasitic. Pyogenic spinal infections include spondylodiscitis, spondylitis, and discitis.

The predisposing and triggers for this infection are diabetes mellitus, age, cardiovascular disorders, drug abuse and longtime steroid intake, alcoholism and nicotine abuse, spinal abnormality, bacteremia (endocarditis), injection drug use, serious trauma, impaired immune competence (chemotherapy and HIV), anemia, cancer, organ failures (renal, liver, or cirrhosis), and rheumatic diseases.

Clinical Presentation

The symptoms of spondylodiscitis are nonspecific and diffuse. More than 90% of patients will complain of localized back or neck pain that is often worse at night and not alleviated by rest and analgesics. Most of them complain an radicular pain which spread to the chest and abdomen. Most of them have fever (less common in patients with tuberculous spondylodiscitis, half of the cases) and neurologic symptoms such as sensory deficit, leg weakness, paralysis, radiculopathy, and sphincter loss. With progression of disease to adjacent structure patient may complain of motor deficit such as limb weakness i.e., paraplegia and quadriplegia. Weight loss may also occur in tubercular or other chronic infections. Lumbar spine infection can precipitate abscesses of the psoas muscle.

Diagnosis

Medical history; often is not characteristic. Either acute fulminant development of symptomatology with localized pain and high fever or gradual insidious onset. The clinical examination includes inspection concentrating on local changes and taking a detailed neurological status. There is typically pain on heel strike, impaction, and percussion, but little local pain on pressure. Diagnosis can delay due to misdiagnosing because symptoms are nonspecific. The laboratory parameters be determined are leukocytes, CRP, and erythrocyte sedimentation rate (ESR). In patients with acute disease, there are a massive increase in the inflammation parameters and in ESR. CRP is typical in chronic cases. Conventional X-ray is the first investigative procedure for diagnosing but is unreliable in early phase of spondylodiscitis (abnormalities cannot be detected until 2–8 weeks). The main methods to diagnose a spondylodiscitis are MRI, biopsy, and microbiological tests such as polymerase chain reaction (PCR) to determine an infectious cause.

An MRI is the diagnostic procedure of choice if spondylodiscitis is suspected. MRI with gadolinium imaging method has a highest sensitivity (93–96%) and specific (92–97%). This provides an image of the whole length of the spinal column so that infection be detected. CT scan can identify cortical destruction and adjacent soft tissue when MRI is contraindicated. The definitive diagnosis of spondylodiscitis is made by bone biopsy with multiple specimens submitted for microbiological culture and pathologic review.

Treatment

Empiric antibiotic therapy can be initiated in emergency department only for severe infection, otherwise antibiotic should be planned after and according to culture and sensitivity report. Antimicrobic therapy for spondylodiscitis should to continue for at least 6 weeks, tuberculosis should take 12 months (consult the infectious disease specialist). Rest and brace use.

Follow-up

Laboratory and X-ray every 6 weeks.

Surgical Treatment

Debridement may be necessary in the setting of epidural or paravertebral abscesses, persistent pain, vertebral destruction/instability, and deformity (consult spine surgeons).

SPINAL EPIDURAL ABSCESS

A spinal epidural abscess (SEA) is an accumulation of pus in the epidural space that can mechanically compress the spinal cord. SEA can develop independently of spondylodiscitis and usually occur in thoracic or lumbar regions. Overall, the incidence of SEA is 1.8 cases per 100,000 persons per year.

Etiology

The most common bacteria that causes SEA come from *Staphylococcus* and *Streptococcus* bacteria followed by *E. coli* and mixed anaerobes. Occasionally the cause is a tuberculosis come from thoracic spine (Pott's disease). Other possible causes of SEA include boils that develop on skin, especially on the scalp and back, septicemia, injury, foreign objects (bullet and knife), and complications from back surgery or puncture procedures. The risk factors who help to develop the SEA are using an anticoagulant agents and blood thinners, a weakened immune system, and a ruptured gallbladder.

Clinical Presentation

Patient with SEA can present to the ED anywhere along a continuum of disease with a wide range of signs and symptoms. The symptoms of an epidural abscess depend on the location of the abscess. Epidural abscess symptoms are headache, disturbed consciousness, fever, movements problems, trouble walking, weakness, (i.e., cauda equina, conus medullaris), inability to control bowels and bladder, erectile dysfunction. A high index of clinical suspicion followed by timely diagnosis of SEA is essential to prevent complications of cord compression and irreversible sensory loss or paralysis.

Diagnosis

Laboratory (CBC, ESR, and CRP). Blood cultures are positive approximately in 60% of patients with SEA. Imaging include X-ray and noncontrast radiology are not much helpful. MRI and CT myelography are highly sensitivity (>90%). Consider MRI to diagnose SEA if patient has unexplained pain. Lumbar puncture is contraindicated because it may trigger cord herniation.

Treatment

If abscess causes neurologic compromise, immediate drainage. Antibiotics with or without aspiration may be sufficient. If the abscess developed after a neurosurgical procedure or urologic instrumentation, an aminoglycoside is added to cover gram-negative bacteria. An epidural requires immediate treatment. Symptoms can include headache, fever, changes in consciousness, vomiting, changes in sensitive, moving or walking, loss of bladder or bowel control, and erectile dysfunction. *Treatment* is with strong antibiotics. Surgery might be needed to drain the fluid from abscess completely.

SEPTIC ARTHRITIS

Septic arthritis is an infection in the fluid and tissues in the joint. It is usually caused by bacteria but occasionally by viruses or fungi. Infectious arthritis can affect people of all ages and genders. The incidence is reported as two to eight cases per 100,000 of general population. In ED, from total number of patients, septic arthritis presenting with 0.01% of all visits.

Acute infectious arthritis caused by bacteria begins quickly. Most cases of septic arthritis are acute, and can affect healthy people as well as people with risk factors. Cartilage within the joint, which is essential with normal joint function, can be destroyed or damaged within hours or days and called as reactive arthritis. In reactive arthritis, the join can be inflamed but not actually infected. Chronic infectious arthritis begins gradually over several weeks. Very little cases of arthritis are chronic and most often affects individuals with risk factors (**Figs. 2A** to **D**).

The joints most commonly infected are the knee, shoulder, wrist, hip, elbow, and the joint of fingers. Most cases of septic arthritis occurs from hematogenous seeding of a joint in the setting of bacteremia. Less frequently, overlying soft tissue infections can spread contiguously to the joint. Direct inoculation of bacteria into a joint can occur through a traumatic arthrotomy, open fracture with dislocation, arthrocentesis or intraarticular injection, and animal bites, e.g., dog cat. Common risk factors are similar as other musculoskeletal infections such as older age, diabetes mellitus, rheumatic arthritis, joint surgery, prosthetic tissue infection, skin infection, injection drug use, alcoholism, sexually transmitted diseases, hemophilia, dialysis, and sickle cell disease (acute septic arthritis).

Etiology

Acute septic arthritis is usually caused by bacteria and viruses. As in other musculoskeletal infections most causative bacteria are *Staphylococcus aureus* and streptococci, but can be caused by other bacteria such as *E.coli* and other gram-negative bacteria Neisseria *gonorrhoeae*. Viruses such as HIV hepatitis B and C can also be causative agent at any age. Spirochetes that cause Lyme disease and syphilis can infect joints. *Candida* septic arthritis may be associated in patients with impaired immune systems. Chronic septic arthritis is usually caused by *Mycobacterium tuberculosis* and fungi. Risk factors for chronic septic arthritis include rheumatoid arthritis, HIV infection, steroid long-time use, chemotherapy, and patients with cancer, an artificial joint.

Clinical Presentation

In acute infectious, symptoms usually begin over hours to a few days. Joint pain associated with warmth, swelling, redness, and restricted movement are the primary presenting features of septic arthritis. Moving and touching is very painful. Fluids collects in the infected joint causing it so swell and stiffen. Symptoms sometimes also include fever and chills. Fever is not diagnostic symptom. In chronic arthritis, symptoms are usually gradual swelling, mild warmth and mild or no redness of the affected joint area, and aching pain that may be mild and less severe than in acute septic arthritis. Usually, a single joint is affected. Unrecognized septic arthritis can progress to joint destruction, OM, and sepsis, with an overall mortality approaching 10%. Early and timely recognition of septic arthritis by the emergency physician is necessary to improve outcomes.

Diagnosis and Differential Diagnosis

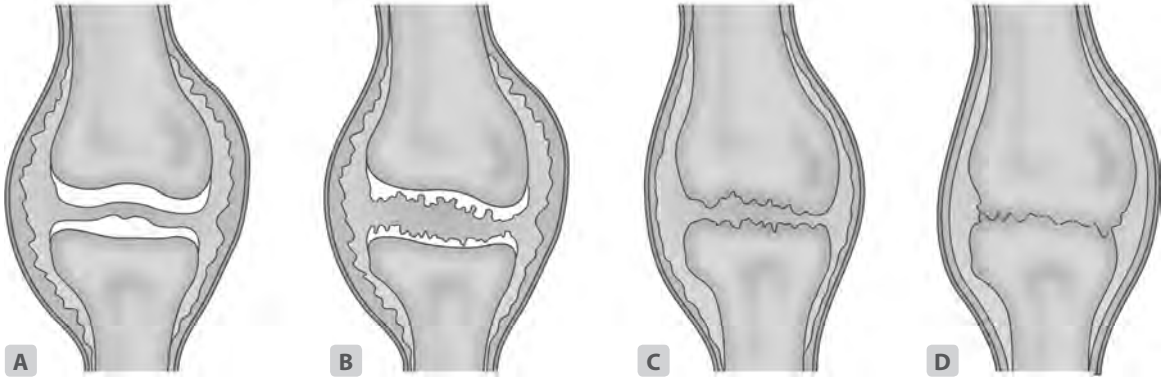
A through history and physical examination are essential of diagnosis, but diagnostic evaluation includes blood tests (CBC, ESR, and CRP), analysis and culture of joint fluid, sometime sputum, spinal fluid, and urine tests. Imaging such as X-ray, CT scan, ultrasonography, and MRI are helpful for diagnosing septic arthritis. Usually a sample of joint fluid (joint aspiration) is essential. Synovial fluid should be submitted for cell count with differential, Gram stain, and microbiological (aerobic and anaerobic) culture. The higher the synovial white blood cell (WBC) count, the greater the chances of septic arthritis. Multiple sets of blood tests and cultures also should be obtained when hematogenous septic arthritis is suspected to improve the chances of identifying a causative microorganism. Imaging helps well such as plain radiography of the infected joint may reveal joint destruction. CT and MRI help in evaluation of septic arthritis also and ultrasonography is done to identify accumulations of fluid or collections of pus (abscesses). Differential diagnosis for septic arthritis includes rheumatic arthritis, Reiter's syndrome, psoriatic arthritis, ankylosing spondylitis, and osteoarthritis.

Therapy

Successful treatment depends on antibiotics, antifungal drugs, removal of the pus, and splinting of the joint, followed by physical therapy.

PERIPROSTHETIC JOINT INFECTION

Performing joint aspirations can identify patients with infection who were erroneously categorized as "aseptic failures". PJIs are one of most challenging and frequent complications after lower extremity joint (hip and knee) arthroplasty.



FIGS. 2A TO D: Acute suppurative arthritis. (A) Pathology in the early stage; (B) There is an acute synovitis with a purulent joint effusion; (C) Soon the articular cartilage is attacked by bacterial and cellular enzymes. If the infection is not arrested, the cartilage may be completely destroyed; (D) Healing then leads to bony ankylosis.

Anywhere from 0.5–2.0% of primarily total hip or knee arthroplasty procedures are complicated by PJI.

Based on the proposed criteria, definite PJI exists when: (1) There is a sinus tract communicating with the prosthesis, (2) a pathogen is isolated by culture from at least two separate tissue or fluid samples obtained from the affected prosthetic joint, (3) four out of six criteria exist [elevated ESR and CRP, elevated synovial WBC, elevated synovial fluid neutrophil, presence of purulent fluid in the affected joint, isolation of microorganism in one culture of periprosthetic tissue or fluid, and >5 neutrophils per high-power field (HPF)]. PJI may be present if fewer than four criteria are met. Risk factors include male gender, tobacco use, elevated body mass (>30 kg/m^2), diabetes mellitus, rheumatic arthritis, corticosteroid use, previous joint surgery (including revision arthroplasty), and depression.

Pathogenesis

Foreign body devices are covered by host proteins (e.g., fibronectin) after implantation favoring bacterial adherence. Absence of implants causes impairment of activation and degranulation of the granulocyte.

Clinical Manifestations

- *Acute exogenous PJI*: Local sign of inflammation (wound dehiscence, secretion, erythema, warmth, swelling, and tenderness in affected joint and surrounding soft tissue).
- *Acute hematogenous PJI*: Pain after implantation without sing for infection and new onset articular effusion.
- *Chronic PJI*: Pain because of early loosening, local inflammation, sinus tract, and chronic articular effusion.

Microbiology

Most frequent microorganisms are *Staphylococcus aureus* and streptococci and *Propionibacterium acnes* (most important microorganism in periprosthetic shoulder infection).

Treatment

Cornerstone of successful treatment is early recognition and diagnosis. Cure is only possible with adequate surgery combined with long-term antibiotic therapy. Appropriate surgical intervention. The total duration of antibiotic treatment following revision surgery should not exceed 12 weeks.

SUMMARY

Patients with musculoskeletal infections can have heterogeneous presentations, as the signs and symptoms are often occult and nonspecific. *Staphylococcus aureus* is the most common microorganism associated with bone and joint infections. Clinical presentations of musculoskeletal infection in patients presenting to emergency care can range from chronic wounds and nonspecific bone or joint pain to functional debilitation, and even neurologic compromise when the spine is involved. Definitive diagnosis requires sampling of affected tissue for Gram stain and microbiologic culture. Emergency physicians play a critical role in early recognition, evaluation, and management of these infections. Appropriate collection of microbiologic cultures (e.g., blood and synovial fluid) before empiric therapy in the ED has significant implications for isolating causative microorganisms and guiding downstream treatment. Antibiotic therapy may even be safely withheld to pursue bone biopsy and culture if the patient is clinically stable. The mainstay of treatment for bone and joint infections is antibiotic therapy, but surgical consultation for irrigation and/or debridement may be necessary in certain clinical situations. A low threshold should adopt to seek orthopedic surgery and infectious disease specialist consultation in patients presenting with bone and joint infections in the ED and many will require hospitalization for definitive care, combing medical and surgical approaches.

195 CHAPTER

Management of Sexually Transmitted Infection

Shahbaz Anees, Durre Aden

INTRODUCTION

Management of patients especially those who are at the highest risk for sexually transmitted infections (STIs) can be challenging at times because of the delay in the diagnosis and disease being asymptomatic many times. Thus, there is a need for proper investigations, management, and follow-up of patients with STIs.

EPIDEMIOLOGY

Sexually transmitted infections include human papillomavirus (HPV), *Neisseria gonorrhoeae* (GC), *Chlamydia trachomatis* (Ct), herpes simplex virus (HSV), syphilis, human immunodeficiency virus (HIV), and pelvic inflammatory diseases (PIDs). The number of cases of STIs has increased and is seen more commonly in young adults, pregnant females, and high-risk groups such as homosexual males. The number of cases of syphilis has increased from 17.6% from 2015 to 2016. Generally, most of the patients are either asymptomatic or go for regular outpatient treatment, but still few patients can come to the emergency department (ED) if health care access is limited or patient has some kind of complications. Around 7–16% of STIs are treated in the ED.

A study done by Pearson et al. in 2017 showed that STI visits to the ED have increased. STI treatment without testing impairs the determination of prevalence and incidence of STIs.

ROLE OF THE EMERGENCY DEPARTMENT

Most of the patients with STIs are either asymptomatic or present with nonspecific symptoms. Screening for STIs in an ED can be difficult and challenging as the healthcare personnel are busy treating other acute emergency medical conditions.

So, most of the patients who are treated for STIs are treated symptomatically in the ED based on their chief complaints, such as vaginal/penile discharge or painful urination. Thus, a significant number of patients with STIs remain either undiagnosed or untreated.

Therefore, emergency care providers must be aware of the prevalence of the disease and can have a high index of suspicion of patients with STIs. Testing for STIs should be done even when test results are not immediately available for any patient coming with symptoms such as vaginal or penile discharge or dysuria and STIs are a differential.

Among the various available test, nucleic acid amplification tests (NAATs) are highly specific and sensitive and can help in diagnosis, management, and follow-up of the patients in different ways.

Once the patient is aware that their test results are positive for an STI, they are less likely to acquire an STI in the future. Reed et al. in 2015 in a study on adolescent women also found that those who were aware of their test results had a reduced number of a subsequent visit to the ED for the diagnoses of STI. Many times symptoms of STIs resolve without treatment and leads to permanent sequelae like infertility or PID. NAAT is especially important in patients with recurrence of symptoms and can help in the appropriate management and drug-resistant case. Once the confirm diagnosis of STI is made, patients can more precisely direct their partners to proper therapy which is known as expedited partner therapy (EPT). A diagnosis of STI may help provide pre-exposure prophylaxis (PrEP) against HIV infection.

RISK FACTORS

Young patients with age <25 years, history of sexual contact with multiple partners, not using proper barrier conceptions, drugs, and exchanging sex for drugs and money are high-risk groups for STIs.

EVALUATION

A proper history including sexual history and complete physical examination should be conducted to narrow down the diagnosis.

INVESTIGATIONS

Gold standard testing for most STIs is NAATs and cultures. This is the delay in test results that leads to a primarily syndromic approach to STI diagnosis and frequent empiric treatment. In one study, patients who tested positive for *Chlamydia* or gonorrhea were more likely to have received appropriate

antibiotics than those patients who were negative for either demonstrating that ED providers use symptoms or clinical findings to avoid overtreatment. ED providers treat about 50% of patients with an STI at the time of visit. Follow-up for these patients with an untreated STI is essential, and challenges can be met with focused follow-up planning. In this chapter, we will be dealing with some of the commonly encountered STIs in the emergency room (ER), their management, and empiric treatment.

CHLAMYDIA

Pathophysiology

Chlamydia is a sexually transmitted disease (STD) caused by Ct, a gram-negative obligate intracellular bacterium. Some serotypes of Ct can cause lymphogranuloma venereum (LGV), which are seen especially in patients that participate in anal sex, specifically among men who have sex with men (MSM). They infect columnar epithelial cells in the cervix, urethra, rectum, and oropharynx.

Adolescent females are predisposed to *Chlamydia* due to continued presence of columnar epithelium in ectocervix.

Clinical Presentation

Most of the patients are asymptomatic; however, some can present with vaginal or urethral discharge, rectal discharge, dysuria, abdominal pain, testicular pain, or symptoms of PID.

Special attention should be paid to patients presenting with rectal pain or discharge who are suspected to have *Chlamydia*.

Physical Examination

An examination may show a watery urethral discharge in men or clear endocervical discharge in women. LGV acquired from receptive anal sex can present with proctocolitis, and the associated lymphadenopathy can cause discomfort. All patients with Ct need instructions to abstain from sex for 7 days after treatment and to seek retesting in 3 months (1 month if pregnant) along with prevention counseling. All sex partners in the previous 60 days should also be tested and treated. Some state laws allow for EPT, which is prescribing treatment to partners of patients with proven Ct via a prescription given to the patient for the partner. Large-scale randomized controlled trials have shown that EPT reduced rates of recurrent infections in patients, but EPT is often not available in the ED setting.

Diagnosis

Gram stain of the sample can be done however culture and NAAT are more specific tests.

Treatment

Chlamydia can be treated with azithromycin 1 g PO single dose or doxycycline 100 mg PO twice daily for 7 days. However, LGV can be treated with doxycycline 100 mg orally twice a day for 3 weeks. All patients should be counseled for abstinence from sex for 7 days after treatment and to come for retesting in 3 months (1 month if pregnant). All sex partners of the patient within the last 60 days should also be evaluated and treated. EPT reduces the rate of recurrence, but it is not available at ED.

GONORRHEA

Epidemiology

Gonorrhea is the second most common STI in the US, after *Chlamydia*.

Pathophysiology

It is caused by *N. gonorrhoeae*, gram-negative intracellular diplococcus. They also infect columnar epithelial cells in the cervix, urethra, rectum, and oropharynx and the risk factors are similar to that of *Chlamydia*.

Clinical Presentation

Patients present with symptoms similar to Ct. Urethral discharge in males is more mucopurulent than clear in appearance.

Diagnosis

The urethral discharge is sent for Gram stain. The organism can be isolated by culture technique in Thayer-Martin media. The gold standard for diagnosis is NAAT, but it is not available at many centers.

Treatment

Drug resistance is seen in GC, thus dual therapy is needed. Both ceftriaxone and azithromycin are used to reduce the development of cephalosporin resistance in GC.

A single dose of ceftriaxone 250 mg intramuscular (IM) with 1 azithromycin 1 g PO once is given. In patients with allergy to cephalosporin or severe penicillin allergy, gentamicin 240 mg IM 1 plus azithromycin 2 g orally is the recommended treatment with later follow-up.

Follow-up for patients with GC is similar to Ct.

Complications

Neisseria gonorrhoeae can disseminate and can present with septic arthritis, polyarticular arthritis, and/or pustular skin lesions and fever. Such patients require hospitalization and treated initially with intravenous (IV) ceftriaxone 1 g TDS for 7 days.

TRICHOMONAS VAGINITIS/BACTERIAL VAGINOSIS

Epidemiology

It is caused by *Trichomonas vaginalis* (TV), a protozoan parasite. Bacterial vaginosis (BV) is caused by *Gardnerella vaginalis*.

Presenting Complaints

Female patients come with the common complaint of vaginal discharge in EDs while the men are mostly asymptomatic. Vaginal discharge can also be seen with infections such as *Chlamydia*, gonorrhea, *Trichomonas*, yeast, or BV. Trichomonas vaginitis is diagnosed in the ED generally.

Physical Examination

The pelvic examination reveals white copious, malodorous discharge, and irritated vaginal mucosa (strawberry cervix).

Diagnosis

Wet mount shows mobile trichomonads in TV while clue cells (vaginal epithelial cells with adherent coccobacillus) are seen in BV. Culture can be used to isolate the organism.

Patients with TV or BV, both will have a vaginal discharge of pH >4.5 and is a low cost and important test for the diagnosis.

Nucleic acid amplification tests are recommended over wet mount examination for definitive diagnosis of *Trichomonas*.

Treatment

Treatment of TV is metronidazole 2 g PO single dose or tinidazole 2 g PO single dose. Metronidazole 500 mg PO twice daily for 7 days can be given for BV.

Prevention and follow-up instructions are similar to other STIs. Patients with BV should be referred to primary care because of a high recurrence rate.

SYPHILIS

Syphilis is caused by the spirochete, *Treponema pallidum*. It is a complex disease with a course of clinical manifestation with a period of latency between primary and secondary stages. Since the symptoms are nonspecific, so it is also known as a great imitator and a high level of suspicion is required for the diagnosis.

Pathophysiology

It enters the body through the erosion in the skin or mucous membrane during sexual intercourse and spreads into the lymphatics and blood in few hours. Transplacental transmission is also seen in syphilis.

Clinical Presentation

Primary syphilis presents as a painless ulcer having indurated border called as a chancre which resolves in 3–6 weeks without treatment.

Secondary syphilis develops after 4–10 weeks after the chancre resolves. It presents as palmar/plantar rash, condyloma lata, arthralgia, and ocular syphilis in the form eye pain and blurry vision.

Tertiary syphilis follows 1–30 years after the infection.

Physical Examination

Ophthalmology evaluation may confirm uveitis or retinitis.

Diagnosis

It cannot be cultured in vitro. In primary syphilis, the sample is collected from chancre and direct fluorescent antibody (DFA) (darkfield microscopy) is done. Serological tests include nontreponemal test [e.g., rapid plasma reagin (RPR) and venereal disease research laboratory (VDRL)]. They are sensitive in immunocompetent patients but nonspecific. So it should be followed by confirmatory treponemal-specific test [fluorescent treponemal antibody absorption (FTA-ABS), *T. pallidum* particle agglutination (TP-PA), *T. pallidum* particle agglutination assay, and enzyme immunoassay (EIA)]. All patient of syphilis should also undergo HIV testing.

Treatment

Treatment of primary, secondary, or early syphilis is benzathine penicillin G 2.4 million U IM single dose. Neurosyphilis or ocular syphilis is treated with aqueous crystalline penicillin G 18–24 million U/day for 10–14 days. Congenital syphilis is recently increasing. Thus pregnant women should be screened and referred to as obstetrics and gynecology.

HERPES SIMPLEX VIRUS

Epidemiology

Herpes simplex virus is the most important cause of painful ulceration. They are of two types; type 1 HSV (HSV-1) and type 2 HSV (HSV-2) which causes oral and genital lesions, respectively. Seroprevalence is high in old age and females.

Pathophysiology

Herpes simplex virus is a double-stranded deoxyribonucleic acid (DNA) virus and spread through by contact of abraded skins and mucus membranes. HSV-1 is transmitted through nonsexual contact, while HSV-2 spreads through sexual contact. The incubation period is 2–12 days after infection.

Once it enters the skin, it goes to peripheral nerves, sensory and autonomic ganglia, and remains in a latent stage for an indefinite period. It can also go to central nervous system (CNS). Reactivation of the latent virus can occur during stress and immunocompromised state.

Clinical Features

Primary HSV present with fever, bilateral lymphadenopathy, and painful lesions. Lesions are blister-like and coalesce to form a shallow ulcer after a few days. The lesion remains for 2–3 weeks.

The patient may also complain of symptoms of cervicitis, urethritis, and proctitis. Other less common features include encephalitis, myelitis, and ocular manifestations. There is also a risk of vertical transmission.

Diagnosis

Viral culture is the preferred method but only sensitive during the vesicular stage. The polymerase chain reaction (PCR) is more sensitive and practiced at many centers. Cerebrospinal fluid (CSF) PCR along with viral culture is the test of choice for CNS infection.

Treatment

Oral antivirals reduce the number of symptomatic days. If swelling or pain is severe, IV acyclovir may be given. Treatment does not eliminate the viral load.

The partner should be informed about HSV status and abstinence from sex when the lesion and use barrier method even when the lesions are absent.

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease is an ascending infection of the upper reproductive tract and can lead to endometritis, salpingitis, tubal ovarian abscess, and pelvic peritonitis. It occurs due to complications of *Chlamydia* and gonorrhea infection. If untreated, it can lead to scarring and infertility.

Clinical Features

Clinical presentation varies from an asymptomatic state to a septic shock. The patient presents with abdominal pain, fever, and vaginal discharge.

Physical Examination

Mucopurulent cervical discharge, cervical motion tenderness, and adnexal tenderness are seen on examining the pelvis.

Diagnosis

All patients should be tested for *Chlamydia*, gonorrhea, and HIV. ESR and C-reactive protein (CRP) are supportive tests. Transvaginal ultrasonography (USG), laparoscopy, MRI, and endometrial biopsy are specific tests.

Treatment

Oral antibiotics are recommended for ambulatory patients. Ceftriaxone 250 mg IM once or 1 doxycycline 100 mg PO twice daily 14 days are considered. Metronidazole 500 mg orally twice daily for 14 days can also be prescribed. Management with hospitalization and IV antibiotics is indicated if patients are not tolerating oral antibiotics or have a complication like tubo-ovarian abscess (TOA) or are pregnant.

Cefoxitin 2 g IV every 6 hours + 1 doxycycline 100 mg PO twice daily for 14 days are given or metronidazole 500 mg PO twice daily for 14 days can also be used. Surgical consultation may need for management of TOA.

SPECIAL SCENARIO

Pediatrics

Sexual abuse should be suspected in case of STIs in pediatric patients. However, transmission from mother to child occurs in the neonates who present with conjunctivitis and pneumonia and can be life-threatening.

Sexually active adolescents are generally at higher risk of transmission due to several biological and behavioral features. Infections are often asymptomatic and follow-up is poor, so empiric treatment should be given.

Pregnant Women

Sexually transmitted infections can complicate the pregnancy in the form of preterm labor, premature rupture of membranes, low birth weight, stillbirth, and congenital infections in the newborn. These are mostly seen in gonorrhea and Chlamydia infections are unrecognized or untreated in the ED. Diagnosis and treatment is similar to nonpregnant patients. However, tetracyclines should be avoided in pregnancy. All pregnant females with STI should undergo regular prenatal care, PID workup, and empiric treatment and close follow-up.

Men having Sex with Men and Transgender

A high-risk group attending ED for STIs includes lesbian, gay, bisexual, and transgender (LGBT). There have to face discrimination in receiving proper healthcare. The National Transgender Health Survey has reported that 33% of transgender have faced discrimination in healthcare and 16% had experienced discrimination in an ED. Direct sexual history should be taken respectfully asking "What is the gender of your sex partner?" The Centers for Disease Control and Prevention (CDC) recommendations should be followed during the STI testing. All the sites of sexual contact must be tested. In MSM, apart from urine/urethral testing, samples from other sites such as pharynx and rectum for NAAT should be taken. For those who are not comfortable with testing, they should be allowed for self-collected NAATs.

Sexual Assault Victims

The ED healthcare provider should be familiar with local STIs prevalence. They should manage the case with professionals who are trained in assessing and counseling patients of sexual assault. As per the CDC STD guidelines, the following screening tests should be done in adult and adolescent victims of sexual assault:

- NAATs at sites of penetration or attempted penetration for GC and Ct
- NAATs from urine or vaginal specimen for trichomonad
- A wet mount with pH and KOH testing for BV and candidiasis
- Serum testing for HIV, hepatitis B, and syphilis

The CDC STD treatment guidelines recommend the following for treatment and prophylaxis:

- Due to low follow-up rate single-dose, empiric treatment is recommended whenever possible (i.e., for *Chlamydia*, gonorrhea, and *Trichomonas*)
- Emergency contraception
- Postexposure hepatitis B vaccination if the assailant is unknown or the victim has not been previously vaccinated
- If not received already, female victims aged 9–26 years, male victims aged 9–21 years (MSM up to 26 years), should receive the HPV vaccination
- *HIV postexposure prophylaxis (PEP)*: HIV PEP should be done in the following conditions:
  - For the patient presenting within 72 hours of the assault
  - Characteristics and HIV risk behavior of the assailant or assailants, if known (e.g., MSM or injection drug use)
  - The local epidemiology of HIV/acquired immunodeficiency syndrome (AIDS)
- *Exposure characteristics of the assault*:
  - Vaginal or anal penetration
  - Ejaculation on mucus membranes
  - Multiple assailants
  - Presence of mucosal lesions
- Any other characteristics that may increase the risk for HIV transmission
- For a specific regimen and to follow-up, infectious disease specialist should be consulted
- Dispense enough medications to last until the follow-up visit in 3–7 days
- Draw baseline complete blood count and complete metabolic panel

SUMMARY

Managing STI-related emergencies can be challenging. With increasing rates of STI, the role of EDs has proved invaluable in taking care of such patients. The healthcare providers must be aware of the incidence and prevalence of STIs in the local community and its treatment protocol. Proper follow-up, retesting, counseling, and treatment of the patient's partner should be done at an appropriate referral center or STIs clinic. Summary of treatment of STD are given in **Table 1**.

TABLE 1: Treatment summary: Sexually transmitted disease.

Genital ulcer disease	*Herpes simplex*	*First episode*	*Recurrent episodes*
		Acyclovir 400 mg orally thrice daily for 7–10 days or valacyclovir 1 g orally twice daily for 7–10 days	Acyclovir 400 mg orally thrice daily or 800 mg twice daily for 5 days or valacyclovir 1 g orally once daily for 5 days or 500 mg orally twice daily for 3 days
Syphilis	*Primary, secondary, or early syphilis*	*Late or unknown duration syphilis*	*Neuro/ocular syphilis*
	Benzathine penicillin G 2.4 million unit intramuscular (IM) single dose. Doxycycline 100 mg orally twice daily for 14 days	• Benzathine penicillin G 2.4 million unit IM once weekly three doses • Doxycycline 100 mg orally twice daily for 14 days	Aqueous crystalline penicillin G 18–24 million U/day for 10–14 days
Urethritis/cervicitis	*Gonorrhea*	*Disseminated gonococcal infection*	*Chlamydia*
	Ceftriaxone 250 mg once + azithromycin 1 g orally once (dual treatment is recommended)	Ceftriaxone 1 g IV daily or cefotaxime 1 g IV 8 hourly for 7 days	Azithromycin 1 g orally single dose or doxycycline 100 mg orally twice daily for 7 days
Pelvic inflammatory disease	*Outpatient*		*Inpatient*
	Ceftriaxone 250 mg IM once + doxycycline 100 mg orally twice daily for 14 days + metronidazole 500 mg orally twice daily for 14 days		Cefoxitin 2 g IV every 6 hourly + doxycycline 100 mg orally + metronidazole 500 mg orally twice daily for 14 days
Vaginitis/vaginosis	*Trichomonas*	*Trichomonas in pregnancy*	*Bacterial vaginosis*
	Metronidazole 500 mg orally twice daily for 7 days. Tinidazole 2 g orally single dose.	Metronidazole 2 g orally single dose	• Metronidazole 500 mg orally twice daily for 7 days • Clindamycin cream 2% intravaginally at bed time for 7 days • Metronidazole gel 0.75% intravaginally once daily once daily for 5 days

196
CHAPTER

HIV Infections

Susmeet Mishra, Ushirin Bose

INDRODUCTION

Human immunodeficiency virus (HIV) is a retrovirus that attacks the body's CD4 subset of T cells making the body prone to infections and cancers. There are two major subtypes of HIV; HIV-1 and HIV-2 of which HIV-1 is the predominant subtype. HIV is a virus and acquired immune deficiency syndrome (AIDS) is a spectrum of conditions caused by infection with HIV. Ever since the breakthrough of antiretroviral drugs, there has been a major paradigm shift in the care of HIV-infected patients in the emergency department (ED) which includes better quality-of-life. With compliance and treatment success, there must be virtual elimination of AIDS-associated opportunistic infections (OIs). As a result, in United States, the emergency clinician is now more often confronted with adverse events related to these medications, but India differs in presentation. India, being a land of cultural bias and serious issues associated with the social stigma pertaining to acquiring the disease, diagnosis and continuation of antiretroviral therapy (ART) stands a matter of major concern. Thus, the emergency room (ER) doctor should have the following goals:

- High index of suspicion in the probable key cases
- Indigenous knowledge of rare OIs probable in HIV
- Identify patients with noncompliance and low CD4 counts
- Counsel each and every patient and his/her kinsmen who is newly diagnosed.

The HIV epidemic is concentrated globally, with 15 countries accounting for nearly 75% of all individuals living with HIV. An estimated 37.9 million people live with HIV out of which 36.2 million were adults and 1.7 million were children below 15 years. In India, the incidence of HIV is 0.1% and the prevalence of HIV is 0.2%.

ETIOLOGY

The HIV is a bloodborne pathogen acquired in nonoccupational settings, most readily either across mucous membranes or parenterally by the following modes of transmission:

- Unprotected sexual intercourse, especially receptive anal intercourse (eightfold higher risk of transmission)
- A large number of sexual partners
- *Prior or current sexually transmitted diseases (STDs)*: Gonorrhea and chlamydia infections increase the HIV transmission risk threefold, syphilis by sevenfold, and herpes genitals by 25-fold during an outbreak
- Sharing of intravenous drug paraphernalia
- Receipt of blood products (before 1985)
- Mucosal contact with infected blood or needlestick injuries
- *Maternal HIV infection (for newborns, infants, and children)*: Steps taken to reduce the risk of transmission at birth include cesarean delivery and prenatal ART in the mother and ART in the newborn immediately after birth.

PATHOPHYSIOLOGY

There are *five stages of HIV/AIDS infection*:

1. Primary or acute infection
2. The window period ending with seroconversion
3. The asymptomatic period
4. The symptomatic period
5. Full-blown AIDS

Human immunodeficiency virus, a ribonucleic acid (RNA) retrovirus targets hosts immune defense systems by infecting and eventually CD4 cells are the central player in both humoral and cell mediated immunity.

The life cycle of HIV-1 is complex and its outcome is largely determined by the target cell and cell activation. Initially, HIV-1 can gain access to cells without causing immediate lethal damages, but the entry process can stimulate further intracellular signal cascades and facilitation viral replication. During the entry process, the external glycoprotein, gp120 binds to the CD4+ receptor and attaches to the cell membrane surface. Subsequent interactions between virus and chemokine coreceptors (e.g., CCR5 and CXCR4) trigger irreversible conformational changes. The act of *fusion* and release of the viral core into the cell cytoplasm occurs within minutes. After the core disassembles, the viral genome is reverse transcribed into deoxyribonucleic acid (DNA) by the virus own reverse transcriptase enzyme. At the midpoint of infection, the viral protein *integrase* in conjunction with host *DNA repair enzymes* inserts the viral genome into the active domains of the host's chromosomal DNA. Integration is facilitated by an integrase binding host factor, lens epithelium-derived growth factor (LEDGF/p75), which irreversibly transforms the cell into a potential virus producer. This is the stage of *primary infection*. It is undetectable by any serological tests.

After HIV-1 breaches the mucosal barrier, a period in which viral propagation is not yet established and host defenses could potentially control viral expansion.

This *window period* could be between 2 and 12 weeks. The patient is infectious, high viral load, still picks up a negative anybody detection test. The initial replication takes place in the regional lymph organs (e.g., draining lymph nodes) and leads to primary amplification. With migration of infected T lymphocytes or virions into the bloodstream, secondary amplification occurs in the gastrointestinal tract, spleen, and bone marrow results in massive infection of susceptible cells. This is the stage of *clinical latency* and is an *asymptomatic stage.* With peaking viremia, clinical symptoms may manifest during primary HIV-1 infection. The level of viremia in a setting of chronic infection may be a magnitude lower than the primary infection. The reason is mainly attributed to reaching a viral set point because of development of CD8+ lymphocytes. This viral set point predicts the further disease progression. A gradual destruction of the naive and memory CD4+ T lymphocyte populations is the hallmark of HIV-1 infection, with *AIDS (full-blown disease) (CD4 <200)* being the last disease stage.

CLINICAL PRESENTATION

A variety of clinical features can make a patient present to the ED, but many patients present to the ED with complaints unrelated to the disease. Evaluation of HIV-infected patients should be carried out with the same priority-based logical approach used for all ED patients. AIDS manifests as recurrent, severe, and occasionally life-threatening infections and/or opportunistic malignancies. The patient may be asymptomatic leading to delay in diagnosis and treatment or may present with signs and symptoms at any of the stages of HIV infection. The asymptomatic phase is generally benign. Generalized lymphadenopathy is common and may be a presenting symptom.

In the acute stage of HIV infection (first 2–6 weeks after being infected), the symptoms may include fever, a blotchy red rash, diarrhea, headache, nausea/vomiting, fatigue, aching muscles, sore throat, and weight loss. The symptoms may last up to 2 weeks and then completely go away as the virus goes into a nonsymptomatic phase.

The second, chronic stage of HIV infection is usually asymptomatic. However, some HIV sufferers may present with conditions/symptoms such as the thrush, shingles, thrombocytopenia, anemia, seborrheic dermatitis, and weight loss. This period can last for over 10 years. It is during this period of time that HIV can be transmitted to others passed. During this, often asymptomatic phase, HIV is slowly destroying the lymphocytes and immune system. A healthy person has a CD4 T-cell count between 450 and 1,400 cells per mL. For an HIV-infected person, the number of CD4 T-cells steadily drops, putting them at a very high risk of developing other infections and AIDS which is the advanced stage of HIV infection. When the CD4 T-cell count drops to below 200, people are diagnosed with AIDS. Various OIs develop at this stage as described in **Table 1**. HIV infection itself does cause some sequelae, including AIDS-associated dementia/encephalopathy and HIV wasting syndrome (chronic diarrhea and weight loss with no identifiable cause).

Red Flags Features for Human Immunodeficiency Virus Infection

The red flags in HIV infection that warrant a patient to come to the ED and if not treated immediately can be life-threatening or causing permanent disability are persistent fever, headache, weight loss, diarrhea, dry cough, dyspnea on exertion, visual disturbance, neurological, and psychiatric manifestations. *Laboratory findings* include viral count >1,000 copies/mm and cell count 200–250 mL or less.

EVALUATION

History and Physical Examination

A detailed clinical history of the patient is absolutely important in making a provisional diagnosis of HIV-related infections. Physical examination findings may be related to the virus itself or secondary to the OIs of late disease:

- *General appearance of the patient*: The appearance of the patient depends on the stage of the disease. The patient may look very healthy or be ill-looking and cachectic
- *Vitals*: Temperature—fever may be present, pulse—tachycardia may be present, blood pressure—hypotension may be present, respiratory rate—tachypnea seen during fever and respiratory tract infections.
- *Skin*: Folliculitis, seborrheic dermatitis, or psoriasis can be present.
- *Eyes*: Retinal hemorrhage or retinal infiltrates.
- *Head*: Tenderness of sinuses may be elicited.
- *Nose*: Inflammation of the nasal turbinate may be present.
- *Ears*: Unilateral or bilateral deafness or discharge from the ears may be found.
- *Throat*: Periodontal disease or oral herpes simplex lesions or oral thrush may be found.
- *Lungs*: Crackles and rhonchi, dullness to percussion, and increased tactile fremitus can be present.
- *Cardiovascular system*: A heart murmur can be found.
- *Abdomen*: Abdominal tenderness, hepatomegaly, or splenomegaly may be detected.
- *Genitourinary*: Vaginal or urethral discharge can be present.
- *Extremities*: Muscle weakness or joint swelling may be present.
- *Central nervous system (CNS)*: Focal neurological deficits, behavioral changes or gait disturbances may be present.

Interpretation of the Finding

- *Visual field defects (loss or distortion)*: Screen for cytomegalovirus (CMV) retinitis
- *Persistent cough or shortness of breath*: Screen for *Pneumocystis carinii* pneumonia (PCP) and tuberculosis (TB)
- *Persistent headache, change in mental status, or focal neurological changes*: Cryptococcal meningitis (CM), toxoplasmosis, CNS lymphoma, and progressive multifocal leukoencephalopathy (PML)
- *Diarrhea*: Screen for isosporiasis, cryptosporidia, and microsporidia
- *Persistent fever, night sweats, or weight loss*: Screen for all OIs.

TABLE 1: List of opportunistic infections and their manifestations and management in emergency department.

Infection	*Symptoms in emergency*	*Treatment*
Candidiasis (bronchi, trachea, esophagus, and lungs)	Dysphagia, dyspnea, hoarseness, LRTI not responding to medical management directed towards bacterial organisms	Clotrimazole 10 mg troches five times a day or nystatin 500,000 units five times a day gargle
Cryptococcosis (*Cryptococcus neoformans*), pulmonary or CNS or disseminated	Pneumonia as it enters through inhalation, cerebral edema leading low GCS, also effects skin, bones, or urinary tract	Amphotericin B (0.7 mg/kg) IV once a day for 2 weeks alone or in combination with flucytosine (25 mg/kg) IV four times a day for 2 weeks and fluconazole 400 mg per day orally for 8–10 weeks
Cytomegalovirus (CMV) (mainly CMV retinitis) medical emergency	Pneumonia, gastroenteritis, encephalitis, and retinitis	• Ganciclovir 5 mg/kg IV twice a day for 2 weeks then 5 mg/kg/day or foscarnet 90 mg/kg every 12 h for 3 weeks then 90 mg/kg once a day • Ganciclovir implant and ganciclovir 1–1.5 g orally three times a day for ophthalmological manifestation
Herpes simplex virus (HSV)	Painful cold sores, severely lowered CD4 counts, infection of the bronchus, pneumonia, and esophagitis	Acyclovir 200 mg orally five times a day in mild disease and 5–10 mg/kg IV every 8 h for 7 days for severe disease
Kaposi's sarcoma	Flat or raised pink purple spots on skin, life-threatening when involves lung, lymph nodes, and intestine	Cryotherapy or radiation for localized disease or chemotherapy with vincristine, vinblastine, or doxorubicin for widespread disease
Mycobacterium tuberculosis	Cough with hemoptysis, night sweats, prolonged fevers, weight loss, and anorexia	Isoniazid 5 mg/kg orally once a day and rifampin 10 mg/kg orally once a day and pyrazinamide 15–30 mg/kg orally once a day and ethambutol 15–20 mg/kg orally once a day
Mycobacterium avium complex	Persistent fever, night sweats, weight loss, diarrhea, anorexia, and malaise	Clarithromycin 500 mg orally twice a day and ethambutol 15 mg/kg orally once a day and rifabutin 300 mg/kg orally once a day
Pneumocystis carinii	Dyspnea, high fever, and dry cough	Trimethoprim/sulfamethoxazole 15–20 mg of trimethoprim per day orally or IV in divided doses three times a day for 3 weeks
Progressive multifocal leukoencephalopathy	Loss of muscle control, paralysis, blindness, speech problems, and altered mental state	Often fatal
Salmonella	Diarrhea	Ciprofloxacin 500 mg orally twice a day for 2–4 weeks
Toxoplasmosis	Multiple organs	Pyrimethamine 200 mg loading and then 50–75 mg orally once a day for 6–8 weeks and sulfadiazine 1.5 g orally every 6 hours for 6 week and folinic acid 10 mg/day orally for 6–8 weeks

(CNS: central nervous system; GCS: Glasgow Coma Scale; IV: intravenous; LRTI: lower respiratory tract infection)

INVESTIGATIONS

Human immunodeficiency virus can be diagnosed through blood or saliva testing. Objectives of testing are transfusion and transplant safety, diagnosis of HIV infection in symptomatic and asymptomatic individuals, and prevention of parent to child transmission; for postexposure prophylaxis (PEP), epidemiological surveillance using unlinked anonymous HIV testing. *Research serological tests for the detection of HIV are classified as first- to fourth-generation tests based on the type of antigens used and principle of the assays* (**Table 2**). *The National AIDS Control Organisation* **(***NACO) recommends* the use of rapid test kits, which detect >99.5% of all HIV-infected individuals and have false-positive results in <2% of all those who are tested.

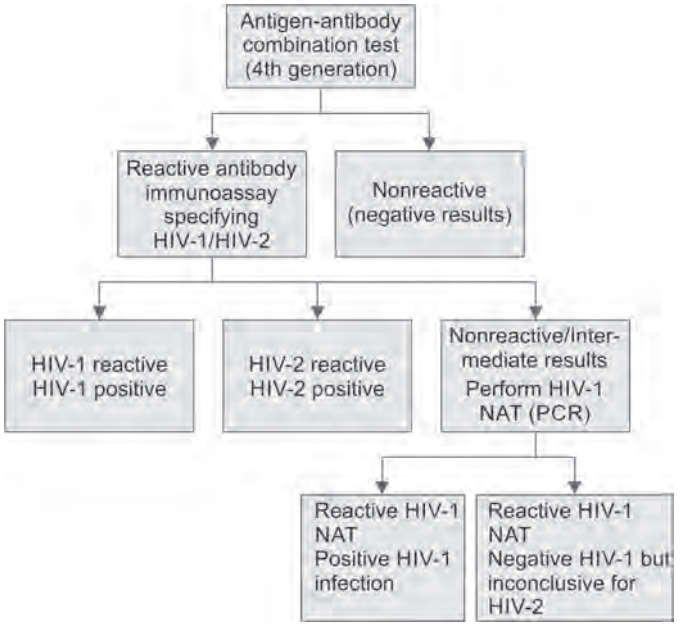
Nucleic Acid Tests

These tests look for the actual virus in your blood (viral load). They also involve blood drawn from a vein. If you might have been exposed to HIV within the past few weeks, your doctor may recommend nucleic acid test (NAT). *NAT will be the first test to become positive after exposure to HIV. Once diagnosis is established the following tests need to be done: Serial CD4 T-cell count monitoring and HIV viral RNA load is a must.* Lower the viral load, lower are the chances of complications and OIs.

More than 50% of new HIV infections are acquired from someone with acute HIV. For every 10-fold increase in viral load, the risk of transmission increases by a factor of 2, 5, 4, 6, and 9. Early diagnosis and treatment of acute HIV has become a public health goal, which translates to ED practice. With the

TABLE 2: Generation of anti-HIV antibody tests.		
First	Antigens from HIV lysates	Lack of sensitivity and specificity
Second	Recombinant proteins and/or synthetic peptides	Improved sensitivity
Third	Recombinant proteins and/or synthetic peptides in an antigen sandwich configuration	• Very high sensitivity. Detects HIV-1 and HIV-2 simultaneously • Reduces window period considerably. Detects IgM antibody in addition to IgG antibody
Fourth	Detection of both HIV antigen (p24) and both antibodies, IgG and IgM	Further reducing the window period

(HIV: human immunodeficiency virus; IgG: immunoglobulin G; IgM: immunoglobulin M)



Antigen-antibody combination test (4th generation)
Reactive antibody immunoassay specifying HIV-1/HIV-2
Nonreactive (negative results)
HIV-1 reactive HIV-1 positive
HIV-2 reactive HIV-2 positive
Nonreactive/Intermediate results Perform HIV-1 NAT (PCR)
Reactive HIV-1 NAT Positive HIV-1 infection
Reactive HIV-1 NAT Negative HIV-1 but inconclusive for HIV-2

(CDC: Centers for Disease Control and Prevention; HIV: human immunodeficiency virus; NAT: nucleic acid test; PCR: polymerase chain reaction)

FLOWCHART 1: CDC-recommended HIV testing algorithm.

Sources: (1) CDC. (2018). Quick reference guide: Recommended laboratory HIV testing algorithm for serum or plasma specimens. [online] Available from https://stacks.cdc.gov/view/cdc/50872. [Last accessed August, 2021]. (2) CDC. (2014). Laboratory Testing for the Diagnosis of HIV Infection: Updated Recommendations. [online] Available from https://doi.org/10.15620/cdc.23447. [Last accessed August, 2021].

advent of fourth-generation antigen-antibody serum tests, acute HIV can now be detected within 10–21 days after exposure. *Point-of-care tests are not as reliable;* therefore the US Centers for Disease Control and Prevention (CDC) recommends laboratory-based testing. A positive antigen-antibody test result, followed by a negative antibody-only test and a positive NAT is expected in cases of acute HIV (**Flowchart 1** shows the testing algorithm). Reverse transcription polymerase chain reaction (RT-PCR) results >1,000 copies/mL indicate likely true positives as the viral load in patients with acute HIV should be several orders of magnitude greater. RT-PCR can detect acute HIV 5 days sooner than the best performing fourth-generation test. However, there is still a window period of 1–2 weeks when patients with very early infection may test negative. In cases highly suspicious for acute HIV with negative testing, repeat testing in 1–2 weeks is recommended. The greatest benefits are experienced if treatment is started as early as possible.

TABLE 3: Antiretroviral drugs.	
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz and rilpivirine
Nucleoside or nucleotide reverse transcriptase inhibitors (NRTIs)	Abacavir, tenofovir, and emtricitabine
Protease inhibitors (PIs)	Atazanavir and darunavir
Integrase inhibitors	Bictegravir sodium/ emtricitabine/tenofovir
Entry or fusion inhibitors	Enfuvirtide and maraviroc

TREATMENT

The ART aim at controlling HIV and preventing its complications rather than curing the infection. So, any patient presenting to the ED should first undergo a thorough assessment of airway, breathing, and circulation to rule out life-threatening conditions followed by definitive therapy. Each class of drugs blocks the virus in different ways. Treatment involves combinations of drugs from different classes to account for individual drug resistance (viral genotype), avoid creating new drug-resistant strains of HIV, and maximize suppression of virus in the blood. *Two drugs from one class plus a third drug from a second class are typically used*. The classes of anti-HIV drugs are presented in **Table 3**. Initiation of antiretroviral treatment associated with numerous side effects such as hypersensitivity and lactic acidosis although starts with mild symptoms but can progress to severe life-threatening complications. Other group-specific complications are summarized in **Table 4**.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

In 2018, 23.3 million people with HIV (62%) were accessing ART globally, 78% of all people who knew their status were accessing ART and 86% of all people receiving ART had viral suppression. ART initiation leads to reduction in viral load in the plasma, temporary improvement in CD4+ T-cell counts, and partial restoration of immune function. However, a certain group of patients develop a dysregulated restoration of antigen-specific immune response and experience clinical deterioration. This was first noted by French et al. in 1992 where he observed a *Mycobacterium avium-intracellulare* infection after zidovudine monotherapy which he explained by a delayed type hypersensitivity (DTH) response to mycobacterial antigens. This phenomenon is known by multitude of names including "immune reconstitution inflammatory syndrome (IRIS)", "immune reconstitution or restoration disease (IRD)", and "immune reconstitution syndrome (IRS)".

TABLE 4: Side effects of antiretroviral therapy.

Group of drugs	*Drug name*	*Side effects*
NRTI	Tenofovir disoproxil fumarate (TDF)	Greater loss BMD than other NRTIs, osteomalacia with renal tubulopathy and urine phosphate wasting, increased serum creatinine, proteinuria, hypophosphatemia, urinary phosphate wasting, glycosuria, and nonanion gap metabolic acidosis
	Tenofovir alafenamide (TAF)	Associated with smaller declines in BMD than seen with TDF. Increase in TG, LDL, HDL, and renal effects but lesser than TDF
	Zidovudine (ZDV)	Anemia, neutropenia, diabetes mellitus, insulin resistance, increased TG and LDL, nausea, vomiting (more than other NRTIs), steatosis, myopathy, and lipoatrophy
	Abacavir (ABC)	Increased risk of MI, contraindicated if patient is HLA-B*5701 in view of HSR
	Lamivudine (3TC)	• Severe hepatic flares when withdrawn in patients with HBV and HCV coinfection • *ddI, ddC, and d4T*: Irreversible peripheral neuropathy
	Emtricitabine (FTC)	Hyperpigmentation
NNRTI	All	Decrease in BMD, neuropsychiatric events such as insomnia, abnormal dreams, dizziness, and depression psychosis (more than other drugs in this group)
	Efavirenz (EFV)	QTc prolongation, dyslipidemia (increased TG, LDL, and HDL), increased transaminases and fulminant hepatitis depression, psychosis, suicidal ideation, ataxia, and nervous system effects such as somnolence, insomnia, abnormal dreams, dizziness, and impaired concentration
	Nevirapine (NVP)	• Severe hepatotoxicity associated with HSR (greater risk with women on NVP with CD4 >250 cells/mm^3 and men with NVP with CD4 >400 cells/mm^3) • Never use NVP for postexposure prophylaxis • EFV and NVP are not recommended in patients with hepatic insufficiency (Child–Pugh B or C) • HSR in form of fever, conjunctivitis, facial edema, general malaise, fatigue, myalgia, arthralgias, blisters, oral lesions, granulocytopenia, and lymphadenopathy
	Rilpivirine (RPV)	QTc prolongation, depression, suicidality, and sleep disturbances
	Doravirine (DOR)	Sleep disorders and disturbances, dizziness and suicidality, and self-harm
PIs	All	Decrease in BMD, PR prolongation, dyslipidemia (LPV/r>DRV/r), lip hypertrophy, diarrhea, nausea, vomiting, drug-induced hepatitis, rash, and Stevens–Johnson syndrome (few reported cases)
	Atazanavir/ritonavir (ATV/r)	Cholelithiasis, kidney stones, jaundice due to indirect hyperbilirubinemia, and chronic kidney disease
	Lopinavir/ritonavir (LPV/r)	Diabetes mellitus and insulin resistance
INSTIs	All	Weight gain, insomnia, depression in patients with preexisting psychiatric conditions, rash, and decrease in bone mineral density

(BMD: bone mineral density; HBV: hepatitis B virus; HCV: hepatitis C virus; HDL: high-density lipoprotein; HLA: human leukocyte antigen; HSR: hypersensitivity syndrome reaction; INSTIs: integrase strand transfer inhibitors; LDL: low-density lipoprotein; NNRTI: non-nucleoside reverse transcriptase inhibitor; NRTI: nucleoside or nucleotide reverse transcriptase inhibitor; PIs: protease inhibitors; TDF: tenofovir disoproxil fumarate; TG: triglyceride)

Definition

A paradoxical clinical worsening of a known condition or the development of a brand new condition after initiating ART in HIV-infected patients resulting from restored immunity to specific infectious or noninfectious antigens is defined as IRIS.

A certain minimum criterion should be fulfilled so as to diagnose IRIS. There must be a temporal association between initiation of ART and subsequent development of symptoms (usually within 3 months), with evidence of virologic and immunological response (decrease in plasma HIV RNA level by quite over 1 $\log_{10}$ copies/mL and a rise in CD4+ T-lymphocyte count from baseline) and must exhibit clinical symptoms and signs in keeping with an inflammatory process. A rise in CD4+ T cells (which is neither sensitive nor specific for immune restoration) is often seen in IRIS. But it is not a vital element for the diagnosis, a falling plasma viral load may be a more important indicator.

Criteria for Diagnosis of Immune Reconstitution Inflammatory Syndrome

French et al. have laid down criteria in order to aid the diagnosis. These are:

- *Major criteria*:
  - Atypical presentation of "OIs or tumors" in patients responding to ART
  - Decrease in plasma HIV RNA level by a minimum of 1 $\log_{10}$ copies/mL
- *Minor criteria*:
  - Increased blood CD4+ T-cell count after highly active antiretroviral therapy (HAART)
  - Increase in immune response specific to the relevant pathogen, e.g., DTH response to mycobacterial antigens
  - Spontaneous resolution of disease without specific antimicrobial therapy or tumor chemotherapy with continuation of ART.

Risk Factors

Out of the patients starting ART, 10–32% are reported to develop IRIS. Multiple studies investigating the risk factors for IRIS differ substantially because of difference of cohort groups depending on the study population. Risk factors identified for the developments of IRIS include lower CD4+ cell count at ART initiation, higher HIV RNA at ART initiation, lower CD4+ cell percentage at ART initiation, lower CD4+:CD8+ ratio at ART initiation, more rapid initial fall in HIV RNA on ART, antiretroviral naive at time of OI diagnosis, and shorter interval between OI therapy initiation and ART initiation.

There can also be a genetic predisposition and certain genes are related to an increased susceptibility to the event of IRIS within the presence of mycobacteria and herpes viruses. Young men are inconsistently related to IRIS.

Pathogenesis

The pathogenesis of IRIS remains largely speculative in spite of numerous studies and research. Current theories regarding the pathogenesis of the syndrome involve a combination of underlying burden of antigen, extent of immune restoration following ART, and genetic susceptibility of the host.

Infection and Immune Reconstitution Inflammatory Syndrome

A variety of mycobacterial, viral, fungal, and parasitic OIs are associated with IRIS. The inflammatory response may be to viable pathogens or to the nonviable pathogens or its residual antigen. The syndrome manifests as either of two patterns, "unmasking IRIS" or "paradoxical IRIS". "Unmasking IRIS" is an immune response against a pathogen that never caused any overt clinical disease before initiation of ART. This type of presentation is usually caused by viable organisms. In "paradoxical IRIS", OIs already present at initiation of ART and worsens after therapy. This may be a response to living pathogens or a response to the antigens of nonviable pathogens. *IRIS* should be termed only after ruling out a deterioration of symptoms due to noncompliance.

Tuberculosis

Mycobacterium tuberculosis is one of the most common pathogen known to cause IRIS with reported incidence varying from 8 to 43%.

Several risk factors for the development of paradoxical TB-IRIS have been identified including shorter delay between commencing TB treatment and ART, low baseline CD4+ cell count, higher baseline viral load, rapid reduction in viral load on ART, and disseminated TB.

Tuberculosis-IRIS generally presents as paradoxical disease within the first 2 months and commonly in the first 2–3 weeks of ART initiation. The patient often presents with worsening or appearance of new clinical or radiological features. Common manifestations include return of symptoms such as fever, lymph node enlargement or suppuration, and appearance of fresh infiltrates, mediastinal lymphadenopathy, or enlarging effusion on chest radiograph. TB-IRIS may also manifest as visceral or cutaneous abscesses, CNS disease, pericardial effusion, acute respiratory distress syndrome (ARDS), airway obstruction, and acute renal failure.

Nontuberculous Mycobacteria

The reported incidence of nontuberculous mycobacterial IRIS is 3.5% among patients with a baseline CD4+ count of <100 cells/μL. *Mycobacterium avium* complex (MAC)-associated IRIS typically develops in severely immunosuppressed individuals, who have an excellent response to ART. The syndrome manifests usually after 2–8 weeks of ART in patients with low CD4 counts. Most common manifestation of MAC-IRIS is fever with suppurative painful lymphadenitis (69%), followed by pulmonary disease (19%). It may also involve the joints, spine, skin, and soft tissue. In contrast to disseminated MAC disease of advanced AIDS, MAC-IRIS usually presents as localized disease.

Tuberculosis diagnosis in patients with HIV is challenging, particularly in resource-limited settings. These patients frequently have atypical clinical presentations, extrapulmonary disease, and normal chest radiographs, particularly in presence of advanced immunosuppression.

Blood cultures are effective in 4–56% in various studies.

Cryptococcosis

Manifestations of cryptococcal IRIS include meningitis, lymphadenitis, pneumonitis, and localized abscess. Overall incidence of neurological IRIS is 1.5% in individuals with CD4+ count of <200 cells/μL. Paradoxical CM-IRIS incidence has been reported as 10–42%, in ART-naive patients with CM. Approximately 60% of cases occur within the first month, although the symptoms may present as late as 10–12 months after treatment. Specific risk factors for the development of cryptococcal IRIS include shorter duration between cryptococcal diagnosis and ART initiation, low CD4 counts (<100 cells/μL), higher baseline plasma HIV RNA levels; and higher cerebrospinal fluid (CSF) cryptococcal antigen titers, opening pressures, white blood cell (WBC) counts, and glucose levels. CM iris carries a very high morbidity and mortality unlike other IRIS infections. It has been suggested to delay ART until CSF sterility is achieved with antifungal combinations such as amphotericin B and flucytosine. However, the exact timing of ART initiation and whether attaining CSF culture sterility is important in avoiding IRIS are unknown. Role of corticosteroids is still unknown.

Pneumocystis Jiroveci Pneumonia

Pneumonia caused by *Pneumocystis jiroveci* is one of the most common OIs in patients with advanced HIV disease. Worsening of treated infection may occur within the first 2–3 weeks after initiation of ART. Patients with PCP-IRIS present with recurrence of fever, worsening hypoxia, and fresh pulmonary infiltrates on chest radiograph. Risk factors for developing PCP-IRIS include severe disease (PaO_2<70 mm Hg), early initiation of ART, and recent completion of steroid therapy for PCP.

Viral Infections

Genital ulceration related to herpes simplex virus and genital warts related to human papillomavirus are among the most common presentations of IRIS. Herpes zoster IRIS usually manifests as uncomplicated disease limited to a single dermatome. Eye disease is the most common presentation of CMV IRIS. Three distinct ocular lesions associated with CMV-IRIS have been described: retinitis, vitritis, and uveitis.

IRIS provoked by hepatitis B and C viruses is characterized by hepatitis flare.

Noninfectious conditions associated with IRIS are lupus-like disease, thyroid disease, rheumatoid arthritis, sarcoidosis, and follicular lymphoma.

Prevention

Antiretroviral therapy should be initiated before the onset of severe immunodeficiency and after the treatment of OIs. A detailed evaluation is required for identification of OIs before ART initiation to prevent the unmasking form of IRIS and identification of high-risk features for development of IRIS. When an OI is present, the risk of delaying ART must be weighed in comparison of deferring the ART.

Treatment for Side Effects of Antiretroviral Therapy

Opportunistic infections should be optimally treated. In general, nonsteroidal anti-inflammatory drugs (NSAIDs) should be reserved for milder manifestations of IRIS and steroids for cases with severe inflammation.

Meintjes et al. demonstrated the reduced need for hospitalization and therapeutic procedures and hastened improvements in symptoms, performance, and quality-of-life in patients with TB-IRIS receiving prednisolone at a dose of 1.5 mg/kg/day for 2 weeks followed by 0.75 mg/kg/day for 2 weeks.

Cryptococcal meningoencephalitis, the most severe form of cryptococcosis, is associated with high mortality rates. CM-IRIS requires prompt control of raised intracranial pressure or hydrocephalus. Corticosteroids are indicated for cerebral edema and raised intracranial pressure. Respiratory failure due to ARDS in pulmonary cryptococcosis should also be treated with corticosteroids.

The development of PCP-IRIS after discontinuation of steroid therapy suggests a role for the reintroduction of steroids in these patients.

Acyclovir is beneficial in IRIS-associated zoster. In cases of ocular CMV-IRIS, systemic or periocular steroid injections have been used, but a clear benefit has not been demonstrated. The role of corticosteroids in PML-IRIS is not clear.

POSTEXPOSURE PROPHYLAXIS

After proper history and documentation, PEP should be considered.

Recommended Regimen

Because PEP has its greatest effect if started within 2 hours of exposure it is essential to act immediately. Ideally, therapy should be started within 2 hours and definitely within 72 hours of exposure. *Fixed drug combination of tenofovir 300 mg plus lamivudine 300 mg plus efavirenz 600 mg once daily for 4 weeks* is the recommended regimen. If the source is already on ART, the exposed person must be started on the above-mentioned regimen at the earliest with proper counseling and then refer for an expert opinion. Also, if it is an unknown exposure or known patient of HIV then assessment of stage of infection is important (**Table 5**). Follow-up after exposure includes testing of HIV, anti-hepatitis C virus (HCV), hepatitis B surface antigen (HBsAg) should be done at baseline, month 3, and month 6.

TABLE 5: Assessing the postexposure risk of HIV.

HIV negative	Source is not HIV infected (but consider HBV and HCV)
Low risk	HIV positive and clinically asymptomatic
High risk	HIV positive and clinically symptomatic
Unknown	Status of the patient is unknown and neither the patient nor his/her blood is available for testing

(HBV: hepatitis B virus; HCV: hepatitis C virus; HIV: human immunodeficiency virus)

DISPOSITION

An infectious disease specialist in coordination with others who are expert in HIV often plays a major role in disposition of an HIV-infected patient. Decisions regarding the disposition of all HIV-infected patients are taken based on whether the patient needs to be admitted as an inpatient or can be done away with as an outpatient, but that too only when patient is taking orally, self-ambulatory, and has availability of proper follow-up.

SUMMARY

Human immunodeficiency virus infects the body's CD4 subset of T cells and predisposes the body to acquire opportunistic or recurrent infections and cancers as the disease progresses. AIDS manifests as recurrent, severe, and occasionally life-threatening infections and/or opportunistic malignancies.

In the acute stage of HIV infection (first 2–6 weeks after being infected), the symptoms may include fever, a blotchy red rash, diarrhea, headache, nausea/vomiting, fatigue, aching muscles, sore throat, and weight loss. The second chronic stage of HIV infection is usually asymptomatic. However, some HIV sufferers may present with conditions/symptoms such as the thrush, shingles, thrombocytopenia, anemia, seborrheic dermatitis, and weight loss.

Human immunodeficiency virus infection itself does cause some sequelae, in which *AIDS-associated dementia/encephalopathy* and *HIV wasting syndrome* with some manifestations which have no identifiable cause as yet.

There are four generations of antibody tests of which the fourth generation used for the detection of both HIV antigen (p24) and both antibodies, immunoglobulin G (IgG) and immunoglobulin M (IgM) has the highest sensitivity and further reduces the window period significantly. Other tests include *NATs* and after diagnosis *serial CD4 monitoring and HIV viral RNA load*.

In ED, any case of HIV infection that is encountered should first include the assessment of airway, breathing, and circulation to save the patient from life-threatening emergencies. Following this, depending on the severity of the disease and the type of OIs, a multicentric approach is undertaken in coordination with the infectious disease specialist which involves the use of antibiotic, antifungal, or antiretroviral therapy of different classes.

197 CHAPTER

Care of Immunocompromised and Transplant Patient

Charu Malhotra, Brunda RL, Ritin Mohindra

INTRODUCTION

With the ever-increasing number of immunocompromised patients presenting to the emergency department (ED), it is pertinent for the emergency physicians to possess the requisite knowledge and skills to recognize the infectious complications in this patient population. As compared to immunocompetent individuals, immunocompromised individuals have infections which are more severe and widespread but are deceptively benign. These patients may present with symptoms and signs that mimic noninfectious complications, only to deteriorate rapidly if they are not evaluated and treated urgently. Various immunocompromised conditions are described in this chapter.

Immune response is broadly categorized as:

- Innate (nonmicrobe specific) immunity:
  - Physical barriers
  - Initial inflammatory response
  - Reticuloendothelial system
- Acquired (microbe specific) immunity:
  - Humoral immunity:
    - Antibodies
    - Immunoglobulin
    - Complement
  - Cell-mediated immunity (CMI)
  - Granulocytic macrophages

NEUTROPENIA

Neutropenia is defined as a neutrophil count of <500 cells/mL (5×10^5 cells/L), including band forms, or <1,000 cells/mL (1×10^6 cells/L) and expected to fall to <500 cells/mL over next 48 hours.

Risk of infection in neutropenic individuals is inversely proportional to the absolute neutrophil count (ANC), being relatively less likely when ANC is >1,000 cells/mL and substantially increasing when ANC falls below 500 cells/mL.

Causes of Neutropenia

- Cytotoxic chemotherapy/radiotherapy (usually seen in first 2 weeks of starting treatment)
- Hematological malignant neoplasms

Common sites of infection in the neutropenic patient:

- Lung (25%)
- Mouth and pharynx (25%)
- Gastrointestinal tract (15%)
- Skin, soft tissue, and intravascular catheters (15%)
- Perineum and anorectal area (10%)
- Urinary tract (5%)
- Nose and sinuses (5%)

Fever in the neutropenic patient is defined as a single temperature of 38.3°C (101°F) or higher or a temperature of 38.0°C (100.4°F) or higher over 1 hour. In neutropenic patients, it is recommended to measure the oral temperature or the ear (tympanic) temperature. Rectal temperature measurements are not recommended as the thermometer can tear the thin rectal skin and introduce bacteria into the bloodstream leading to an infection. Fever may be suppressed by immunosuppressive agents such as corticosteroids or nonsteroidal anti-inflammatory drugs.

Neutrophils being an integral part of innate immunity, pose increased risk of bacterial and fungal infections in neutropenic patients. These infections may be manifested by unexplained tachypnea or tachycardia, mental status changes, metabolic acidosis, increased volume requirements, rapid changes in serum glucose or sodium concentration, or acute abdominal pain. Evaluation and management of febrile neutropenia patient is described in **Box 1**.

Risk Assessment and Disposition

Febrile neutropenic cancer patients can be classified into high-risk and low-risk groups by using the Multinational Association of Supportive Care in Cancer (MASCC) risk index score (**Table 1**) or Clinical Index of Stable Febrile Neutropenia

BOX 1: Evaluation and management of adult patient with febrile neutropenia in the ED.

History: Fever or history of fever may be present. The patient has signs and symptoms of acute infection

Physical examination (may give a clue for the offending pathogen):

- Ulcerative lesion in mouth: Viridans streptococci, herpes simplex, *Candida*, and anaerobes
- Necrotizing skin lesions: *Pseudomonas aeruginosa*, *Aeromonas hydrophila*, *Aspergillus*, and *Mucor*
- Nontender subcutaneous nodules: *Nocardia* and *Cryptococcus*
- Nontender pink skin papules: *Candida*
- Black eschar of nose/palate: *Aspergillus* and *Mucor*
- Generalized macular red rash: Viridians streptococci
- Right lower quadrant abdominal pain, tenderness, distention, bloody diarrhea: Typhlitis (neutropenic enterocolitis) caused by *Pseudomonas aeruginosa*, *Escherichia coli*, and *Clostridium septicum*
- Perineal pain and tenderness without inflammation or abscess: Gram-negative bacilli and anaerobes
- Redness or pain at vascular catheter sites: Coagulase-negative staphylococci, *Corynebacterium*, and *Bacillus* species

Investigation

- Complete blood count shows neutropenia (neutrophil count <500 cells/mL, including band forms, or <1,000 cells/mL and expected to fall to <500 cells/mL)
- Obtain blood for measurement of electrolytes, renal and hepatic function, and serum lactic acid
- Obtain blood cultures from each lumen of any existing central venous catheters and from at least one peripheral site, or two blood cultures from separate venepunctures of peripheral veins if no central venous catheter is present
- Chest radiograph if symptoms or signs of respiratory disease are present
- Urinalysis and urine culture if symptoms or signs of urinary tract infection are present
- Stool for culture for routine pathogens and PCR testing for *Clostridium difficile* if acute diarrhea or if acute abdominal pain without diarrhea is present
- Specimens for culture from any site of inflammation, including inflamed or draining catheter exit sites
- If severe mucositis, obtain herpes simplex culture (or PCR testing) if not receiving antiherpes prophylaxis, and obtain smear (Gram stain) for *Candida* pseudohyphae
- Lumbar puncture is not recommended as a routine procedure unless subtle symptoms or signs of meningitis are present
- Consider ultrasonography over a subcutaneous tunneled catheter track and its vein of insertion, which may reveal the presence of an abscess or infected thrombus
- Urgent CT scanning may be indicated: If the chest radiograph is normal or inconclusive in a patient with acute respiratory symptoms/signs, If facial pain or swelling is present, consider obtaining a CT scan of the sinuses without contrast enhancement. In patients with abdominal pain and tenderness, obtain a CT scan of the abdomen and pelvis with intravenous contrast

Treatment

- Assess the need for administration of intravenous fluids
- Febrile neutropenic patients should receive initial assessment within 15 min of triage and first dose of empiric antibiotic within 1 h of arrival at emergency room, as delay in treatment has been associated with poor outcomes and mortality
- Initiate empirical intravenous antimicrobial monotherapy with an antipseudomonal beta-lactam agent (cefepime, meropenem, imipenem-cilastatin, or piperacillin-tazobactam) as soon as possible after cultures are obtained. Other antimicrobials (such as, an aminoglycoside and/or vancomycin) may be added for hypotension or pneumonia (i.e., azithromycin) or if antimicrobial resistance is suspected. For suspected polymicrobial anaerobic infections (such as, intra-abdominal or perianal source), add an anaerobic drug metronidazole or clindamycin) if cefepime is used as the beta-lactam agent. For patients with history of severe penicillin allergy, consult an infectious diseases specialist
- Empirical use of vancomycin is not routinely indicated for all febrile neutropenic patients, but should be considered if there is suspicion for serious catheter-related infection; known colonization with MRSA or penicillin-resistant pneumococci; known isolation of a gram-positive organism before final identification and susceptibility is known; presence of shock; severe mucositis; prior fluoroquinolone prophylaxis; and institutions in which MRSA, vancomycin-susceptible enterococci, and *Streptococcus mitis* (viridans *Streptococcus* group) are frequent pathogens
- Empirical antifungal therapy is only rarely indicated in the ED and should not be initiated by the emergency clinician without consultation with an infectious diseases specialist
- *Aspergillus* and *Candida* species are the most common fungi producing infection in cancer patients with fever and neutropenia. Infection is most likely to develop in neutropenic patients treated with broad-spectrum antimicrobials and in those whose fever persists for > days
- Cell stimulation therapy: For prevention of chemotherapy-related neutropenia, some centers routinely use human recombinant hematopoietic or colony-stimulating growth factors. It may improve outcomes in high-risk patients. However current evidence does not recommend its use in all patients

(ED: emergency department; MRSA: methicillin-resistant *Staphylococcus aureus*; PCR: polymerase chain reaction)

TABLE 1: Multinational Association of Supportive Care in Cancer (MASCC) risk index score.

Characteristics	*Score*
Burden of febrile neutropenia with mild or no symptoms	5
No hypotension (systolic blood pressure >90 mm Hg)	5
No chronic obstructive pulmonary disease	4
Solid tumor or hematologic malignancy with no previous fungal infection	4
No dehydration requiring parenteral fluids	3
Burden of febrile neutropenia with moderate symptoms	3
Outpatient status	3
Age younger than 60 years old	2
MASCC score ≥21 indicates low risk of complications	

TABLE 2: Clinical Index of Stable Febrile Neutropenia (CISNE) tool.

Characteristics	*Points*
Eastern Cooperative Oncology Group performance score	2
Stress induced hyperglycemia	2
Chronic obstructive pulmonary disease	1
Chronic cardiovascular disease	1
Mucositis grade ≥2	1
Monocytes <200 cells/μL	1
CISNE score of <1 is considered low-risk group with risk of complications <1.5% in next 7 days. Outpatient therapy can be considered in low-risk patients	

(CISNE) (**Table 2**) tool in conjunction with clinical assessment. Both scores have been found to have fair discriminatory power. Both these tools used to dispose the patient.

The only recommended outpatient oral antimicrobial therapy for these patients is ciprofloxacin or levofloxacin plus amoxicillin/clavulanate (or plus clindamycin for those with penicillin allergy).

DIABETES

Diabetic patients have increased susceptibility to infection because of defects in immune function, excess substrate for fungal and bacterial growth, vascular insufficiency related to microangiopathy and atherosclerosis, and sensory neuropathy that lead to wound neglect.

Infections seen with increased frequency in diabetic patients include rhinocerebral zygomycosis (formerly mucormycosis) caused by *Rhizopus* and *Mucor* species; malignant (or necrotizing) otitis externa caused by *Pseudomonas aeruginosa*; pneumonia caused by *Staphylococcus aureus* and gram-negative bacilli; tuberculosis, emphysematous cholecystitis, and urinary tract infections including emphysematous cystitis and pyelonephritis; polymicrobial necrotizing fasciitis involving the perineum (Fournier's gangrene) and lower extremities; and psoas abscess, spinal epidural abscess, foot infections with osteomyelitis, and postoperative surgical site infection.

ALCOHOLISM AND CIRRHOSIS

Alcoholics exhibit an increased incidence of oropharyngeal colonization by gram-negative bacteria (35–59% of ambulatory alcoholic patients) compared with control subjects (14–18%). Alcoholics are also more likely to aspirate because of loss of reflex glottic closure associated with acute intoxication, withdrawal seizures, and encephalopathy.

RENAL FAILURE

Infections are a major cause of death in patients with chronic renal failure and are the second most common cause of mortality after coronary artery disease. These patients are often diabetic, which increases their risk for serious morbidity and mortality from infections.

FUNCTIONAL OR SURGICAL ASPLENIA

Functional or surgical asplenia predisposes to fulminant infection with pneumococci and other encapsulated organisms (*Haemophilus influenzae*, *Neisseria meningitidis*, and *Capnocytophaga canimorsus* after dog bites) and, when seen early, may be misdiagnosed as a viral illness, gastroenteritis, or food poisoning.

CORTICOSTEROID

High doses of corticosteroids cause profound dysfunction of neutrophils and mononuclear cells and impair CMI, resulting in an increase in infections caused by pyogenic bacteria, varicella-zoster and herpes simplex viruses, tuberculosis, and a wide variety of other bacteria, fungi, and parasites.

TRANSPLANT PATIENT CARE

Organ transplant patient population is growing rapidly, with the kidney being the most commonly transplanted organ (58%), followed by liver (21%), heart (8%), lung (5%), pancreas (5%), and, less commonly, combined organ transplants and intestine transplants.

Infections are the most common cause of death in transplant patients. Most common symptoms with which patients present to ED is fever.

Transplant patients can develop a number of acute to life-threatening emergencies:

- Transplant-related infection
- Medication side effects
- Rejection
- Graft-versus-host disease (GVHD)
- Postoperative complications or complications secondary to the transplanted organ

GENERAL APPROACH TO TRANSPLANT PATIENT

Transplant organs being devoid of their native innervations are dependent of surgical anastomosis to vessels and other viscera. They may hence present with nonspecific symptoms of pain and seemingly subtle signs and symptoms can be a harbinger of life-threatening complications. High suspicion for

drug toxicities and risk of infection due to immunosuppression needs to be considered in all transplant patients. General approach to post-transplant patient is summarized in **Box 2**. Also important for emergency physician to know various immunosuppressive medication used in post-transplant patient and their adverse effect (**Table 3**) which will be helpful in evaluating the patient.

BOX 2: General approach to transplant patient.

History:

- History of increase or decrease in body temperature
- Changes in baseline function
- Kidney transplant patients—reduced urine output
- Heart transplant patients—reduced exercise tolerance
- Date of transplant surgery
- History of rejection
- History of change in medication history

Physical examination:

- Vital signs
- Volume status assessment
- Head, ear, ear, nose, and throat—periorbital edema (glomerulonephritis), retina (opportunistic infections), sinuses (*Staphylococcus aureus*, mucormycosis, and invasive fungal disease), mouth (*Candida* and HSV), neck (meningismus and retropharyngeal abscess), lymphadenopathy (CMV, EBV, hepatitis, and post-transplant lymphoproliferative disorder)
- Lungs—sign of pneumonia which may be bacterial, viral, or parasitic
- Heart—new heart murmur suggestive of infection
- Pericardial friction rub suggests rejection
- Abdomen—pancreatitis and peritonitis
- Graft site examination
- Skin—graft-versus-host disease
- Extremities—signs of thrombophlebitis
- CNS—meningitis/encephalitis

Investigations:

- CBC, LFT/RFT, CRP, serum procalcitonin, lactate, NCCT head, serum cyclosporine, and tacrolimus levels. Cultures—blood, urine, stool, sputum, vascular access, wound sites, creatine kinase, and urinalysis
- Chest X-ray and chest CT biopsy

Empirical antimicrobial therapy:

- All patients—discuss with transplant team
- Neutropenia—third-generation cephalosporin such as ceftazidime or a carbapenem plus coverage for MRSA
- Suspected MRSA—vancomycin and linezolid
- Parasitic infections—trimethoprim-sulfamethoxazole
- Viral infections—ganciclovir or valganciclovir for CMV and acyclovir for herpes simplex and varicella zoster
- Fungal infections—agent depends on site and severity of illness

(CBC: complete blood count; CMV: cytomegalovirus; CNS: central nervous system; CRP: C-reactive protein; EBV: Epstein–Barr virus; HSV: herpes simplex virus; LFT: liver function test; MRSA: methicillin-resistant *Staphylococcus aureus*; NCCT: noncontrast computed tomography; RFT: renal function test)

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease is an important complication seen with allogenic stem cell transplant. GVHD has been classically divided into acute and chronic variants based on the time of onset using a cut off of 100 days.

Hyperacute GVHD is an unusual and severe form of acute GVHD. Onset occurs in the first week after hematopoietic stem cell transplantation and is characterized by fever, generalized erythroderma, severe hepatitis, fluid retention, widespread inflammation, and shock.

Acute GVHD is typically characterized by involvement of three different systems: skin (rash), gastrointestinal, and liver (jaundice and hepatitis). Consider GVHD in any patient with a rash.

Prophylaxis: Combination of a calcineurin inhibitor (e.g., cyclosporine and tacrolimus) with methotrexate.

Treatment: Treatment is directed by the transplant team, typically PO prednisone or intravenous (IV) methylprednisolone, at 1–2 mg/kg daily, and possibly adjustment of other immunosuppressant doses. Patients may require resuscitation with balanced crystalloids, blood product resuscitation (leukocyte-depleted and irradiated red blood cells), electrolyte replacement, and broad-spectrum antibiotics.

Chronic GVHD is a late complication characterized by immune dysregulation (>100 days after transplantation). It results in severe morbidity, with complications affecting skin (sclerodermatous contractures), muscles (myopathy), bone (osteoporosis), eyes (keratoconjunctivitis sicca), nerves (peripheral neuropathy), and the cardiopulmonary system (physical deconditioning), resembling autoimmune disorders. Risk factors include older age, cytomegalovirus (CMV) seropositivity, and a male who received a stem cell transplant from a multiparous woman. Management is similar to the acute form with prolonged immunosuppression.

TRANSPLANT-SPECIFIC PROBLEMS

Renal Transplantation

Renal transplantation is the treatment of choice for end-stage renal disease. Important complications of renal transplantation are given in **Table 4**.

Common presentations are hypertension, fever malaise, oliguria, graft pain, and tenderness over site worsening renal function with decreased urine output.

Diagnostic workup includes biochemical investigations, serum creatinine, urinalysis, cyclosporine/tacrolimus level, and radiological investigations. *Ultrasound* is done in cases of increased graft size, loss of corticomedullary junction, and prominent hypoechoic pyramids. Renal Doppler studies may demonstrate elevated vascular resistance indices. Biopsy may be required during admission.

Liver Transplantation

Pain abdomen and fever are the most common reasons for ED visits. Other complications and their approaches are discussed in **Box 3**.

TABLE 3: Transplant medication effects (immunosuppressants and relevant adverse effects).

Medication	*Adverse effects*
Cyclosporine	Acute/chronic nephrotoxicity, electrolyte derangements (hyperkalemia and hypomagnesemia), gout, hemolytic-uremic syndrome, gingival hyperplasia, hirsutism, hypertension, and hyperlipidemia
Tacrolimus	Neurotoxicity (headache, tremor, paresthesia, and seizures), hair loss instead of hirsutism, and less hypertension/hyperlipidemia
Azathioprine	Bone marrow suppression, macrocytosis, anemia, hepatotoxicity, and pancreatitis
Mycophenolate mofetil	Abdominal pain, decreased oral intake, nausea/vomiting, diarrhea, anemia, leukopenia, and thrombocytopenia
Corticosteroids	Weight gain, cataracts, acne, skin thinning, bruising, osteoporosis, GI bleeding, hyperglycemia, hyperlipidemia, psychological effects, and Cushingoid appearance
Sirolimus	Thrombocytopenia, leukopenia/anemia (less common), diarrhea, mucosal irritation, buccal ulceration, interstitial pneumonitis, and hyperlipidemia
Polyclonal antibodies	Fever, serum sickness, anaphylaxis, anemia, and thrombocytopenia
Monoclonal antibodies	• OKT3: Headache, aseptic meningitis, encephalopathy, seizures, nausea, vomiting, diarrhea, pulmonary edema, and nephrotoxicity • IL-2 receptor antibodies have rare adverse effects such as anaphylaxis

(GI: gastrointestinal; IL-2: interleukin-2)

TABLE 4: Postrenal transplant complications.

Vascular complications	*Nonvascular complications*
• Renal artery stenosis • Allograft infarction • Arteriovenous fistulas • Pseudoaneurysm • Graft hematoma • Renal artery or vein thrombosis	• Ureteral obstruction • Urine leak • Perigraft and allograft fluid collections (hematomas, lymphoceles, and abscesses) • Neoplasms • GI complications • Post-transplant lymphoproliferative disease

(GI: gastrointestinal)

BOX 3: Postliver transplant complications.

Biliary complications:

- Complication are bile leak, biliary stricture, and biloma
- Necessary investigations are liver enzymes, ultrasound, ERCP, CT, and MRI
- Treatment options are antibiotics, ERCP, and drainage of biloma

Hepatic artery complications:

- Hepatic artery thrombosis, hepatic vein thrombosis, portal vein complications, and pseudoaneurysm
- *Investigations*: Ultrasound (venous thrombus) and CT angiography (arterial thrombus)
- *Treatment*: Thrombolysis and transcatheter ablation

Neurological complications:

- Stroke, cerebral abscess, hypertensive encephalopathy, osmotic demyelination syndrome, and sinus thrombosis
- MRI is preferred in these situation
- Treatment as per complication

(ERCP: endoscopic retrograde cholangiopancreatography)

BOX 4: Approach to patient with lung transplant rejection.

History:

- Patients commonly present with fever, cough, and increasing dyspnea which may often be confused with a respiratory tract infection

Physical examination:

- Cyanosis, diaphoresis, use of accessory muscles of respiration, signs of congestive heart failure, and peripheral perfusion

Investigation:

- Chest radiography, arterial blood gas, and bronchoscopic biopsy (confirmatory diagnosis)

Treatment:

Beta-agonists and anticholinergics. Methylprednisolone 15 mg/kg intravenous (IV), common practice to cover both infections and rejection till definitive diagnosis with biopsy or cultures is confirmed

Lung Transplantation

Lung transplant involves three important anastomoses; airway, pulmonary arterial, and pulmonary vein. Lung transplant-related complications are summarized in **Box 4**.

Cardiac Transplantation

Cardiac transplantation is performed in patients with end-stage heart failure both in newborn and adults. Transplanted heart differs from a normal heart in terms of being denervated and therefore there is no response to centrally mediated tachycardia due to exercise and stress. The denervated heart however is catecholamine responsive. Thus, response to stress and exercise is blunted. However, with proper conditioning a normal response to stress may be ensured. The donor heart has two sinus nodes; one of the recipients and one of the donors.

The electrocardiogram (ECG) therefore has two distinct P waves often being mistaken as atrial fibrillation. Common complications postcardiac transplant are listed as **Table 5**.

TABLE 5: Postcardiac transplant complications.

- Altered physiology
- Dysrhythmia
- Sinus node dysfunction
- Cardiac ischemia
- Rejection
- Infection
- Congestive heart failure
- Stroke (ischemic/hemorrhagic)
- Complications related to ventricular assist devices
- Cardiac allograft vasculopathy
- Infection
- Pulmonary complications:
  - Pneumonia
  - Thromboembolic disease
  - Exercise-induced hypoxemia
  - Pneumothorax
  - Interstitial fibrosis

SUMMARY

While managing the patient in ED, emergency physician should be aware of immunocompromised state of any triaged patient as transplant patient are increasing day by day. So, emergency physician should be aware of various complications and evaluation of the conditions.

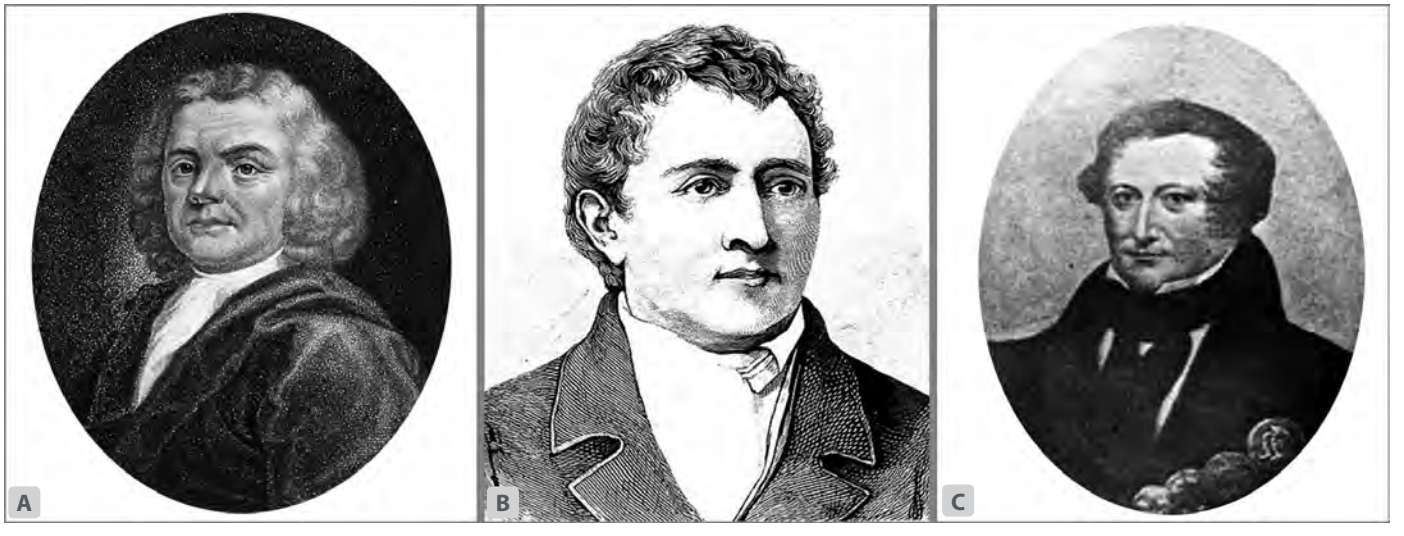
VV Pillay

INTRODUCTION

Scientific methods of analysis for poisons have only recently been developed. Until the 19th century, doctors and scientists harbored faulty notions about the effect of poisons on the human body. It was believed that if a dead body was black, blue, or spotted in places, or "smelled bad," the cause of death was a poison. Other fallacious ideas were that the heart of a poisoned person could not be destroyed by fire and that the body of a person dying from arsenic poisoning would not decay. The first person to suggest a method for detecting poisons in tissues was the Dutch physician *Hermann Boerhaave* (**Fig. 1A**) who theorized that various poisons in a hot vaporous condition yielded typical odors. He placed substances suspected of containing poisons on hot coals and tested their smells. Owing to the widespread use of arsenic as a homicidal poison in the middle ages, it is a small wonder that the first milestones in the chemical isolation and identification of a poison in body tissues and fluids centered around arsenic. In 1775, *Karl Wilhelm Scheele* (**Fig. 1B**) the famous Swedish chemist, discovered that white arsenic (arsenic trioxide) was converted to arsenious acid by chlorine water, and the addition of metallic zinc reduced the arsenious acid to arsine gas. Gently heating the ensuing gas led to the deposition of metallic arsenic on the surface of a cold vessel. In 1821, *Sevillas* utilized the decomposition of arsine for the detection of small quantities of arsenic in stomach contents and urine in poisoning cases. In 1836, *James Marsh* (**Fig. 1C**), a British chemist, developed the first reliable method to determine an absorbed poison (arsenic) in body tissues and fluids such as liver, kidney, and blood.

We have come a long way since then to the present era of sophisticated analytical techniques which can detect even micrograms of virtually any poison in almost any kind of biological specimen. Today, an analytical (toxicology) laboratory has become a vital adjunct to the proper management of poisoned patients. However, it is to be noted that the cornerstone of the management of such patients—*intensive supportive therapy*—is mostly independent of the kind of poison implicated, and hence routine employment of expensive analytical techniques should be avoided. The attending physician must be judicious in calling for necessary investigations and exercise discretion in the choice of tests to be done. At the time that the IV catheter is inserted, blood samples for glucose, electrolytes, blood urea nitrogen (BUN), a complete blood count (CBC), and any



FIGS. 1A TO C: (A) Herman Boerhaave (1668–1738); (B) Karl Wilhelm Scheele (1742–1786); (C) James Marsh (1794–1846).

indicated toxicologic analysis can be drawn. If the patient has an altered mental status, the attending physician may be tempted to send blood and urine specimens to identify any central nervous system (CNS) depressants or drugs of abuse, along with other medications, but the indiscriminate ordering of these tests rarely provides clinically useful information. For the potentially suicidal patient, a paracetamol concentration should be routinely requested, along with tests affecting the management of any specific xenobiotic such as carbon monoxide, lithium, theophylline, iron, salicylates, and digoxin (or other cardioactive steroids), as suggested by history, physical examination, or bedside diagnostic tests. In the vast majority of cases, the blood tests that are most useful in diagnosing toxicologic emergencies are not the toxicologic assays but the "nontoxicological" routine metabolic profile tests such as BUN, glucose, electrolytes, and arterial blood gases (ABGs) or venous blood gases (VBGs).

The potential indications for seeking the help of a toxicology laboratory are as follows:
All the seven indications mentioned can be remembered by the mnemonic *PROMISE*:

1. *P*rognosis: To assess the outcome of a case of poisoning
2. *R*esearch: Into toxicokinetics and mechanisms of toxicity
3. *O*rder: From court or law enforcement officer
4. *M*onitoring: Of treatment measures and their efficacy
5. *I*dentification: Of the nature of poison
6. *S*everity: To assess the seriousness of a given case
7. *E*xclusion: Or confirmation of toxic exposure

Mahoney and associates have categorized the treatment of a poisoning case into four groups with respect to toxicological evaluations:

1. *Toxicity correlates very well with serum levels and specific drug therapy can be instituted*, e.g., digoxin, ethylene glycol, lithium, methanol, paracetamol, salicylates, theophylline.
2. *Toxicity correlates closely with serum level, but only nonspecific care is required*, e.g., barbiturates, ethanol, phenytoin.
3. *Toxicologic testing only serves to confirm fairly clear-cut clinical parameters of poisoning*, e.g., cyanide, narcotics, organophosphates, tricyclics.
4. *Toxicity correlates poorly with serum level, and only nonspecific care is required*, e.g., amphetamines, benzodiazepines, cocaine, neuroleptics.

In fact, most poisoned patients can be treated successfully without any contribution from the laboratory other than routine clinical biochemistry and hematology. This is particularly true when there is no doubt about the poison involved and when the results of a quantitative analysis would not significantly affect therapy. In those cases where an analytical toxicological investigation is deemed beneficial, an orderly progression is desirable in the performance of necessary tests and their interpretation (**Table 1**).

TABLE 1: Phases of analytical toxicological investigation.

Preanalytical phase	*Analytical phase*
• Obtain details of current admission, including circumstantial evidence of poisoning, and results of biochemical and hematological investigations • Obtain the patient's medical history and decide the priorities for analysis	• Interpret the results and discuss them with the clinician looking after the patient • Perform additional analyses if indicated

TABLE 2: Toxic causes of hypo- and hyperglycemia.

Hypoglycemia	*Hyperglycemia*
Acetohexamide, Amprenavir, Chloramphenicol, Chlorpromazine, Chlorpropamide, Cibenzoline, Clove, Ethanol, Ethionamide, Fluorodeoxyglucose, Gatifloxacin, Ginseng, Glibenclamide, Gliclazide, Glimepiride, Glipizide, Gliquidone, Glisolamide, Glisoxepide, Insulin, Iron salts, Lanreotide, Levomepromazine, Mitiglinide, Nateglinide, Paracetamol, Pazopanib, Pentamidine, Perazine, Pipothiazine, Pramlintide, Quinine, Repaglinide, Ritonavir, Salicylates, Saquinavir, Somatostatin, Sulfamethoxazole, Temafloxacin, Tolazamide, Tolbutamide, Trimethoprim	Amphetamines (acute toxicity), Antipsychotic agents (some), Beta-blockers, Corticosteroids, Duloxetine, Epinephrine, L-asparaginase, Niacin, Octreotide, Olanzapine, Pentamidine, Protease inhibitors, Salbutamol, Salicylates, Theophylline, Thiazide diuretics

BIOCHEMICAL AND HEMATOLOGICAL TESTS USEFUL IN TOXICOLOGY

Biochemical Tests

- *Blood glucose*: Apart from insulin and other antidiabetic drugs, *hypoglycemia* is a common feature of poisoning with ethanol, iron salts, paracetamol, and salicylates (**Table 2**). *Hyperglycemia* may be seen less commonly in salicylates, while it is more common in salbutamol and theophylline overdose.
- *Electrolytes, blood gases, and pH*: The value of these parameters in various kinds of poisoning is discussed in the respective chapters dealing with specific poisons.
- *Plasma enzymes*: Shock, coma, and convulsions are often associated with nonspecific increase in plasma or serum activities of enzymes such as *lactate dehydrogenase, aspartate aminotransferase,* and *alanine aminotransferase*. In severe cases, there may be evidence of rhabdomyolysis and disseminated intravascular coagulation manifested by high serum aldolase or creatine kinase, together with myoglobinuria. High serum potassium, uric acid, and phosphate concentrations indicate the onset of acute renal failure. The plasma activities of hepatic enzymes are enhanced in poisoning due to carbon tetrachloride, copper salts, and paracetamol. Chronic alcoholism is often associated with increased *gamma-glutamyl transferase activity*.

Depressed plasma *cholinesterase* activity is a useful indicator of exposure to organophosphate or carbamate pesticide.

Hematological Tests

- *Blood clotting*: Prothrombin time and other blood clotting parameters are likely to be abnormal in acute poisoning with hepatotoxic agents, rodenticides containing anticoagulants, and in certain types of snake bite (especially viper).
- *Hematocrit*: Acute overdose involving iron salts, nonsteroidal anti-inflammatory drugs (NSAIDs), and salicylates can cause gastrointestinal bleeding leading to anemia. Anemia may also result from chronic exposure to heavy metals such as arsenic and lead. A less common (indirect) cause is *glucose-6-phosphate dehydrogenase* deficiency when any of the following drugs have been administered: chloramphenicol, chloroquine, nitrofurantoin, primaquine, etc.
- *Leukocyte count*: Leukocytosis is a recognized feature of acute metabolic acidosis resulting from the ingestion of poisons such as ethylene glycol and methanol. It is also seen as a secondary feature of hypostatic pneumonia following prolonged coma.

ANALYTICAL METHODS USED IN TOXICOLOGY

Toxicology laboratories use several methods to screen for poisons/drugs since there is no single, accurate, and inexpensive method for this purpose. Each method differs in cost, accuracy, complexity, speed, and specificity. The actual equipment required depends on the size of the laboratory and the kind of testing done. A basic, ideal laboratory should have the following facilities/resources:

- Calibrated laboratory balances
- Benchtop centrifuge
- Vortex mixer
- Water bath and heating block
- Butane gas burner
- Fume cupboard/fume hood
- Refrigerator and freezer
- pH meter
- Automatic/semiautomatic pipettes
- Low power polarizing microscope
- Thin-layer chromatography (TLC) plates
- Ultraviolet (UV) spectrophotometer
- UV lamp
- Conway microdiffusion apparatus
- Porcelain spotting tile
- Modified Gutzeit apparatus

In addition, it is desirable to have the following specialized equipment, although they are quite expensive:

- High-performance liquid chromatography (HPLC)[1*]
- Gas chromatography (GC)
- Mass spectrometry (MS)
- Facility for radioimmunoassay (RIA)
- Enzyme-mediated immunoassay technique (EMIT)[†]

There should also be access to sophisticated systems of analysis which are normally beyond the scope of a toxicology laboratory, such as atomic absorption spectrophotometry (AAS), and neutron activation analysis (NAA). In a given case of poisoning, it may be sufficient to know just the nature of poison (*qualitative analysis*) or there may be a need for identification as well as estimation of its concentration in the body (*quantitative analysis*).

QUALITATIVE ASSAYS

- *Trinder's test*: Add 100 mL of *Trinder's reagent* (40 g mercuric chloride in 850 mL water and 120 mL aqueous hydrochloric acid mixed with 40 g hydrated ferric nitrate diluted to 1 L with warm water) to 2 mL urine and mix for 5 seconds.
- A violet or purple color indicates the presence of salicylates (salicylic acid, salicylamide, and methyl salicylic acid). If the specimen merely darkens, the result is considered negative. If only stomach contents or scene residues are available, hydrolyze it by heating with 0.5 mol/L hydrochloric acid in a boiling water bath for 2 minutes and neutralize it with 0.5 mol/L sodium hydroxide before performing the test. The test has a sensitivity of 94% and a specificity of 74% for identifying patients whose salicylate concentrations are greater than 30 mg/dL (2.17 mmol/L). False-positive concentrations (2.8–14.3 mg/dL) have been reported to occur in neonates with hyperbilirubinemia, premature neonates, and children who are seriously ill (e.g., children who have extensive burns).
- *Ferric chloride test*: Add 1 mL of 5% ferric chloride solution to 2-mL urine. A persistent purple color indicates the presence of phenol, phenothiazines, phenylbutazone, oxyphenbutazone, or salicylates.
- *Network FPN test*: Add 1 mL of FPN reagent (a mixture of 5-mL aqueous ferric chloride, 45-mL aqueous perchloric acid, and 50-mL aqueous nitric acid) to 1 mL of urine or stomach contents and mix for 5 seconds. Colors ranging from pink, red, violet to blue may indicate the presence of phenothiazines. Tricyclics may give a green or blue color.
- *O-cresol test*: Add 0.5-mL concentrated hydrochloric acid to 0.5-mL urine or stomach contents, heat it in a boiling water bath for 10 minutes, and cool. Add 1 mL of aqueous O-cresol solution (10 g/L) to 0.2 mL of the hydrolysate, followed by 2-mL ammonium hydroxide, and mix for 5 seconds. A blue or blue-black color indicates the presence of paracetamol or phenacetin.
- *Dichromate test*: Add equal volumes of 10% sodium dichromate in 50% sulfuric acid to the urine sample. Development of a green color indicates the presence of ethanol.
- *Marquis test*: Add a mixture of 3-mL concentrated sulfuric acid and three drops of formalin to the gastric fluid. A purple color, which gradually turns blue, indicates the presence of opium or its derivatives.
- *Lee Jones test*: Add a few crystals of ferrous sulfate and four to five drops of 2% sodium hydroxide to 5-mL gastric fluid. Boil and cool. Add 8 to 10 drops of 10% hydrochloric acid. A greenish-blue color indicates cyanide, while a purple color indicates salicylates in the sample.
- *Reinsch test*: 20 mL of stomach contents or urine is placed in a conical flask along with 10-mL hydrochloric acid and a small strip of copper. This is gently heated for an hour in a boiling water bath inside a fume cupboard. The copper is then removed and examined. A silvery deposit indicates mercury poisoning, while a black deposit indicates

*Also referred to as high-pressure liquid chromatography.

[†]Also referred to as enzyme multiplied immunoassay technique.

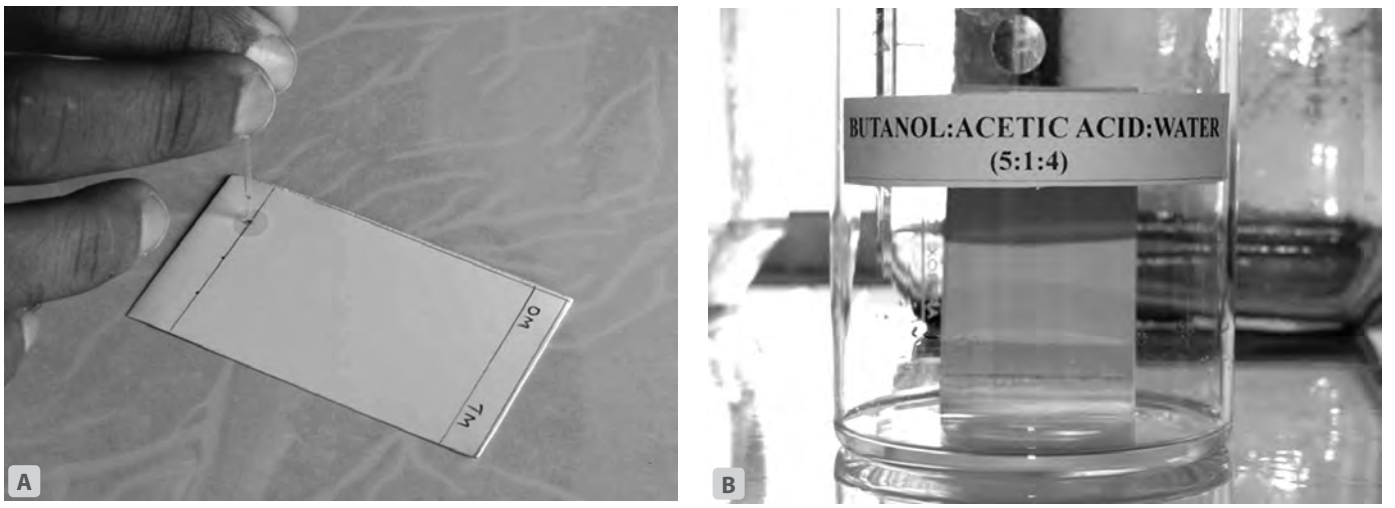
arsenic or bismuth, and a purplish-black deposit indicates antimony.

- *Qualitative desferrioxamine color test*: 2 mL of gastric fluid and two drops of 30% hydrogen peroxide are placed in two plastic tubes. 5 mL of desferrioxamine solution (500 mg in 4 mL of distilled water) is placed in one tube, and the resulting color change is compared with the other tube (control). If an orange or red color develops, it indicates the presence of toxic levels of iron. The test must be done within 2 hours of poisoning or else it is unreliable. A variation of this test is the *desferrioxamine challenge test (DCT)*, in which 25–50 mg/kg of desferrioxamine is administered to the patient by intramuscular injection. Iron poisoning is indicated if the urine, which is voided subsequently, is pinkish in color (*vin rosé urine).*
- *Meixner test*: This test can be done on either a stool or a gastric sample. Dilute the sample with methanol, centrifuge, and filter it. Add a drop or two to a piece of newspaper. Encircle the spot with a pencil and dry it. Add a few drops of concentrated hydrochloric acid to the spot. If a blue color forms within a few minutes, it is indicative of the presence of amatoxin (present in most toxic mushrooms).
- *Forrest test*: Add 1-mL Forrest reagent (a mixture of 25-mL aqueous potassium dichromate, 25-mL aqueous sulfuric acid, 25-mL aqueous perchloric acid, and 25-mL aqueous nitric acid) to 0.5 mL of the sample and mix for 5 seconds. A yellow-green color deepening to blue indicates the presence of imipramine or related compounds.
- *Fujiwara test*: To three 10-mL tubes, add 1-mL portions of (1) the sample, (2) purified water, and (3) aqueous trichloroacetic acid (10 mg/L), respectively. Add 1-mL sodium hydroxide solution (5 mol/L) and 1-mL pyridine to each tube, mix carefully, and heat in a boiling water bath for 2 minutes. An intense red/purple color in the top layer of tube 1 as in tube 3 indicates the presence of trichloro compounds such as chloral hydrate, chloroform, and trichloroethylene. Tube 2 should show no coloration.
- *Isonitrile test*: Mix a small amount of gastric contents with 10-mL water and add 1-mL purified aniline, followed by 2-mL 20% sodium hydroxide. Heat gently for a few minutes. A foul odor (*skunk odor)* will be perceived if one of the following poisons is present: carbon tetrachloride, chloral hydrate, chloroform, methyl bromide, or any other chlorinated hydrocarbon.
- *Tensilon test (edrophonium challenge test)*: When 10-mg edrophonium is given intravenously in a case of sudden paralysis, there will be dramatic recovery if it is due to myasthenia gravis, while a case of poisoning (e.g., botulism) will not show any improvement.
- *Melzer's test*: This is a test done to confirm whether a given mushroom is toxic (especially *Amanita phalloides*). The spores obtained from the mushroom are stained with 1 drop of Melzer's reagent (mixture of 20-mL water, 1.5-g potassium iodide, 0.5-g iodine, and 20-g chloral hydrate) and viewed under a microscope. Spores of *A. phalloides* and a few other deadly mushrooms will show a bluish-black color ("amyloid reaction"). However, a negative reaction does not mean that the mushroom is nontoxic.

Thin-layer Chromatography

Thin-layer chromatography is a *qualitative technique* which involves the movement by the capillary action of a liquid phase (usually an organic solvent) through a thin, uniform layer of the stationary phase (usually silica gel) held on a rigid support (usually a glass, aluminum, or plastic sheet). Compounds are separated by partition between the mobile and the stationary phases.

A very thin layer of silica gel or aluminum oxide is applied to a glass plate, 20 × 20 × 0.5 cm, and vertical lines are drawn 1.5 cm apart to allow individual runways for each sample. Purified tissue extracts dissolved in 0.5 mL of methanol are serially spotted with a micropipette and dried in a small circle in the lower center of a runway 1.5 cm from the bottom (**Fig. 2A**). Other samples are similarly spotted in other runways. A horizontal line (stop point) is drawn 10 or 15 cm above these starting points. A TLC tank is filled with suitable developing solvents to a depth of about 1 cm from the bottom. The plate properly spotted is then dipped into the solvent, the lid is firmly closed, and the atmosphere is allowed to saturate with vapor (**Fig. 2B**). When the solvent front just touches the 10-cm



(TLC: thin-layer chromatography)

FIGS. 2A AND B: (A) Spotting on a TLC plate; (B) Saturation of TLC plate inside TLC chamber.

Courtesy: Dr Ramakrishnan, UK.

horizontal mark, quickly remove the plate and examine it under UV light (at 254 and 366 nm) for characteristic fluorescence or absorbance. Calculate the Rf value. This can also be done after spraying the plate with appropriate reagents to bring out characteristic color spots.[2*] This widens the scope of the analysis and increases the confidence of identification.

$$\text{Rf is the ratio of } \frac{\text{Solute front}}{\text{Solvent front}} \times 100$$

Approximate quantitation can be done by comparison with standards, similarly prepared on the same plate, for the intensity of color and area size. The Rfs suggested in the literature can be used as a guide for identifying various poisons, though it is preferable that each analyst should prepare and establish his/her own Rf according to his/her own conditions and technique.

The recommended TLC visualization reagents are as follows:

- Mercurous nitrate reagent (acidic extract) which gives white spots with a gray center on a darker background with barbiturates and related compounds
- Acidified iodoplatinate reagent (basic extract) which gives mainly purple, blue, or brown spots with a range of basic and neutral drugs and metabolites
- Mandelin's reagent (basic extract) which gives colors ranging from blue and green to orange and red with a variety of basic compounds
- Sulfuric acid (500 mL/L) (basic extract) gives red, purple, or blue spots with many phenothiazines and their metabolites

Thin-layer chromatography is a simple and inexpensive technique which is widely used. It is to be noted that many additional mobile phase and spray reagent combinations could be used in place of those suggested here. It takes only about 2 hours from beginning to completion. It is also a very versatile method since the order of separation of compounds can be altered simply by changing the nature of the developing agent. However, the interpretation of the plates can prove difficult and calls for a trained eye with considerable experience in recognizing colors, spot shapes, and metabolite patterns. It is also well known that TLC can produce false-positive results because of interference between xenobiotics. It is always desirable to confirm results by more sophisticated methods, especially in forensic cases.

Troubleshooting

- *The compound runs as a streak rather than a spot*: It means that the sample was overloaded. Run the TLC again after diluting the sample. Or, the sample might just contain many components, creating many spots which run together and appear as a streak, i.e., the procedure did not go as well as expected. Repeat!
- *The sample runs as a smear or an upward crescent*: Compounds that possess strongly acidic or basic groups (amines or carboxylic acids) sometimes show up on a TLC plate with this behavior. Add a few drops of ammonium hydroxide (amines) or acetic acid (carboxylic acids) to the eluting solvent to obtain clearer plates.
- *The sample runs as a downward crescent*: Likely, the adsorbent was disturbed during the spotting, causing the crescent shape.
- *The plate solvent front runs crookedly*: Either the adsorbent has flaked off the sides of the plate or the sides of the plate are touching the sides of the container (or the paper used to saturate the container) as the plate develops. Crookedly run plates make it harder to measure Rf values accurately.
- *No spots are seen on the plate*: The operator may not have spotted enough compound, perhaps because the solution of the compound is too dilute. This can be resolved by concentrating the solution or spotting it several times in one place, allowing the solvent to dry between applications. Some compounds do not show up under UV light; try another method of visualizing the plate.
- If the solvent level in the developing jar is deeper than the origin (spotting line) of the TLC plate, the solvent will dissolve the compounds into the solvent reservoir instead of allowing them to move up the plate by capillary action. In such a case also, spots will not be seen after the plate is developed.

Note: All spray reagents used are very toxic. Spraying must be performed in a fume cupboard or under an efficient fume hood.

QUANTITATIVE ASSAYS

Ultraviolet Spectrophotometry

Ultraviolet spectrophotometry (UVS) is based on the principle that many drugs, when in solution, will absorb UV radiation. The degree of absorption depends on the chemical structure of the drug, its concentration in the solution, and the wavelength of the ultraviolet radiation (UVR). The functioning of this instrument is relatively straightforward. A beam of light from a visible and/or UV light source is separated into its component wavelengths by a prism or diffraction grating (**Fig. 3**). The monochromator can select from the light source an UV ray of any given wavelength from 200 to 340 nm. The sample extract in the aqueous medium is placed in a transparent quartz cuvette in the path of the radiation. Each monochromatic (single wavelength) beam in turn is split into two equal-intensity beams by a half-mirrored device. One beam, the sample beam, passes through a small transparent container

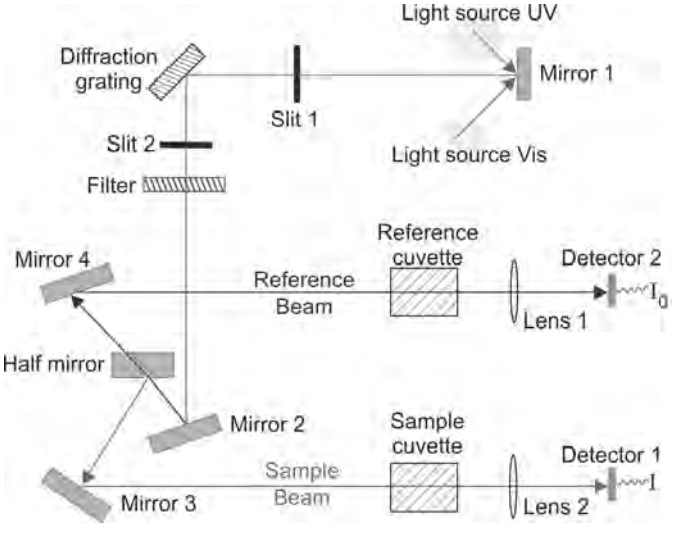


FIG. 3: Schematic diagram of a ultraviolet spectrophotometer.

(cuvette) containing a solution of the compound being studied in a transparent solvent. The other beam, the reference, passes through an identical cuvette containing only the solvent. The intensities of these light beams are then measured by electronic detectors and compared. The intensity of the reference beam, which should have suffered little or no light absorption, is defined as I_0. The intensity of the sample beam is defined as I. Over a short period of time, the spectrometer automatically scans all the component wavelengths in the manner described. The UV region scanned is normally from 200 to 400 nm, and the visible portion is from 400 to 800 nm.

If the sample compound does not absorb light of a given wavelength, $I = I_0$. However, if the sample compound absorbs light then I is less than I_0, and this difference may be plotted on a graph versus wavelength, as shown on the right. Absorption may be presented as *transmittance* ($T = I/I_0$) or *absorbance* ($A = \log I_0/I$). If no absorption has occurred, $T = 1.0$ and $A = 0$. Most spectrometers display absorbance on the vertical axis, and the commonly observed range is from 0 (100% transmittance) to 2 (1% transmittance). The wavelength of maximum absorbance is a characteristic value, designated as λ_{max}. Different compounds may have very different absorption maxima and absorbances. Intensely absorbing compounds must be examined in dilute solution, so that significant light energy is received by the detector, and this requires the use of completely transparent (nonabsorbing) solvents. The most commonly used solvents are water, ethanol, hexane, and cyclohexane. Solvents having double or triple bonds, or heavy atoms (e.g., S, Br, and I) are generally avoided. Because the absorbance of a sample will be proportional to its molar concentration in the sample cuvette, a corrected absorption value known as the *molar absorptivity* is used when comparing the spectra of different compounds. Molar absorptivities may be very large for strongly absorbing compounds ($\varepsilon > 10{,}000$) and very small if absorption is weak ($\varepsilon = 10$–100).

The amount of UV radiation that passes through the solution is measured by the photocell. By steady rotation of the monochromator, it is possible to pass sequentially UV rays of all wavelengths from 200 to 340 nm through the extract. The photocell monitors the amount of radiation absorbed at each wavelength and this is transcribed onto a recorder chart. The shape of the spectrum, the wavelength at which absorption is at a maximum, and any changes brought about by changing the pH of the extract are all used as an aid to characterize the agent present. This technique is ideal to quantitate blood levels of paracetamol and salicylates as well as urine levels of phenothiazines.

A major disadvantage of UVS is the possibility of interference in multiple drug overdose. In such a case, UV scanning can produce a composite spectrum of bewildering complexity from which neither qualitative nor quantitative information can be derived. Conventional spectrophotometric methods are known for producing false-positive results which can be disastrous in medicolegal cases.

Gas Chromatography

Gas chromatography is a more sophisticated system of quantitative analysis and has found great favor with analytical toxicologists since it offers a way of simultaneously separating, identifying, and measuring drugs and other organic poisons (**Fig. 4**). Gas chromatography—specifically gas-liquid chromatography—involves a sample being vaporized and injected onto the head of the chromatographic column. The sample is transported through the column by the flow of inert, gaseous mobile phase. The column itself contains a liquid stationary phase which is adsorbed onto the surface of an inert solid. The liquid or solid specimen dissolved in a solvent is injected into the chromatograph. The specimen is vaporized by heat and is carried through a column by an inert carrier gas (usually nitrogen). The choice of carrier gas is often

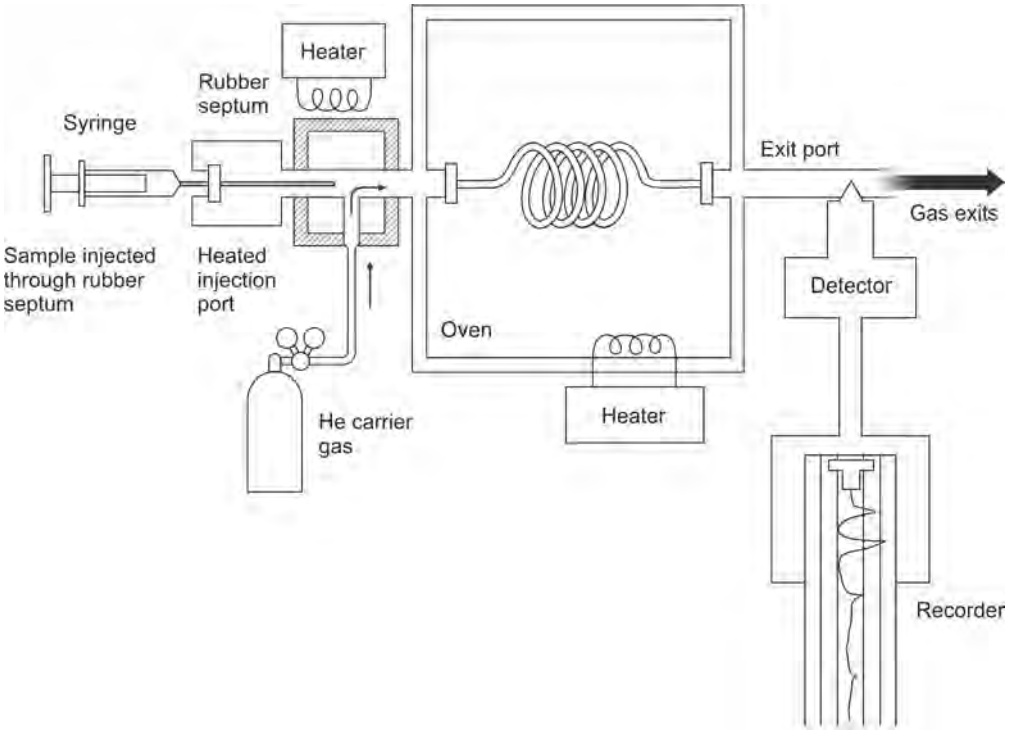

FIG. 4: Schematic diagram of a gas chromatograph.

dependent upon the type of detector which is used. The carrier gas system also contains a molecular sieve to remove water and other impurities. The column is packed with a substance like carbowax or adiponitrile, which is capable of changing the migration time of the specimen as it traverses the column.

For optimum column efficiency, the sample should not be too large and should be introduced onto the column as a "plug" of vapor—slow injection of large samples causes band broadening and loss of resolution. The most common injection method is where a microsyringe is used to inject a sample through a rubber septum into a flash vaporizer port at the head of the column. The temperature of the sample port is usually about 50°C higher than the boiling point of the least volatile component of the sample. For packed columns, the sample size ranges from tenths of a microliter up to 20 μL. Capillary columns, on the other hand, need much less sample, typically around 10^{-3} μL. For capillary GC, split/splitless injection is used.

The injector can be used in one of two modes: split or splitless. The injector contains a heated chamber containing a glass liner into which the sample is injected through the septum. The carrier gas enters the chamber and can leave by three routes (when the injector is in split mode). The sample vaporizes to form a mixture of carrier gas, vaporized solvent, and vaporized solutes. A proportion of this mixture passes onto the column, but most exits through the split outlet. The septum purge outlet prevents septum bleed components from entering the column.

A detector recognizes the presence of the chemical and graphically plots its emergence as a function of time. The retention time and peak area for a chemical compared to the known standard are used to identify and quantitate its presence. There are many detectors which can be used in gas chromatography. Different detectors will give different types of selectivity. A *nonselective* detector responds to all compounds except the carrier gas, a *selective detector* responds to a range of compounds with a common physical or chemical property, and a *specific detector* responds to a single chemical compound. Detectors can also be grouped into *concentration-dependent detectors* and *mass flow-dependent detectors*. The signal from a concentration-dependent detector is related to the concentration of solute in the detector and does not usually destroy the sample. Dilution of make-up gas will lower the detector's response. Mass flow-dependent detectors usually destroy the sample, and the signal is related to the rate at which solute molecules enter the detector. The response of a mass flow-dependent detector is unaffected by make-up gas.

The most common means of detecting the compounds is by flame ionization. On leaving the column, the inert gas is mixed with hydrogen and either air or oxygen, and the mixture is ignited to give a continuous jet of flame. It is decomposed into electrically charged fragments which are collected at an electrode. This results in an electrical signal which is amplified and transmitted to a pen recorder operating at a constant chart speed. This peak is transcribed each time a compound emerges from the column. Flame ionization detectors (FIDs) are mass sensitive rather than concentration sensitive; this gives the advantage that changes in mobile phase flow rate do not affect the detector's response. The FID is a useful general detector for the analysis of organic compounds; it has high sensitivity, a large linear response range, and low noise. It is also robust and easy to use, but unfortunately, it destroys the sample.

Gas chromatography is most commonly employed to quantitate blood levels of volatile liquids such as ethanol, ethylene glycol, and methanol. Other detectors have recently been developed which widen the scope of plasma screening, such as the *electron capture detector* and the *alkali flame detector (nitrogen detector)*.

High-performance Liquid Chromatography

High-performance liquid chromatography is similar to GC, except that it is not restricted to volatile compounds. A high-pressure (1,000–6,000 pound per square inch) pump facilitates the movement of the specimen through the columns packed with chromatographic adsorbents, e.g., silica gel and alumina. The effluent stream passes through a detector, usually an UV spectrophotometer, and the appearance of a drug in the solvent is signaled by a recorder peak in the same way as in GC (**Fig. 5**). Again, the size of the peak is proportional to the concentration of the drug in the sample. HPLC can be used to separate and analyze complex mixtures.

Applications of High-performance Liquid Chromatography

- *Preparative HPLC* refers to the process of isolation and purification of compounds. Important is the degree of solute purity and the throughput, which is the amount of compound produced per unit of time. This differs from *analytical HPLC*, where the focus is to obtain information about the sample compound. The information that can be obtained includes identification, quantification, and resolution of a compound.
- *Chemical separations* can be accomplished using HPLC by utilizing the fact that certain compounds have different migration rates given a particular column and mobile phase. Thus, the chromatographer can separate compounds from each other using HPLC; the extent or degree of separation is mostly determined by the choice of stationary phase and mobile phase.
- *Purification* refers to the process of separating or extracting the target compound from other (possibly

FIG. 5: High-performance liquid chromatography system.
Courtesy: Dr Ramakrishnan, UK.

structurally related) compounds or contaminants. Each compound should have a characteristic peak under certain chromatographic conditions. Depending on what needs to be separated and how closely the samples are related, the chromatographer may choose the conditions, such as the proper mobile phase, to allow adequate separation in order to collect or extract the desired compound as it elutes from the stationary phase. The migration of the compounds and contaminants through the column need to differ enough so that the pure desired compound can be collected or extracted without incurring any other undesired compound.

- *Identification* of compounds by HPLC is a crucial part of any HPLC assay. In order to identify any compound by HPLC, a detector must first be selected. Once the detector is selected and is set to optimal detection settings, a separation assay must be developed. The parameters of this assay should be such that a clean peak of the known sample is observed from the chromatograph. The identifying peak should have a reasonable retention time and should be well separated from extraneous peaks at the detection levels in which the assay will be performed. To alter the retention time of a compound, several parameters can be manipulated. The first is the choice of column, another is the choice of mobile phase, and the last is the choice in flow rate.
- Identifying a compound by HPLC is accomplished by researching the literature and by trial and error. A sample of a known compound must be utilized in order to assure identification of the unknown compound. Identification of compounds can be assured by combining two or more detection methods.
- *Quantification* of compounds by HPLC is the process of determining the unknown concentration of a compound in a known solution. It involves injecting a series of known concentrations of the standard compound solution onto the HPLC for detection. The chromatograph of these known concentrations will give a series of peaks that correlate with the concentration of the compound injected.

Mass Spectrometry

Mass spectrometry is usually combined with gas chromatography *(GC-MS)* (**Fig. 6**) and is considered to be the best technique for quantitative analysis of a wide variety of chemicals, but its expense (capital as well as operational costs) greatly restricts its use. In the simplest terms, the GC-MS instrument represents a device that separates chemical mixtures (the GC component) and a very sensitive detector (the MS component) with a data collector (the computer component). Once the sample solution is introduced into the GC inlet, it is vaporized immediately because of the high temperature (250°C) and swept onto the column by the carrier gas (usually helium). The sample flows through the column experiencing the normal separation processes. As the various sample components emerge from the column opening, they flow into the capillary column interface. This device is the connection between the GC column and the MS. Some interfaces are separators and concentrate the sample via removal of the helium carrier. The sample then enters the ionization chamber.

Two potential methods exist for ion production. The most frequently used method for toxicological purposes is electron impact (EI). The occasionally used alternative is chemical

FIG. 6: Gas chromatograph-mass spectrometer.

ionization (CI). For EI ionization, a collimated beam of electrons impacts the sample molecules causing the loss of an electron from the molecule. A molecule with one electron missing is represented by M+ and is called the molecular ion (or parent ion). When the resulting peak from this ion is seen in a mass spectrum, it gives the molecular weight of the compound. CI begins with the ionization of methane (or other gas), creating a radical which in turn will impact the sample molecule to produce M.H+ molecular ions. Some of the molecular ions fragment into smaller daughter ions and neutral fragments. Both positive and negative ions are formed, but only positively charged species will be detected.

Less fragmentation occurs with CI than with EI. Hence, CI yields less information about the detailed structure of a molecule, but it does yield the molecular ion; sometimes the molecular ion cannot be detected by the EI method. Hence, the two methods complement one another. Once ionized, a small positive potential is used to repel the positive ions out of the ionization chamber.

The next component is a mass analyzer (filter), which separates the positively charged particles according to their mass. Several types of separating techniques exist: quadrupole filters, ion traps, magnetic deflection, time-of-flight, radiofrequency, cyclotron resonance, and focusing, to name a few. The most common are quadrupoles and ion traps. After the ions are separated according to their masses, they enter a detector and then on to an amplifier to boost the signal. The detector sends information to the computer which acts as a "clearinghouse." It records all the data produced and converts the electrical impulses into visual displays and hard copy displays. The computer also drives the mass spectrometer.

Identification of a compound based on its mass spectrum relies on the fact that every compound has a unique fragmentation pattern. Even isomers can be differentiated by the experienced operator. Generally, more information is generated than could possibly be used. A library of known mass spectra, which may be several thousand compounds in size, is stored on the computer and may be searched using computer algorithms to assist the analyst in identifying the unknown. It is important to incorporate all other available structural information (chemical, spectral, and sample history) into the interpretation wherever appropriate.

A mass spectrometer can also be connected to a liquid chromatograph (LC-MS) (**Fig. 7**) for the detection of non-volatile compounds. Tandem MS consists of double mass spectrometers connected to gas chromatograph (GC-MS-MS) or liquid chromatograph (LC-MS-MS). These are very costly and sophisticated instruments that can refine the chemical analysis to an almost flawless degree.

Radioimmunoassay

Radioimmunoassay is a slow and expensive method of detecting drugs in the blood but is highly accurate. It involves mixing known quantities of a drug-specific antibody with a known amount of a radioactively labeled drug, which allows analysis of the precipitate with a gamma counter. The amount of emittance inversely correlates with the presence of assayed drug. This test is excellent for the detection of drugs in extremely low blood concentrations [cannabis, digoxin, lysergic acid diethylamide (LSD), paraquat, etc.].

Principle

In RIA, a fixed concentration of labeled tracer antigen is incubated with a constant amount of antiserum such that the concentration of the antigen-binding sites on the antibody is limiting; for example, only 50% of the total tracer concentration may be bound by antibody. If an unlabeled antigen is added to this system, there is a competition between the labeled tracer and the unlabeled antigen for the limited and constant number of binding sites on the antibody, and thus the amount of tracer bound to the antibody will decrease as the concentration of unlabeled antigen increases. This can be measured after separating antibody-bound from free tracer and counting either the bound fraction, the free fraction, or both. A calibration or standard curve is set up with increasing amounts of known antigen, and from this curve, the amount of antigen in the unknown samples can be calculated. Thus, the four basic necessities for a RIA system are an antiserum to the compound to be measured, the availability of a radioactively labeled form of the compound, a method whereby an antibody-bound tracer can be separated from the unbound tracer, and a standard unlabeled material.

Radioimmunoassay is widely used because of its great sensitivity. Using antibodies of high affinity ($K_0 = 10^8$–$10^{11}\ M^{-1}$), it is possible to detect a few picograms (10^{-12} g) of antigen in the tube.

FIG. 7: Liquid chromatograph-mass spectrometer.

Enzyme-mediated Immunoassay Technique

This is a fast, expensive method with good accuracy, which works on the principle that the amount of drug present is proportional to the inhibition of an enzyme-substrate reaction. A known quantity of a drug is labeled by chemical attachment to an enzyme. Drug-specific antibodies added to the specimen bind the drug–enzyme complex, thereby reducing enzyme activity. A free drug in the specimen competes with the enzyme-labeled drug and limits the antibody-induced enzyme inactivation. Enzyme activity correlates with drug concentration in the specimen as measured by absorbance change resulting from the enzyme catalytic action on a substrate.

Enzyme-mediated immunoassay technique is preferred over other RIA methods in the emergency situation because of its simplicity and speed in providing information on toxic drug concentrations (approximately one sample per minute). It eliminates the complex separation phase necessary in *RIA*. There are two types: (1) *EMIT-st* (*single test*), which consists of a compact spectrophotometer for small laboratories, and (2) *EMIT-dau (drugs of abuse*) for larger hospitals. The two main disadvantages are as follows:

1. A negative result does not exclude the ingestion of a drug that may be present in undetectable quantities.
2. Antibody cross-reactions can produce false-positive results.

Atomic Absorption Spectrophotometry

Atomic absorption spectrophotometry is the best method for detecting inorganic elements (arsenic, lead, mercury, thallium, etc.). However, it requires a large sample of blood for accurate analysis. The blood sample is introduced into a high-temperature oxyacetylene flame situated in the path of a beam of radiation. The organic matrix is combusted and the metal forms a cloud of atoms which absorbs a fraction of the radiation in proportion to the concentration of metal in the sample. Light of a suitable wavelength for a particular element is shone through the flame, and some of this light is absorbed by the atoms of the sample. The amount of light absorbed is proportional to the concentration of the element in the solution and hence in the original object. Measurements are made separately for each element of interest in turn to achieve a complete analysis of an object, and thus the technique is relatively slow to use. However, it is very sensitive and it can measure trace elements down to the part per million level as well as it is able to measure elements present in minor and major amounts.

The equipment is highly complex and can be operated only by trained personnel (**Fig. 8**). The capital cost is prohibitive. Flame AAS techniques are the oldest methods, and they can measure parts-per-million element concentrations with accuracies in the 1–3% range. Graphite furnace AAS, a more recent development, uses much smaller samples and can make parts-per-billion measurements with about 20% accuracy. The newest technique, diode laser AAS, can look at several elements in a sample simultaneously using an array of lasers that emit various wavelengths of light. A mathematical process is then used to separate the mixture of light wavelengths that reaches the detector.

FIG. 8: Atomic absorption spectrophotometer.

Inductively coupled plasma atomic emission spectroscopy (ICP-AES) is a new development that allows simultaneous multielement analysis. elements can be measured from a single sample: aluminum, barium, cadmium, chromium, copper, iron, lanthanum, lead, manganese, molybdenum, nickel, platinum, silver, strontium, tin, titanium, and zinc. **Table 3** gives the comparative status of efficiency of the commonly used laboratory techniques in toxicology.

TABLE 3: Comparison of analytical methods used in toxicology.

Method	*Specificity*	*Sensitivity*	*Speed*
Thin-layer chromatography	++	++	++
Gas-liquid chromatography	+++	+++	+
High-performance liquid chromatography	+++	+++	+
Spectrophotometry	+	++	+++
Gas chromatography-mass spectrometry	++++	++++	+
Immunology	+++	+++	++++

Neutron Activation Analysis

Neutron activation analysis was discovered in 1936 when Hevesy and Levi found that samples containing certain rare earth elements became highly radioactive after exposure to a source of neutrons. From this observation, they quickly recognized the potential of employing nuclear reactions on samples followed by measurement of the induced radioactivity to facilitate both qualitative and quantitative identification of the elements present in the samples.

This is a highly sophisticated and expensive method of detection of a variety of inorganic elements at levels well below the limits of conventional analytical techniques. The sensitivity attained is remarkable—sometimes 100 or even 1,000 times better than by any other method. It is based on the principle that many substances become radioactive when exposed to bombardment by neutrons. The induced radioactivity is highly specific of the elements contributing to it. Consequently, a study of this radioactivity permits the identification and quantitative estimation of many elements. Radioactivity is a spontaneous disintegration of the atomic nucleus. It occurs in a number of naturally occurring elements including radium, uranium, and thorium. Radioactive varieties (isotopes) of all other elements may be made artificially, as explained above, by exposing them to bombardment by neutrons. However, this requires the use of a nuclear reactor, although attack by charged particles, such as protons and deuterons, obtained from high-energy accelerators may also be serviceable. Assay of the induced radioactivity can be done by means of either a Geiger counter or a scintillation counter.

Neutron activation analysis is a sensitive analytical technique useful for performing both qualitative and quantitative multielement analyses of major, minor, and trace elements in samples from almost every conceivable field of scientific or technical interest. For many elements and applications, NAA offers sensitivities that are superior to those attainable by other methods, on the order of parts per billion or better. In addition, because of its accuracy and reliability, NAA is generally recognized as the "referee method" of choice when new procedures are being developed or when other methods yield results that do not agree. Worldwide application of NAA is so widespread that it is estimated that approximately 100,000 samples undergo analysis each year. NAA can be used for the estimation of any of the 90 naturally occurring elements including antimony, arsenic, cadmium, copper, iron, lead, mercury, phosphorus, selenium, thallium, and zinc.

SUMMARY

Analytical toxicology is helpful in the diagnosis, treatment, prognosis, and prevention of poisoning by detecting, identifying, and often also by measuring drugs and other foreign compounds (xenobiotics) in biological and related specimens. Analytical toxicology is important as it provides objective evidence (such objective evidence is needed in a court of law) of the nature and magnitude of exposure to a particular compound or group of compounds. Establishing analytical toxicology facilities in each and every country is the need of the hour as part of governmental forensic science laboratories.

199 CHAPTER

General Management of Poisoning

VP Chandrasekaran, Balaji Muruga B

INTRODUCTION

What is poison? Anything taken in excess is a poison. As quoted by a famous Tamil proverb "ALAVUKKU MINJINAAL AMIRDHAMUM NANJU" carries the meaning of "Even Elixir when consumed beyond prescribed quantity, it will become poison." A material intended for treating, when taken in excess, is called an overdose and when some material is consumed, which is not prescribed to treat, resulting in toxicity, it is called poisoning. India is a unique country having citizens with multiple languages and a mix of cultures where the rural population is more than the urban population. The rural population is mainly based on agriculture as a profession and carries an unstable economy due to drought, poverty, and natural disasters. Similarly, in urban areas, there is joblessness, low wages, and work-related stress resulting in more cases of deliberate self-harm. Children are more prone to unintentional and accidental poisoning.

The scope of this chapter is to cover the general management of poisoning in an urban as well as a rural setup.

SETTING UP A POISONING CENTER

Location

A dedicated place for toxicology should be set up at the emergency room (ER) where the regular traffic of patients is relatively less than other areas in the ER.

Facilities

A decontamination area with an exhaust fan to maintain negative pressure, water facility to wash the patients, crash cart with all life-saving medications, defibrillator, monitors, ventilators, gastric lavage facilities, personal protective equipment to the staff, and good water draining facility should be available. Good illumination is a must. A good backup of a laboratory; intensive care unit; cardiac unit for intra-aortic balloon pump (IABP), extracorporeal membrane oxygenation (ECMO), and pacing; nephrology unit for extracorporal removal of poisoning; and transplant unit for liver transplant should also be available. A counseling room with video and audio recording facilities is recommended. Textbooks and Internet connectivity for reference about poisoning should be available.

The Team

A team under the leadership of an emergency physician is preferred and when not possible, he/she shall be replaced by an intensivist, anesthetist, or general physician. The team should be supported by forensic experts, emergency medical technologists, nurses, trained ward assistants, and trained toxicology lab technicians. Some poisons may result in the immediate collapse of patients [cyanide, organophosphorus (OPC), aluminum phosphide, etc.] and some other poisons can result in delayed toxicity (*Cleistanthus collinus*, paraquat, 3% yellow phosphorous poisoning, etc.). Hence, many patients may need immediate resuscitation and some may need close monitoring until few days to months.

PRIMARY TOXICOLOGY SURVEY AND STABILIZATION

Airway and Breathing

All patients who have low Glasgow Coma Scale (GCS), altered sensorium with unprotected airway, impending rapid deterioration, increased work of breathing, severe refractory hypoxia, and anticipated airway compromise must be immediately intubated. A patient with hair dye poisoning may have severe laryngeal edema and it is better to intubate preemptively when the patient develops a husky voice than to wait and watch until stridor develops. Succinylcholine should not be used in OPC poisoning as both act by the same mechanism and the recovery may be delayed. Video-assisted laryngoscopes and bougies may help to aid the challenging intubations and the tracheostomy tray must be kept ready to protect the unanticipated failed airways. It is preferred to go for conscious intubation with midazolam and fentanyl in any case. Propofol is preferred when the patient is not in shock and has no cardiac comorbidity. Ketamine, atropine, and midazolam or ketofol are preferred when the patient is hemodynamically unstable. A "cannot-intubate-cannot-ventilate" situation is not uncommon in the ER, and in case of such a situation, it is

must to have a good backup of a team of doctors and resources. Unlike western countries, where ER has a strong backup from other specialties, Indian ERs, unless located in cities or big towns, do not have the same privilege. Although most of the studies have proven the efficacy of neuromuscular blocking agents in intubation, Dr Rajan et al. have proved acceptable intubating conditions without using any neuromuscular blockers in children posted for cleft lift surgeries. Keeping in mind the Indian rural emergency room scenario, muscle relaxant should be avoided.

It is better not to depend on noninvasive intubation in case of respiratory insufficiency secondary to poisoning as sudden deterioration is common in poisoning. Do not use heat and moisture exchange (HME) filters in poisonings like OPC as the poison may get filtered at HME and returned instead of completely getting exhaled. While setting the ventilator, do not just keep the routine ventilator settings at a fixed rate of 10–12/min and volume of 4–6 mL/kg. While deciding the ventilator settings, one needs to monitor the presence of metabolic acidosis, raised intracranial pressure (ICP), bronchospasm, etc. A patient with severe metabolic acidosis needs more respiratory rate and minute ventilation than normal and needs to maintain the pCO_2 less than the normal range to balance the pH. Similarly, a patient with a raised ICP needs hyperventilation to maintain pCO_2 between 30 and 35 mm Hg, whereas a patient with bronchospasm needs more expiratory time and less tidal volume to prevent air trapping and auto-positive end-expiratory pressure (auto-PEEP). Unexplained hypoxia with chocolate-colored arterial blood with saturation gap [low SpO_2 in monitor and normal saturation in arterial blood gas (ABG)] will respond to methylene blue or exchange transfusion only and may not respond to ventilation or oxygen.

Circulation

It is wise to have at least two intravenous (IV) access to counter any unforeseen events. One needs to go for central venous access, when there is a need for using irritant drugs such as potassium chloride, sodium bicarbonate, and vasopressors. Tachycardia should be managed by treating the reversible cause (correction of fluid and electrolyte imbalance, hypoxia). Tachycardia secondary to drug overdose such as tricyclic antidepressant (TCA) antipsychotics and drugs causing QT prolongation should be treated with sodium bicarbonate. Amiodarone can be harmful in treating the ventricular tachycardia secondary to these poisoning. Neostigmine can be used for atropine derivatives and use of beta-blockers is beneficial for thyroxine. Bradycardia which is refractory to atropine and drugs such as adrenaline needs pacing. In contrast to the bradycardia algorithm of advanced cardiac life support (ACLS), atropine should be given even beyond the vagolytic dose in case of OPC poisoning. If cath lab facility is not available, transcutaneous pacing (TCP) or transvenous pacing (TVP) with the help of bedside echocardography should be performed in cases of refractory bradycardia. ECMO shall be of valuable support in cardiovascular collapses secondary to poisoning like aluminum phosphide poisoning and not responding to vasopressors and IABP.

Calcium gluconate, insulin and dextrose (hyperinsulinemic euglycemic therapy), and glucagon were tried when the shock was secondary to beta-blocker and calcium channel blocker overdoses. Recently, lipid emulsion therapy has been found to be promising in refractory shock secondary to drug overdoses and poisoning. A dose of 1.5 mL/kg IV bolus repeatedly up to three doses and an infusion of 0.25 mL/kg/h has been used to treat refractory shock. Levosimendan and glucose–insulin–potassium infusion are promising in takotsubo cardiomyopathy.

Dysfunction

Any poisoned unconscoius patient brought to emergency room should be checked for blood glucose level and should be treated accordingly. Naloxone should be given in suspected opioid toxicity and it should be started with 0.4 mg IV. If the patient does not respond, 2 mg IV should be started later and up to 20 mg shall be given in highly suspicious conditions. Flumazenil should be given only in isolated benzodiazepine overdose and it should not be given in mixed overdoses. Altered sensorium is common in many poisonings, either because of the primary effect of the poison like benzodiazepine, TCA, and antipsychotics or secondary to hypoxia and hypotension. Seizures must be treated with benzodiazepine, phenobarbitone, or levetiracetam. Phenytoin sodium does not have any role in seizures secondary to poisoning. Seizures secondary to isoniazid (INH) should be treated with pyridoxin and those secondary to lignocaine overdose should be treated by lipid emulsion. A refractory seizure must be addressed with thiopentone or midazolam infusion. If seizures are refractory even to general anesthetic agents, it may be necessary to paralyze the patient to prevent rhabdomyolysis (secondary to repeated muscular contractions of seizures), severe metabolic acidosis, and death; and electroencephalogram (EEG) may help to monitor the seizure activities. Altered sensorium, irritability, tremor, rigidity, sweating, hyperthermia, and autonomous disturbances in a psychiatric patient receiving serotonin should raise the suspicion of serotonin syndrome. This can be treated with cyproheptadine, tepid sponging, and benzodiazepines. Similar clinical findings with a history of OPC poisoning and concomitant use of haloperidol should raise the suspicion of neuroleptic malignant syndrome and should be treated with bromocriptine, tepid sponging, and benzodiazepines.

Exposure

Clear all the dresses and wash the patient with water. Also, look for any trauma due to a fall or that happened while shifting the patient. The scalp should be palpated for hematoma as hair will cover the scalp.

G Vitals

Arterial blood gas , CBG, electrocardiogram (ECG), human chorionic gonadotropin (hCG), and ultrasonography (USG) are the G vitals, and these vitals will help us in immediate assessment and actions at ER. The role of G vitals in poisoning is given in the following text.

Arterial Blood Gas

It helps us to identify the type 1 and 2 respiratory failure, saturation gap, metabolic acidosis, and electrolyte abnormalities.

Severe hypoxia needs oxygenation and ventilation and CO_2 retention needs ventilation support. CO_2 retention, hyperventilation, and history of charcoal administration should raise the suspicion of charcoal aspiration, which is fatal.

Early bronchoscopy and aggressive bronchoalveolar lavage will save the patient.

Severe metabolic acidosis (aluminum phosphide poisoning, acid poisoning, salicylate poisoning, methyl alcohol poisoning, etc.) needs immediate hemodialysis. If the patient is unstable, plan for continuous renal replacement therapy (CRRT) or sustained low-efficiency dialysis (SLED). $NaHCO_3$ infusion shall be planned until the dialysis catheter is inserted.

The combination of hypokalemia and metabolic acidosis is the unique feature of *Cleistanthus collinus* poisoning and where only the hemodialysis should be done and $NaHCO_3$ should not be infused.

Hyperkalemia in digoxin/*oleander* seed poisoning denotes high mortality unless attended aggressively; mortality is inevitable even after pacing.

Capillary Blood Glucose

Hypoglycemia could be identified in seconds and replacement with dextrose solution will provide dramatic regaining of consciousness.

Electrocardiogram

Long QT, widened QRS, R/S ratio in aVR >0.7 ms, and VT should make the diagnosis of TCA and antipsychotics. Bradycardia with varying heart blocks is common in OPC and *oleander* seed poisoning, beta-blocker, calcium channel blocker, antihypertensives, and digoxin toxicity. Reverse tick sign is again a sign of digoxin toxicity. Acute coronary syndrome with exotic poisoning should raise the suspicion of cocaine and amphetamine toxicity.

Ultrasonography

The ultrasound may help us to identify the reason for shock and to decide the need for fluids or vasopressors. Poor left ventricular (LV) dysfunction takotsubo cardiomyopathy, is common in scorpion sting, aluminum phosphide poisoning, and many other poisonings. Presence of the above findings will mandate the need for vasopressor, IABP, or ECMO. Similarly, good cardiac contractility and collapsing inferior vena cava (IVC) shall help us to give more fluids. The presence of pneumothorax secondary to corrosive poisoning, paraquat, and airway accidents shall be identified at the earliest. Other complications such as pulmonary embolism and deep vein thrombosis (DVT), which arises in prolonged immobilization of poisoning cases, also shall be identified.

Human Chorionic Gonadotropin

Human chorionic gonadotropin will help us to identify the early pregnancy and take necessary precautions.

SECONDARY TOXICOLOGY SURVEY

A secondary survey for toxicology should be started once the patient is stabilized. Secondary survery for the poisoned patient should be performed under following headings.

History

Any unstable patient or patient with altered sensorium and unexplained by clinical assessment should arouse the suspicion of toxicity. It is also good to know the type of poison, time of exposure, time window between exposure and the presentation, and history of similar episodes in the past.

Clinical Assessment

Look for circumstantial evidence and toxidrome. OPC poison will have a typical smell and cyanide smells like bitter almond. IV drug abuser will have multiple needlestick marks. Repeated attempts of deliberate self-harm may have evidence such as hesitation marks.

Organophosphorus, opioids, phenothiazines, and clonidine toxicity will present with pinpoint pupils while sympathomimetics such as ephedrine and parasympatholytic such as *Atropa belladonna* seeds will have dilated pupils. Salivation is a common feature of OPC and dryness is the feature of antidepressants and antipsychotics. Coma with bullae is seen in barbiturate overdose. Tachycardia itself may not give us clear guidance to either identify or treat with antidotes as it is not only seen in sympathomimetics, thyroxin, and bronchodilators such as salbutamol, albuterol, and methylxanthine but also in hypoxia, shock, hypovolemia, and anxiety. Bradycardia is seen in beta-blocker and calcium blocker overdose, OPC poisoning, and *oleander* seed poisoning. Hence, toxidrome shall give us only little guidance and may not always be relied upon solely. Therefore, diagnosis should always be made after complete history, circumstantial evidence, toxidrome, laboratory investigations, clinical assessment, and judgment.

Unexplained hypoxia not responding to oxygenation in the ER should always arouse the suspicion of pulmonary thromboembolism, whereas in case of poisoning, one should think about methemoglobinemia. A clear chest, normal cardiac examination with good respiratory drive, and a fall in saturation with normal saturation in ABG (saturation gap) with chocolate color arterial blood is a typical case of methemoglobinemia, which is common in nitrobenzene, flowering agents, and dapsone toxicities. Some common toxidromes are described in **Table 1**. Various antidotes are described in **Table 2**.

REMOVAL OF POISONING

Gastric Lavage

The role of gastric lavage is highly controversial. While the Western literature is bluntly stating this as a harmful procedure, one needs to consider the regional variation in the poisoning scenario. Though India is still suffering from poisonings such as OPC, weedicides, and many plant poisons which are lethal with prolonged toxicity, Western countries have almost switched to tablet overdoses which are quickly absorbed into the circulation; the availability of antidotes and easy access to extracorporeal removal made their researchers conclude that gastric lavage is either harmful or contraindicated in patient who braught to ER after an hour of drug overdose or poison. But even westen literature favors gastric lavage in overdose of sustain release tablets or preparation. Most common agricultural poison organophosphorus compound (OPC) remain in enterohepatic circulation for longer duration, and prolonged toxicity can not be ruled out. Considering the variation in the poisoning scenario, unavailability of antidotes, and nature of poisons, we still feel that agricultural poisons deserve a good gastric lavage and late-presentation tablet overdoses do not require lavage. As we practice in a country

TABLE 1: Toxidrome: Common toxic syndrome.

Drugs	*Common syndromic features*
Cholinergic: Organophosphorus carbamates insecticides physostigmine edrophonium some mushroom	Confusion CNS depression weakness salivation lacrimation urinary/fecal incontinence GI cram vomiting muscle fasciculation pulmonary edema miosis bradycardia/tachycardia seizure
Anticholinergics: Antihistamine antiparkinsonians, atropine scopolamine amantadine antipsychotics antidepressants antispasmodics muscle relaxants	Delirium tachycardia dry flushed skin, dilated pupil myoclonus, temperature, urinary retention diminished bowel sound, seizure
Sympathomimetics: Cocaine amphetamines methamphetamines, decongestant in cough syrup (phenylpropanolamine, ephedrine, pseudoephedrine)	Delusion, paranoia tachycardia hypertension hyperpyrexia diaphoresis mydriasis hyperreflexia seizure hypotension arrhythmias
Opioid/sedative/ethanol: Narcotics, barbiturates benzodiazepines ethchlorvynol glutethimide, ethanol clonidine meprobamate	Respiratory depression, hypotension, miosis bradycardia hypothermic, pulmonary edema diminished bowel sound hyporeflexia seizure coma
Salicylates	Fever, metabolic acidosis, respiratory alkalosis, tinnitus, and altered sensorium
Serotonins: SSRI, TCA, and MAOI	Hyperreflexia, clonus, sweating, hyperreflexia, clonus, sweating, tremor, flushing, and hypertension tremor, flushing, and hypertension

(MAOI: monoamine oxidase inhibitors; SSRI: selective serotonin reuptake inhibitors; TCA: tricyclic antidepressants)

with a mixed culture, we should justify the role of lavage appropriately on an individual basis.

Multidose Charcoal

Charcoal adsorbs the poison directly from the gut as well as acts as a gut dialyzer across the membrane (i.e., between the gut wall and the arterial wall). The toxins are adsorbed from blood to charcoal in the gut as well as by breaking enterohepatic recirculation. Do not use charcoal when airway reflexes are not patent or impending respiratory failure of aspiration is possible. It is more useful in treating plant poisons.

Whole-bowel Lavage

Polyethylene glycol is used as a purgative, and appropriately added electrolytes prevent dyselectrolytemia. It is good to use whole-body lavage in all the cases and especially with sustained-release tablets and poisonous seeds. Whole-body wash is useful in poisons that are easily absorbed through skin and inhalation.

Forced Alkaline Diuresis

Forced alkaline diuresis is commonly used in TCA, phenobarbitone, and salicylate toxicities. Normal renal function is a must. It carries high risk including hypokalemia, hypernatremia, fluid overload, and pulmonary edema. Hence, it is better to avoid this.

Extracorporeal Removal of Drugs and Toxins

Hemodialysis

Hemodialysis removal is possible in toxins with physical characters of low molecular weight, water solubility, and less protein-bound (e.g., lithium, ethanol, methanol, ethylene glycol, valproate, salicylate and theophylline) **Flowchart 1**. Hemodialysis may not be effective for the removal of toxins that are lipid-soluble, protein-bound, or possess high molecular weight. However, the newer dialysis membranes have the capacity for removal of larger molecules and highly protein-bound poisons such as carbamazepine and phenytoin.

Continuous Renal Replacement Therapy

Slow-release toxins, poisons with large volume of distributions, and those who are with hemodynamic instability can be benefited from this therapy.

Plasmapheresis or Exchange Blood Transfusion

Blood is removed and centrifuged to remove the plasma. The remaining blood components are returned to circulation. The volume of plasma removed during a single procedure is between 30 and 60 mL/min over 3–4 hours. It is beneficial in toxins with a low volume of distribution and protein binding. It is useful in 3% yellow phosphorous poisoning and paracetamol overdoses when N-acetyl cysteine is considered to be ineffective or failed to give the desired benefit.

Charcoal Hemoperfusion

High molecular weight, low volume of distribution, protein-bound, and lipid-soluble toxins can be removed using this technique. Blood is passed through the charcoal filter or resin filter and the toxins are filtered. It has shown benefit in OPC, phenobarbitone, valproic acid, carbamazepine, theophylline, and plant poisonings. It is used widely to treat paraquat poisoning but the benefit is questionable. Treatment of drug overdose and poisoning are described in **Tables 3** and **4**, respectively.

TABLE 2: Antidotes and their indications.

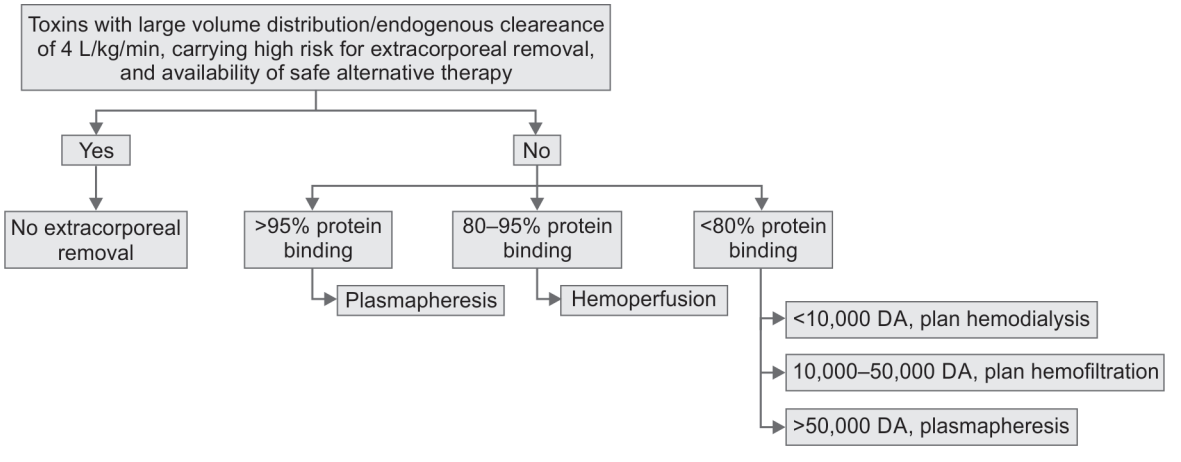
Antidotes	*Indication*	*Dose*
Amyl nitrate	Cyanide poisoning	2–6 inhalations of vapor from crushed 0.3-mL capsules. It may be repeated after 5 min
Atropine	OPC	Until secretions are dried (tachycardia and dilatation of pupil are not the endpoints)
	Oleander seed, digoxin, beta-blocker toxicity with bradycardia	Maximum 3 mg IV
Calcium gluconate/ calcium chloride	Calcium channel blockers and beta-blocker toxicity	30 mL/kg of calcium gluconate or 10 mL/kg of calcium chloride. Maximum dose is 1 g. It should not be given in hyperkalemia secondary to digoxin/*oleander* seed poisoning
	Hydrofluoric acid poisoning	Injected locally as 2.5% solution and through a nebulizer in inhalation injury
Dantrolene	Malignant hyperthermia secondary to anesthetic agents	• 1 mg/kg with additional dose up to 10 mg/kg • 25–100 mg, four doses per day up to 7 days or as needed
D-penicillamine	Heavy metal poisoning	250–500 mg PO 8th hourly
Deferoxamine	Iron toxicity	Maximum initial dose of 1 g as 15 mg/kg/h shall be repeated; maximum 60 mg/kg until vin-rose color urination
Dextrose	Hypoglycemia secondary to OHAs, insulin, or any toxicity	40–100 mL of D25W solution or 20–50 mL of D50W solution IV; may require repeated boluses in severe cases
Dimercaprol	Arsenic/gold poisoning	• Day 1–2: 10–12 mg/kg/day divided q6h deep IM × 2 days • Day 3: 5–6 mg/kg/day divided q12h deep IM × 1 day • Day 4–14: 2.5–3 mg/kg deep IM every day × 11 days
	Mercury poisoning	• Day 1: 5 mg/kg deep IM × 1 day • Day 2–11: 2.5 mg/kg deep IM q12–24h × 10 days
	Lead poisoning	• Initial 4 mg/kg IM • Repeat dose at least 4 h later (but not until adequate urine flow established) and then • 4 mg/kg + EDTA 250 mg/m^2 IM q4h × 3–5 days
	Wilson disease	Rarely used because of deep IM injection of 2–3 mL that is painful 2.5–3 mg/kg IM BID/TID
Flumazenil	Symptomatic, isolated toxicity of benzodiazepine	• 0.2 mg IV over 15–30 s • If no response after 30 s, administer 0.3 mg over 30 s, 1 min later; if no response, repeat a dose of 0.5 mg IV over 30 s at 1-min intervals to a maximum cumulative dose of 3 mg/h
Glucagon	Beta-blocker and calcium channel blocker	• 50–150 µg/kg IV over 1 min initially and then • 3–5 mg/h or 50–100 µg /kg/h IV
Hydroxocobalamine	Cyanide poisoning	5 g IV
Lipid emulsion	Local anesthetics, OPC, TCA, and many lipid-soluble drugs	1.5 mg/kg IV stat and to be repeated every 5 min for a maximum of 3 times and then 0.5–1 mL/kg infusion
Naloxone	Opioid poisoning	0.4–2 mg IV/IM/SC; repeat every 2–3 min; not to exceed 10 mg (0.01 mg/kg)
N-acetyl cysteine	Acetaminophen toxicity, 3% yellow phosphorous poisoning	140 mg/kg in 500 mL 5D/NS over 2 h, 70 mg/kg in 250 mL IV over 45 min every 4th hourly for 72 h. It may be continued up to 7 days
	Glyphosate, hair dye poisoning, paraquat, *Cleistanthus collinus* (Oduvanthalai), and any poisons expected to cause renal or liver injuries	140 mg/kg in 500 mL 5D/NS over 2 h, 50 mg/kg in 250 mL IV over 4 h, and 150 mg/kg in 500 mL of D5/NS over 16 h
P2AM	OPC poisoning	25–40 mg per kg IV stat and 10 mg/kg/h infusion

Continued

Continued

Antidotes	*Indication*	*Dose*
Physostigmine	*Datura*/*Atropa belladonna* poisoning	0.5–2 mg slow IV, not to exceed 1 mg/min; if no response, repeat every 20 min
Phytomenadione (vitamin K)	Warfarin	10 mg IV
Propranolol	β-adrenergics and thyroxin	• 10–30 mg PO q6–8h • 1–3 mg IV at 1 mg/min initially; repeat every 2–5 min to a total of 5 mg • Once response or maximum dose achieved, do not give additional dose for at least 4 h
Pyridoxine	INH overdose	100 mg/kg IV
Isoprenaline	Any drug overdose with AV block	5 µg/min IV infusion initially and then doses of 2–20 µg/min based on patient's response
4-methylpyrazole (Fomepizole)	Methanol and ethylene glycol	• Loading dose: 15 mg/kg IV infusion over 30 min, then • 10 mg/kg IV q12h for four doses, then increase to 15 mg/kg q12h
Naloxone	Opioid overdose	0.4–2 mg IV/IM/SC; repeat every 2–3 min; not to exceed 10 mg (0.01 mg/kg)
Neostigmine	Nondepolarizing neuromuscular blockade reversal	0.03–0.07 mg/kg slow IV, not to exceed 0.07 mg/kg or a cumulative total of 5 mg, whichever dose is less
	Neurotoxic snake envenomation	Neostigmine 1.5 mg IV stat (with atropine) and repeat dose of neostigmine 0.5 mg (with atropine) every 30 min for five doses
Oxygen	Carbon monoxide, cyanide, and hydrogen sulfide	Hyperbaric oxygen therapy
Sodium nitrite	Cyanide	300 mg (10 mL) IV infused at a rate of 2.5–5 mL/min
Sodium thiosulfate	Cyanide	• 12.5 g (50 mL of 25% solution) slow IV over 10 min immediately following sodium nitrite administration; adjust infusion rate according to blood pressure • If signs of poisoning reappear, repeat treatment using one half the original dose of both sodium nitrite and sodium thiosulfate
Charcoal	All poisons except heavy metals, hydrocarbons, and corrosives	1 g/kg in water initially and 0.5 g/kg per dose every 6–8th hourly
Antisnake venom	Cobra, krait, viper, and sea snake	• 10 vials initially if symptomatic and shall be repeated within 6 h • If no response, plan plasmapheresis
Egg white	Corrosives	6–10 raw egg whites shall be given to patients who consumed corrosives
Fuller's earth	Paraquat	A handful of fuller's earth in water

(AV: atrioventricular; EDTA: ethylenediaminetetraacetic acid; IM: intramuscular; INH: isoniazid; IV: intravenous; NS: normal saline; P2AM: pyridine-2-aldoxime methiodide; SC: subcutaneous; TCA: tricyclic antidepressants)



FLOWCHART 1: Extracorporeal removal of drugs and toxins.

TABLE 3: Intervention in drug overdose.

Drug or toxin	*Potential intervention*
Acetaminophen overdose and 3% yellow phosphorous poisoning	• N-acetyl cysteine 140 mg/kg in 500 mL normal saline over 1–2 h, then 70 mg/kg in 250 mL over an hour every 4 h for 72 h and can be extended up to 7 days • Plasmapheresis shall be planned in patients with delayed presentation/patients who consumed more/patients with low body weight
Carbamazepine	Repeat-dose charcoal, hemoperfusion
Digoxin and *oleander* seed poisoning	Digoxin-specific antibodies/pacing
Methanol or ethylene glycol	Ethanol or fomepizole therapy, hemodialysis
Iron	Deferoxamine chelation
Lithium	Hemodialysis
Methanol	Ethanol or fomepizole therapy, hemodialysis
Methemoglobinemia	Methylene blue 2 mg/kg repeated maximum up to 7 mg/kg and exchange transfusion
Salicylic acid	Alkalinization, hemodialysis
Theophylline	Repeat-dose charcoal, hemoperfusion
Valproic acid	Hemodialysis, repeat-dose charcoal

TABLE 4: Management of poisoning.

Drug or Toxin	*Management*
OPC poisoning	• *A, B, C* stabilization to be done and elective ventilation if *secretions* and *poor neck holding* • *Low serum cholinesterase:* ○ High diagnostic value ○ No prognostic value • *Gastric lavage:* ○ *MDAC* (charcoal) 1 g/kg stat followed by 0.5 mg/kg every q6h for 48 h ○ *Intralipid* 100 mL stat followed by 25 mL/h infusion ○ Injection atropine to be administerd until secretions are dry—*drug of choice* ○ 1–3 mg IV and doubling doses followed by 10% cumulative dose infusion (tachycardia or dilatation of pupils are not the endpoints) ○ *PAM can be given in moderate-to-severe poisoning cases as early as possible* ○ *2 g stat followed by 500 mg/h for 48–72 h* ○ As aging occurs very early, *no role of PAM in dimethyl* group of OPC poisonings *Early tracheostomy* may help to wean early
Oduvanthalai (*Cleistanthus collinus*) poisoning	• *MDAC* (charcoal) 1 g/kg stat followed by 0.5 mg/kg every q6h for 48 h • *NAC*: *NAC* dosage 150 mg/kg stat over 45 min followed by 75 mg/kg q4H for 72 h • *Correction of electrolyte abnormalities*: ○ *If metabolic acidosis*, sodium bicarbonate to be given ○ *If refractory*, plan renal replacement therapy • *If hypotension and shock*: ○ *ECHO* can identify poor cardiac contractions ○ *Noradrenaline and dobutamine* to be started • IABP, if inotropes fail

Continued

Continued

Drug or Toxin	Management
Oleander seed poisoning	• Attach to transmembrane Na-K ATPase that *increases* intracellular *calcium* • Gastric lavage and whole-bowel irrigation • *Bradycardia and heart blocks*: ○ Initially, *atropine* to be given ○ *If ineffective:* – Transcutaneous pacing Or – Dopamine infusion Or – Epinephrine infusion *Consider transvenous pacing* • *Hyperkalemia*: ○ *Gastrointestinal* (25% dextrose 100 mL with 10 units of regular insulin) ○ Salbutamol nebulization ○ Soda bicarbonate ○ Resins ○ Lasix ○ *Renal replacement therapy* ○ *No calcium gluconate* • *Tachyarrhythmia*: ○ *Membrane-stabilizing agents* ○ Lignocaine ○ Magnesium sulfate may be beneficial • *DigiFab*: 5–12 vials if available
Glyphosate poisoning	• *Toxicity is due to surfactant in glyphosate* • *MDAC* (charcoal) 1 g/kg stat followed by 0.5 mg/kg q6h for 48 h • *NAC*: ○ NAC dosage 150 mg/kg stat over 45 min followed by 75 mg/kg ○ q4h for 72 h • *ABG*: ○ *Metabolic acidosis*, due to cardiac compromise ○ Inotropes ○ Soda bicarbonate ○ Hemodialysis *No metabolic acidosis*, observation
Sani powder (yellow auramine-O)	• *Gastric lavage*: *MDAC* (charcoal) 1 g/kg stat followed by 0.5 mg/kg q6h for 48 h • *If seizures present*: ○ *Injection lorazepam* 4 mg IV stat followed by 4 mg thrice daily ○ *Injection phenobarbitone* 20 mg/kg IV stat and 10 mg IV TDS for 3 days ○ If refractory seizures or persistent low GCS, *intubate and ventilate* • *Watch for*: ○ *Electrolyte* abnormality ○ Respiratory distress
Paraquat poisoning	• *MOA—oxygen radical damage* • *Prehospital care: Immediate* advice → Ask them to take a handful of fuller's earth (*multani mitti*) and charcoal/soil • *Serum and urine dithionite* to detect the poison • Initial stabilization of *ABCs* in ER • *Avoid oxygen* • (*MDAC*) 1 g/kg stat followed by 0.5 g/kg body weight q6h for 48 h • *PEGLEC* • *NAC* 150 mg/kg stat followed by 75 mg/kg q4h • Vitamins *C and E*

Continued

Continued

Drug or Toxin	Management
	• *Glutathione* 600 mg BD • *Pirfenidone* 200 mg OD • *Charcoal—hemoperfusion and dialysis*—when initiated as early as possible, it will help in adsorbing the toxin • *Initiation of immunosuppressive therapy*: ○ Injection *methylprednisolone* 300 mg/h infusion ○ Injection *cyclophosphamide* 15 mg/kg IV for 3 days • *Maintain immunosuppressive therapy*: Injection hydrocortisone/tablet prednisolone for at least 1 month or until symptom-free
Aluminum phosphide poisoning	• A, B, C stabilization and elective intubation • Gastric lavage with *coconut oil and MDAC* (charcoal) • *NAC* dosage 150 mg/kg stat over 45 min followed by 75 mg/kg q4h up for 72 h • *ABG* and *lactate* levels to be checked • If *metabolic acidosis*: ○ $NaHCO_3$ infusion 100 cc stat followed by 50 cc/h ○ *CRRT* for 72 h • If *lactate* levels are high or *poor cardiac contractility:* ○ Start *GIK* (100 mL of 25% dextrose + 10 mEq/L potassium chloride + 8 units of regular insulin) at the rate of 50 cc/h ○ Noradrenaline/Dobutamine/Dopamine ○ Vasopressin ○ IABP
Ratol poisoning (yellow phosphorous)	• *Cellular toxin* • Gastric lavage with *coconut oil and MDAC* (Charcoal) • *NAC* dosage 150 mg/kg stat over 45 min followed by 75 mg/kg q4h for 72 h • *Glutathione* 600 mg BD • *Plasmapheresis* to be initiated if consumption is more than half tube: >90% survival rate, if *initiated within* 12 h of poisoning • *Repeat LFT*; if prolonged PT, initiate *plasmapheresis:* ○ If normal, *Tablet NAC* 1.2 g PO BD ○ If increased, continue *NAC* dosage • *Repeat LFT/coagulation profile*: ○ *Liver function deranged* ○ *Decreased sensorium* ○ *Coagulation abnormality* ○ FFP/Vitamin K ○ Plan for *liver transplantation*
Methemoglobinemia secondary to poisoning	• *Suspect, if* ○ *Unexplained hypoxemia* (refractory to oxygenation treatment), secondary to poisoning in the absence of cardiorespiratory cause and having saturation gap *(pulse oximetry shows hypoxia but ABG shows normal PaO_2)* ○ When history reveals exposure to *Hb oxidizing chemicals, flowering agents and drugs* such as nitrites and benzene compounds (*amyl nitrite, aniline, isobutyl nitrite, nitrobenzene, nitroglycerine, sodium nitrite*) • *Clinical features*: ○ *Chocolate brown*-colored blood ○ Central and peripheral cyanosis *(>1.5 g/dL* of *methemoglobin)* • *Bedside echocardiography to rule out* cardiac and pulmonary etiology of cyanosis • *Treatment*: ○ ABCs ○ Decontamination with MDAC ○ *Antidote* ○ *Methylene blue 1–2 mg/kg* IV over 5 min up to 7 mg/kg If refractory to methylene blue, therapeutic *exchange transfusion* is the Rx modality ○ Adjuncts: Vitamin C (ascorbic acid)

Drug or toxin	*Management*
Snakebite	• 10–20 vials of ASV IV if signs and symptoms of envenomation appear • If coagulopathy persists even after 20 vials of ASV, plan for emergency plasmapheresis (remove 40 mL/kg plasma and replace with fresh plasma)
Scorpion sting	• Bupivacaine + lignocaine 50%; 50% locally to alleviate the pain (only lignocaine will last for less than an hour) • Autonomic disturbances—prazosin 30 microgram/kg/dose PO every 4th hourly until autonomic disturbances settle • Levosimendan is beneficial in takotsubo cardiomyopathy secondary to toxicity and cardiogenic shock • Antidote—if available • Supportive care

(ABG: arterial blood gas; ASV: antisnake venom; ARDS: acute respiratory distress syndrome; CCB: calcium channel blocker; CNS: central nervous system; CRRT: continuous renal replacement therapy; ECHO: echocardiogram; FFP: fresh frozen plasma; GIK: glucose–insulin–potassium; GCS: Glasgow Coma Scale; IABP: intra-aortic balloon pump; IV: intravenous; IVC: inferior vena cava; LFT: liver function test; MDAC: multiple-dose activated charcoal; NAC: N-acetyl cysteine; PAM: pralidoxime; PT: prothrombin time)

SUMMARY

Poisoning is a global problem of both developing and developed countries in which large number of healthcare resources are consumed and responsible for premature death. Individuals exposed to poison by ingestion, inhalation, injection, insufflation, and through cutaneous and mucous membrane route. Poisoning presents in different ways, in children as accidental poisoning due to lack of childproof medicine containers, in adult as either suicidal or as drug abuse by various route smoking, intravenous. Patient may also present as acute as well as chronic poisoning from environmental, industrial agriculture toxins exposure. Drug's reaction, drug interactions and envenomation are also common presentation as emergency patient who need immediate resuscitation. Management of poisoned patient consists of general management and specific action for toxins by antidotes. Expert advice from medical toxicologist and regional poison centre are helpful in management of poisoned patient.

CHAPTER

Common Pesticides Poisoning in India

VV Pillay

INTRODUCTION

Poisoning due to pesticides are the major problems in India. Pesticides are compounds that are used to kill or repel pests which may be insects, rodents, fungi, nematodes, mites, ticks, mollusks, and unwanted weeds or herbs. They include substances which prevent, destroy, repel, or mitigate any pest or are used as a plant regulator, defoliant, or desiccant. Classification of pesticides discussed below. In this chapter, only organophosphorus (OP) compound (organophosphate), carbamate insecticide, and aluminum phosphide poisoning will be discussed. Pesticides can be classified as shown in **Table 1**.

ORGANOPHOSPHORUS POISONING

Organophosphorus insecticides (henceforth referred to as organophosphates, for the sake of convenience) are among the most popular and most widely used insecticides in India. **Table 2** lists common varieties along with respective brand

TABLE 1: Classification of pesticides.

Group	*Compounds*
Insecticides	Compounds which kill or repel insects and related species *Examples*: Organophosphates, carbamates, organochlorines, diethyltoluamide (DEET), and pyrethrum and its derivatives (pyrethroids)
Rodenticides	Compounds which kill rats, mice, moles, and other rodents *Examples*: Anticoagulants (bromadiolone), thallium, vacor, phosphorus, alpha-naphthyl-thiourea, cholecalciferol, arsenic, barium carbonate, bromethalin, fluoroacetamide, sodium monofluoroacetamide, red squill, strychnine, and zinc phosphide
Herbicides	Compounds which kill weeds *Examples*: Acrolein, dalaphon, glyphosate, paraquat, diquat, atrazine, propazine, simazine, nitrofen, trichloroacetic acid, and chlorophenoxy compounds
Fungicides	Compounds which kill fungi and moulds *Examples*: Thiocarbamates, captan, captafol, bavistin, vitavax, hexachlorobenzene, and sodium azide
Nematicides	Compounds which kill nematodes (i.e., worms) *Examples*: ethylene dibromide
Acaricides	Compounds which kill mites, ticks, and spiders *Examples*: Azobenzene, chlorobenzilate, tedion, and kelthane
Molluscicides	Compounds which kill molluscs such as snails and slugs *Examples*: metaldehyde
Fumigants	Methyl bromide, phosphine, aluminium phosphide, naphthalene, paradichlorobenzene, dichloropropene, hydrogen cyanide
Miscellaneous pesticides	Neonicotinoid compounds, phthalic acid diamides (flubendiamide), compounds of lead, copper, and mercury, nicotine, rotenone, sabadilla, tetrachloroethylene, trichloroethane, dinitrophenol, dinitrocresol, dinitrobutylphenol, pentachlorophenol, chlorfenson, chloralose and fipronil. Dioxins which are present as contaminants of some herbicides also can produce toxicity

TABLE 2: Common organophosphate compounds.

Generic name	*Brand name*
Acephate	Acemil, Acet, Acetaf, Agrophate, Asataf, Dhanraj, Hilfate, Hythane, Orthene, Ortran, Sicothene, Starthene, Torpedo
Anilofos	Aniloguard, Arozin, Dhanudan
Chlorfenvinphos	Birlane, Chlorfenvinphos
Chlorpyriphos	Agrofas 20, Calban, Chlorofos 20, Classic, Coroban, Cyfos, Daspan, Dermite, Dermot, Dhanuchlor, Dhanvan, Dursban, Force, Gilphos, Hildan, Hyban 20, Lasso, Lethal, Nuchlor, Phors 20, Primaban, Radar, Roban, Ruban 20, Sicobon, Strike, Suchlor, Tafaban, Tefaban, Tricel
Cyclopyriphos	Duramet
Demeton-methyl	Metasystox
Diazinon	Agroziron, Basudin, Bazanon, Ditaf, Suzinon, Tik 20, Zincoseal 50
Dichlorvos	Agrovan 76, Agro 76 EC, Bangvas, Cockroach killer, Dash, DDVP, Divap, Divisol, Madhuvun, Nuvan, Nuvasul 76, Paradeep, Savious, Vapona, Vapox, Vegfru
Dimethoate	Agrodimet 30, Agromet 30EC, Bangor 30EC, Corothate, Cropgor 30, Cycothate, Cygon, Devigor, Dimethoate, Dimex, Entogor, Hexagor, Hygro 30, Klex Dimethoate, Krogar, Methovip, Milgor, NB Dimethoate, Paragor, Parrydimate, Primogor, Ramgor, Rogor, Tagor, Tara 909, Tara Dimex Sulgor, Tka 30, Unigor, Vijaygor, Vikagor
Ediphenphos	Hinosan, Nukil
Ethion	Challenge, Demite, Dhanumit, Dhan-unit, Ethion, Ethione, Ethiosul 50, Fosmit, Mit 505, Mitex, Miticil, Mitvip, Phostech, RP-thion, Tafethion, VegFru Fosmite, Volathin
Fenitrothion	Accothion, Agrothion, Danathion, Fenicol, Fenitrosul, Folithion, Sicothoin, Sumithion, Vikathion
Fenthion	Agrocidin, Baytex, Fenthiosul, Labaycid, Lebaycid, Lebazate
Formothion	Anthio
Iprobenfos	Tagkite
Malathion	Agromal, Bharat, Celthion, Cythion, Dhuthione, Finit, Himalaya, Kathion, Licel, Madhuthione, Maladan, Maladol, Malafil, Malathione, Malazene, Primothion, Sulmathion, VegFru Malatox
Methyl parathion	Ant repellant,* Agropara, Agrotex, Ekatox, Folidol, Folidol-M, Harvest Kempar, Kilex-M, Metacid, Metapar, Metpar, Milphor, Paracrop, Paradol, Parahit, Parataf, VegFru Paratox
Monocrotophos	Atom, Azodrin, Balwan, Corophos, Entophos, Hilcrone, Luphos, Macrophos, Microphos, Monocil, Monochrovin, Monocrome, Monocron, Monocrown, Monocyl, Monodhan, Monokem, Monostar, Monovip, Nuvacron, Phoskill, Sicocil, Sufos, Unicron
Oxydemeton-methyl	Dhanuciytax, Hexasystox, Hymox, Knock Out, Metaciyta, Metasystox
Phenthoate	Agrofen, Delsan, Elsan, Guard, Phentox
Phorate	Anuphorate, Croton, Dhan, Dhang, Dragnet, Fortan, Glorat, Luphate, Phorachem, Phoratox, Phrotax, Thimate 10G, Thimet, VegFru Foratox, Vijayphor, Volphor
Phosalone	Zolone
Phosmet	Phosmite
Phosphamidon	Agromidon 85, Bangdon 85, Bilcran 85, Cildon, Delphamidon, Demacron, Demecron, Dimecron, Directon, Eagle, Entecron 85, Hildon, JK Midon, Midon, Phamidon, Phosul, Rilon, Sudon, Sumidon, Vimidon
Phoxim	Phoxin
Pirimiphos-methyl	Acetellic
Profenfos	Carina, Curacrone, Polytrine, Profex
Quinalphos	Agroquin, Agroquinol, Bayrusil, Chemlox, Coroqueen, Dhanulux, Dyalux, Ekalux, Fact, Flash, Kilex, Quenguard, Quick, Quinal, Quinaltof, Quinseed 25, Silofos, Solux, Vazara, Vikalux
Temephos	Abate 50EC, Farmico's
Thiometon (morphothion)	Agrothimeton, Ekatin
Triazophos	Hostathion, Sutathion, Triphos, Truso
Trichlorphon	Dipterex

**Caution*: *The same brand name may refer to lindane.*

names. These compounds are available as dusts, granules, or liquids. Some products need to be diluted with water before use and some are burnt to make smoke that kills insects.

Usual Fatal Dose

The following compounds are *extremely toxic* (*LD50*: *1–50 mg/kg*) or highly toxic (*LD50*: *51–500 mg/kg*): Chlorfenvinphos, Chlorpyriphos, Demeton, Diazinon, Dichlorvos, Dimethoate, Disulfoton, Ediphenphos, Ethion, Fenitrothion, Fensulfothion, Fenthion, Fonophos, Formothion, Methyl Parathion, Mevinphos, Monocrotophos, Oxydemeton Methyl, Phenthoate, Phorate, Phosphamidon, Quinalphos, Tetraethyl pyrophosphate (TEPP), and Thiometon.

The following compounds are *moderately toxic* (*LD50*: *501–5,000 mg/kg*) or slightly toxic (*LD50*: *>5,000 mg/kg*): Abate, Acephate, Coumaphos, Crufomate, Famphur, Malathion, Phenthoate, Primiphos Methyl, Ronnel, Temephos, Triazophos, and Trichlorphon. Even in cases where treatment was begun early with atropine and oximes, mortality in organophosphate poisoning is generally to the extent of 7–12%.

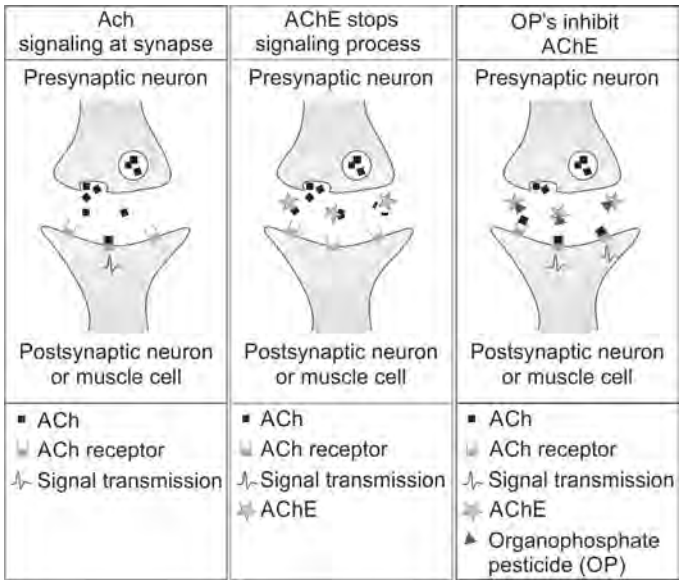
Toxicokinetics

Organophosphorus compounds are very well absorbed from the lungs, gastrointestinal (GI) tract, skin, mucous membranes, and conjunctiva following inhalation, ingestion, or topical contact. Even percutaneous exposure can cause severe toxicity. The difficulty in removing these compounds from the skin and clothing may explain some chronic poisonings, and inadequate skin and respiratory protection during pesticide application is responsible for most of the remainder. Most OP insecticides are lipophilic. Adipose tissue gradually accumulates the highest levels. Cholinergic crisis may recur in patients when unmetabolized OP agents are mobilized from fat stores. More lipophilic compounds, such as fenthion and chlorfenthion, are more likely cause of this phenomenon.

The peak levels of most OP insecticides are measured around 6 hours after oral ingestion in man. Although the serum half-lives of these compounds range from minutes to hours, prolonged absorption or redistribution from fat stores may allow for measurement of circulating insecticide concentrations for up to 48 days.

Organophosphorus insecticides are metabolized by various mixed-function oxidases in the liver and intestinal mucosa, although the exact pathways are not yet clearly understood. The phosphorylating ability of these substances is lost when any of the side chains are hydrolyzed. Certain indirect-acting compounds are activated to a more toxic compound by this initial metabolism. Particularly lipophilic OP compounds may be protected from metabolism by fat storage, markedly prolonging their eliminated half-life. Inactive metabolites of these compounds are excreted in the urine.

Recent studies have suggested a possible relationship between human serum paraoxonase (PON) activity and susceptibility to acute and chronic effects of OP poisoning. PON is an A-esterase that can hydrolyze the active (oxon) metabolites of some OP compounds. Some animal models of OP poisoning demonstrate protection from toxicity when exogenous PON is administered and greater susceptibility to poisoning when enzyme-deficient animals are exposed. Some authors have postulated that genetic polymorphisms in human PON activity may lead to variations in interindividual susceptibility to some OP insecticides.



(AChE: acetylcholinesterase)

FIG. 1: Mode of action-organophosphate pesticides.

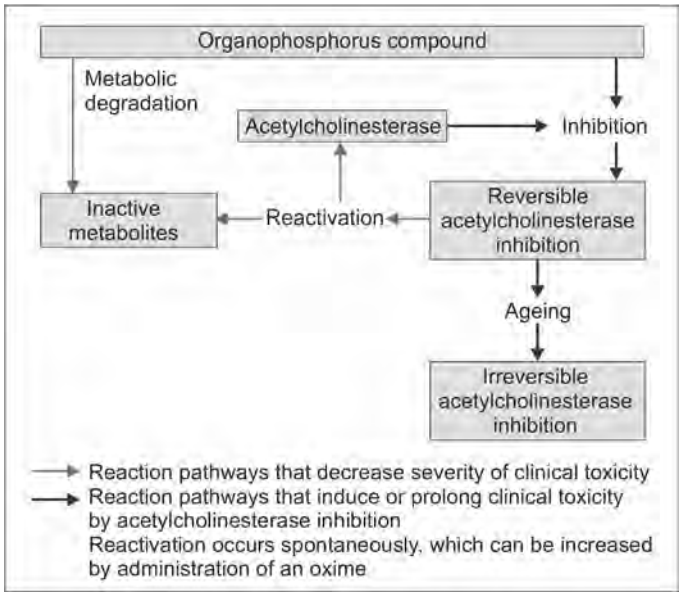
Mode of Action

Organophosphates are powerful inhibitors of acetylcholinesterase (AChE) which is responsible for hydrolyzing acetylcholine to choline and acetic acid after its release and completion of function (i.e., propagation of action potential). As a result, there is accumulation of acetylcholine with continued stimulation of local receptors and eventual paralysis of nerve or muscle* (**Fig. 1**). Although organophosphates differ structurally from acetylcholine, they can bind to the AChE molecule at the active site and phosphorylate the serine moiety. When this occurs, the resultant conjugate is infinitely more stable than the acetylcholine-AChE conjugate, although endogenous hydrolysis does occur. Depending on the amount of stability and charge distribution, the time to hydrolysis is increased. Phosphorylated enzymes degrade very slowly over days to weeks, making the AChE essentially inactive (**Flowchart 1**).

Figure 2 represents the basic formula for OP compounds. The "X" or "leaving group" determines the main characteristics of the compound and is useful in classifying organophosphates into four main groups:

1. Group 1 compounds contain quaternary nitrogen at the X position and are called phosphorylcholines. These chemicals, originally developed as chemical warfare agents, are powerful cholinesterase inhibitors and can also directly stimulate cholinergic receptors because of their structural resemblance to ACh. Example: Echothiophate iodide.
2. Group 2 compounds are called fluorophosphates because they possess a fluorine molecule as the leaving group. Like group 1 compounds, these compounds are volatile and highly toxic, making them also well suited for chemical warfare. Examples: Dimefox, sarin, and mipafox.

*Acetylcholine is the neurotransmitter at pre- and postganglionic parasympathetic synapses, sympathetic preganglionic synapses, and the neuromuscular junction.



FLOWCHART 1: Organophosphates: Reaction pathways.

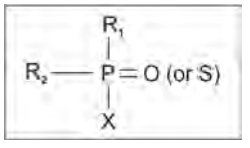


FIG. 2: Formula for organophosphorus compounds.

3. The leaving group of group 3 compounds is a cyanide molecule or a halogen other than fluorine. Examples: Cyanophosphates such as tabun.
4. The fourth group is the broadest and comprises various subgroups based on the configuration of the R_1 and R_2 groups, with the majority falling into the category of either a dimethoxy or diethoxy compound. Most of the insecticides that are in use today fall into this last class.
   i. Leaving group
      (a) *Dimethoxy*: Azinphos-methyl, bromophos, chlorothion, crotoxyphos, dicapthon, dichlorvos, dicrotophos, dimethoate, fenthion, malathion, mevinphos, parathion-methyl, phosphamidon, temephos, trichlorfon
      (b) *Diethoxy*: Carbophenothion, chlorfenvinphos, chlorpyriphos, coumaphos, demeton, diazinon, dioxathion, disulfoton, ethion, methoxsalen, parathion, phorate, phosfolan, TEPP
      (c) *Other dialkoxy*: Isopropyl paraoxon, isopropyl parathion
      (d) *Diamino*: Schradan
      (e) *Chlorinated and other substituted dialkoxy*: Haloxon
      (f) *Trithioalkyl*: Merphos
      (g) *Triphenyl and substituted triphenyl*: Triorthocresyl phosphate (TOCP)
      (h) *Mixed substituent*: Crufomate, cyanofenphos

"Direct"-acting OP insecticides can inhibit AChE without being structurally altered by the body. However, many OPs, such as parathion and malathion, are "indirect" inhibitors or prodrugs requiring partial metabolism (to paraoxon and malaoxon, respectively) within the body to become active. Most of the indirect inhibitors undergo desulfuration in the intestinal mucosa and liver following absorption to form the more active phosphate or "oxon" metabolites. The active form is a more potent cholinesterase inhibitor. The covalent bond is completed as the leaving group of the OP insecticide is split off by AChE, resulting in a stable but reversible bond between the remaining substituted phosphate of the OP compound and AChE, effectively inactivating the enzyme. Although the splitting of the choline-enzyme bond in normal ACh metabolism is completed within microseconds, the severing of the OP compound-enzyme bond can be prolonged. In OP poisoning, the complex becomes irreversibly bound during the next 24–72 hours when one of the R groups leaves the phosphate molecule. This step is termed "aging." As this occurs, the enzyme can no longer spontaneously hydrolyze and becomes permanently inactivated. De novo synthesis of AChE is required to replenish its supply once aging has occurred.

Apart from AChE, organophosphates exert powerful inhibitory action over other carboxylic ester hydrolases such as chymotrypsin, plasma cholinesterase (pseudocholinesterase), hepatic carboxylesterase, PONs, and other nonspecific proteases. It has been proposed that delayed peripheral neuropathy caused by organophosphates is due to phosphorylation of some esterase(s) other than AChE, such as neurotoxic esterase, also known as neuropathy target esterase (NTE). Neuropathy caused by inhibition of NTE may develop 2–5 weeks after an acute poisoning.

Clinical Features

Acute Organophosphates Poisoning

Patients with massive ingestions can become symptomatic very quickly, sometimes within 5 minutes following ingestion, and deaths have occurred within 15 minutes of ingestion. Most victims, however, become symptomatic in about 8 hours of exposure and virtually all within 24 hours. Delays usually occur with compounds requiring metabolic activation, such as malathion, or highly lipid-soluble agents, such as fenthion. Symptoms may last for variable periods of time, again based on the exact compound and the nature of the exposure. For example, lipophilic compounds such as dichlofenthion can cause cholinergic excess for several days following ingestion.

- *Muscarinic effects (hollow organ parasympathetic manifestations)*: Common manifestations include bronchoconstriction with wheezing and dyspnea, cough, pulmonary edema, vomiting, diarrhea, abdominal cramps, increased salivation, lacrimation, sweating, bradycardia, hypotension, miosis, and urinary incontinence. Excessive salivation, nausea, vomiting, abdominal cramps, and diarrhea are common muscarinic effects and have been reported even following the cutaneous absorption of organophosphate. Bradycardia and hypotension occur following moderate-to-severe poisoning. Bronchorrhea can be so profuse that it mimics pulmonary edema even when the lungs are not edematous.
- *Nicotinic effects (autonomic ganglionic and somatic motor effects due to stimulation of nicotinic adrenal receptors and postganglionic sympathetic fibers)*: Nicotinic effects include fasciculations, weakness, hypertension, tachycardia, and paralysis. Mydriasis has been reported in as many as 13% of cases, presumably from nicotinic stimulation of

sympathetic receptors.Muscle weakness, fatiguability, and fasciculations are very common.

Hypertension can occur in up to 20% of patients. Tachycardia is also common. Cardiac arrhythmias and conduction defects have been reported in severely poisoned patients. Electrocardiogram (ECG) abnormalities may include sinus bradycardia or tachycardia, atrioventricular and/or intraventricular conduction delays, idioventricular rhythm, multiform premature ventricular extrasystoles, ventricular tachycardia or fibrillation, torsades de pointes, prolongation of the PR, QRS and/or QT intervals, ST-T wave changes, and atrial fibrillation.

Bronchodilation and urinary retention can occur as a result of sympathetic activity on smooth muscle.

Rarely, patients may present only with paralysis from nicotinic effects without any other initial signs and symptoms suggestive of OP toxicity. This is more common with chemical warfare OP compounds (sarin, tabun, soman, etc.).

Central nervous system effects: Restlessness, headache, tremor, drowsiness, delirium, slurred speech, ataxia, and convulsions are the central nervous system (CNS) effects. Coma supervenes in the later stages. In a review of 16 cases of pediatric organophosphate poisoning, all 16 children developed stupor and/or coma.

Death usually results from respiratory failure due to weakness of respiratory muscles as well as depression of central respiratory drive. Acute lung injury (noncardiogenic pulmonary edema) is a common manifestation of severe poisoning. Acute respiratory insufficiency, due to any combination of CNS depression, respiratory paralysis, bronchospasm, acute respiratory distress syndrome (ARDS), or increased bronchial secretions, is the main cause of death in acute organophosphate poisonings. Metabolic acidosis has occurred in severe poisonings.

A characteristic kerosene-like odor is often perceptible in the vicinity of the patient since the solvent used in many organophosphate insecticides is some petroleum derivative such as aromax.

The Peradeniya Organophosphorus Poisoning (POP) scale is predictive of death, a necessity for mechanical ventilation, and the required total atropine dose over the first 24 hours. This scale rates five clinical variables, each on a 0–2 scale: (1) Miosis; (2) Muscle fasciculations; (3) respiration; (4) Bradycardia; and (5) Level of consciousness.

It is important to note that:

- In a given case, there may be either tachy- or bradycardia and hypo- or hypertension.
- Miosis, while being a characteristic feature, may not be apparent in the early stages. In fact, mydriasis is very often present, and hence treatment should not be delayed if there is absence of pupillary constriction.Blurred vision may persist for several months.
- Ocular exposure can result in systemic toxicity. It can cause persistent miosis despite appropriate systemic therapy and may necessitate topical atropine (or scopolamine) instillation.
- Exposure to organophosphate vapors rapidly produces symptoms of mucous membrane and upper airway irritation and bronchospasm, followed by systemic symptoms if patients are exposed to significant concentrations.
